Tension Field Theory

The Mechanical Constitution of the Spacetime Lattice from Quantum Gravity to Cosmic Kinematics

Rasel Khan
Independent Researcher, Los Angeles, California

Version 1.0 — August 18, 2026

Version 1.0. This monograph is a developing research framework. Later versions may refine constitutive closures, correct errors, and add microscopic and observational tests. Prior versions remain part of the scholarly record.

Abstract

This manuscript establishes Tension Field Theory (TFT), a unified framework that models the universe as a strictly mechanical, visco-elastic continuum. TFT fundamentally replaces the abstract expanding geometries of General Relativity and the probabilistic wavefunctions of Quantum Mechanics with the discrete, dual-scale architecture of the Spacetime Gravitational Floor (SGF).

In Part I, we define the active vacuum as a Face-Centered Cubic (FCC) lattice. We demonstrate that fundamental particles are topological phase defects, deriving inertial mass strictly from the hydrodynamic impedance of the interstitial condensate, and reinterpreting the "Dark Sector" as the inherent geometric packing fraction of this physical medium.

In Part II, we redefine gravity as the restorative structural tension gradient ($-\nabla\tau$) of this lattice. We eliminate non-physical mathematical singularities by modeling Black Holes as deterministic crystallographic phase transitions into a saturated Simple Cubic (SC) State-II configuration at the substrate structural limit, preserving quantum unitarity topologically through strict geometric phase segregation. Furthermore, we mechanize quantum dynamics, unifying the fundamental forces as distinct geometric projections of a single topology-normalized scale-invariant mass moment ($\hat{J}$).

In Part III, we project these solid-state mechanics to global cosmology, formally replacing the expanding FLRW metric. We model the genesis event as the Catastrophic Decompression of a globally percolated fault line (The Big Rupture), and demonstrate that cosmic redshift is driven by visco-elastic damping ($\Gamma_D \equiv H_0$). This mechanical lattice damping natively resolves the Hubble discrepancy and extracts the exact mathematical signature of Dark Energy without invoking negative pressure—ultimately proving the universe operates as a closed, perpetual macro-oscillator.

Contents

Prologue: The Architecture of the Theory **10**

Part I Foundations of the Dual-Phase Vacuum: The Mechanical Origin of the Dark Sector, Mass, and Light **11**

1 Introduction **12**
1.1 The Limits of the Continuous Manifold . . . 12
1.2 The Spacetime Gravitational Floor (SGF) . . . 12
1.3 Objectives of Part I . . . 12

2 Foundational Framework **14**
2.1 The Zeroth Law: The Foundational Tension Field . . . 14
2.2 The Mechanical Postulates . . . 14
2.3 The Fundamental Definitions . . . 17

3 The Dual-Scale Architecture of the Vacuum **21**
3.1 The Coherence Boundary and the Kinematic Ceiling . . . 21
3.1.1 Multi-Parameter Global Calibration of the FCC Node (r_{D}) . . . 21
3.1.2 Post-Calibration Consistency Check Against the Kinematic Ceiling ($E_{\max}$) . . . 22
3.2 The Scale Hierarchy and the Cosmic Boundary . . . 22
3.2.1 The Kinematic Boundary (R_{U}) . . . 23
3.2.2 The Kinematic Lattice Index (N_{D}) . . . 23
3.2.3 The Quantum-Cosmic Consistency Identity . . . 23
3.3 The Constitution of the SC Phase Hard Floor Substrate . . . 24
3.3.1 The Master Geometric Scaling Law . . . 28
3.4 The Constitution of the FCC Phase Soft Floor Active Vacuum . . . 28
3.4.1 Leading Constitutive Closure of the Active FCC Vacuum . . . 30

4 Lattice Constraints and Quantization **35**
4.1 The Resolution Limit . . . 35
4.2 Quantization of Action (Origin of h) . . . 35
4.3 The Mechanical Origin of the Pilot Wave . . . 37

5 The Mechanical Origin of Mass **38**
5.1 The Singularity Paradox . . . 38
5.2 The Surface State Topology . . . 38

5.3 The Three Faces of Mass . . . 39
5.4 The Mechanism of Kinematic Mass: Conservative Added Inertia . . . 39
5.5 Reduced Thin-Layer Mass Law . . . 40
5.6 Conservative Inertia versus Dissipative Resistance . . . 40
5.7 The Amplitude Hierarchy: Node Radius versus Defect Amplitude . . . 40
5.8 Topological Stability, Creation, and Annihilation . . . 42
5.9 The Resolution of Wave-Particle Duality . . . 43

6 Geometric Basis of the Cosmic Energy Budget 44
6.1 The Principle of Maximal Stability . . . 44
6.2 The Kepler Conjecture and Lattice Packing . . . 44
6.3 The Vacuum Packing Fraction . . . 45
6.4 Dynamic Selection of the FCC Lattice . . . 45
6.5 Identification of the Cosmological Sectors . . . 46
6.5.1 Structural Volumetric Energy Closure . . . 47
6.5.2 Dynamical Distinction between the Vacuum Components . . . 48

7 The Origin of Inertia, Light, and Motion 50
7.1 The Tension Cell: Potential vs. Kinetic . . . 50
7.2 Inertia as the Speed Regulator . . . 50
7.3 The Two Regimes of Propagation . . . 50
7.4 The Kinematic Velocity Budget . . . 51
7.5 The Two Mechanical States (Light and Mass) . . . 52
7.5.1 The Mechanical Emergence of the Lorentz Factor . . . 53
7.5.2 The Mechanical Origin of Length Contraction . . . 53
7.6 Force Transfer Efficiency (Impedance Matching) . . . 54
7.6.1 The Mechanical Derivation of $E = mc_{\mathrm{E}}^2$ . . . 55
7.7 The Impedance Mismatch of the Dark Sector . . . 55

8 Conclusion: The Vertical Unity and Falsifiability 57
8.1 The Governing Equations of the Spacetime Gravitational Floor . . . 57
8.2 Strict Falsification Criteria . . . 58
8.3 Diagnostic Comparison of Core Phenomena . . . 59
Summary: The Vertical Unity of the Vacuum . . . 60

Part II The Mechanics of Gravity, Black Holes, and the Quantum Structure of the Vacuum and the Atom 62

9 Introduction 63
9.1 The Limits of the Abstract Metric . . . 63
9.2 The Restorative Lattice Postulate . . . 63
9.3 The Phase Transition of Spacetime . . . 63
9.4 Objectives of Part II . . . 64

10 The Foundations of Restorative Gravity 65
10.1 The First Law: Manifestation of Gravity (Restorative Tension) . . . 65
10.1.1 The Gravitational Constant (G): Universal Substrate Coupling . . . 65
10.2 Gravitational Acceleration from the Conserved Tension Gradient . . . 67

10.3 Structural Gravitational Coupling (α_{G}) . . . 69
10.4 Discrete Soft-Floor Endpoint-Transfer Closure . . . 70
10.4.1 Serial Endpoint Transfer . . . 70
10.4.2 Strain-Induced Refraction and Effective Inertia . . . 71
10.4.3 Constitutive Limits and Saturation . . . 72
10.5 The Mechanical Equivalence Principle: Topological Mass Identity . . . 72
10.5.1 The Mechanism of Inertia: Tying and Untying . . . 73
10.5.2 The Topological Loading Identity . . . 73
10.5.3 Universal Free Fall as the Test-Body Limit . . . 74
10.5.4 Extension to Self-Gravitating Bodies . . . 74
10.6 Bound-Orbit Strain Coupling and Perihelion Precession . . . 75
10.7 The Galactic Rotation Solution: Cosmic Impedance . . . 76
10.8 The Master Acceleration Equation . . . 77
10.8.1 Environmental Acceleration Field . . . 77
10.8.2 Definition of the Terms . . . 78
10.8.3 Precision Bound-Orbit Extension . . . 78
10.8.4 Mechanical Interpretation . . . 79
10.8.5 Regime Limits . . . 80

11 The Gravitational Field: Waves, Curvature, and the Optical Analogy 82
11.1 Gravitational Waves: Static Field vs. Dynamic Propagation . . . 82
11.1.1 The Static Field (Restorative Tension) . . . 82
11.1.2 The Dynamic Wave (Transverse Shear) . . . 83
11.1.3 GW150914: Continuum Strain Calibration . . . 84
11.1.4 The Collective Spin-2 Quadrupole Response . . . 85
11.2 Gravitational Curvature and the Vacuum Catastrophe . . . 86
11.2.1 The Gravitational Saturation Radius (R_{sat}) . . . 86
11.2.2 Resolution of the Vacuum Catastrophe . . . 86
11.3 The Gravity Field Equation . . . 86
11.3.1 Remaining Active Capacity and Induced Lattice Strain . . . 86
11.3.2 The Tension Formulation: Remaining and Converted Capacity . . . 88
11.3.3 The Tensor Projection of the Active Tension Balance . . . 89
11.3.4 Cosmological Integration: The $\beta \to T_{\mu\nu}$ Mapping . . . 91
11.4 The Optical Analogy: Gravity as a Refractive Medium . . . 94
11.4.1 The Vacuum as a Variable Dielectric . . . 94
11.4.2 From Strain-Weighted Paths to the Effective Optical Metric . . . 96
11.4.3 The Mechanics of Light Propagation ($2\alpha_{\mathrm{G}}$) . . . 99
11.4.4 Gravitational Lensing ($4\alpha_{\mathrm{G}}$) . . . 100

12 Microphysics of Black Holes: The Vacuum Phase Transition 102
12.1 Postulate: The Substrate Core . . . 102
12.2 Black Hole Formation . . . 102
12.2.1 Phase-Locked Core and Live Boundary . . . 103
12.3 The Microphysics of Convergence: Vacuum Crystallization and Topological Phase Segregation . . . 104
12.4 The Micro-Black Hole Limit and the Vacuum Safety Margin . . . 104
12.4.1 The Phase Transition Trigger (m_{sat}) . . . 104
12.4.2 The Stable Micro-Black Hole ($M_{\mathrm{D,G}}$) . . . 105

12.4.3 The 10^{17} Safety Margin of the Vacuum . . . 105
12.5 Merging with the Substrate: The Scale Transition . . . 105
12.6 The Resolution of the Information Paradox (Phase Segregation) . . . 108
12.6.1 The Decoupling of Capacity and Occupancy . . . 108
12.6.2 The Solution: The Blank Ledger Reality . . . 109
12.6.3 Numerical Proof and the Vacuum Safety Margin . . . 109
12.6.4 The Topological Invariant and Absolute Unitarity . . . 110
12.7 The Absolute Ground State and the Impossibility of Evaporation . . . 110
12.8 Conclusion: The Black Hole Horizon and the Failure of Causality . . . 111

Prologue: The Architecture of the Theory

Physics currently suffers from a fundamental schism: the macroscopic universe is governed by the continuous geometry of General Relativity, while the microscopic universe is governed by the probabilistic mathematics of Quantum Mechanics. Tension Field Theory (TFT) resolves this schism by abandoning abstract geometry and probabilistic nature entirely in favor of strict quantum continuum mechanics.

To achieve this, TFT replaces the empty void of standard physics with the Spacetime Gravitational Floor (SGF)—a contiguous, dual-scale material structure. At its absolute foundation lies the Latent Substrate (the "Hard Floor"), a perfectly rigid, topologically locked Simple Cubic lattice at the $\approx 10^{-35}$ m scale that serves as the absolute reference frame. Emerging from this substrate is the Active Vacuum (the "Soft Floor"), an elastic Face-Centered Cubic lattice at the $\approx 10^{-26}$ m scale. It is a universal, dual-phase visco-elastic medium exhibiting supersolid-superfluid mechanics. This active medium is mechanically full: its solid nodes ($\approx 74\%$ geometric packing fraction) provide the shear stiffness required for light, while its interstitial condensate ($\approx 26\%$ volumetric capacity) provides the hydrodynamic impedance that generates mass.

Because this framework reconstructs physical law from the absolute quantum substrate to the total cosmic reservoir, this manuscript is divided into three sequential parts:

- **Part I: Foundations of the Dual-Phase Vacuum** establishes the exact geometric and mechanical constitution of spacetime, redefining energy, force, and inertial mass.
- **Part II: The Mechanics of Gravity and the Quantum Structure** applies these foundational rules to derive black holes, deterministic entanglement, atomic structure, and the unification of the fundamental forces through vacuum lattice mechanics.
- **Part III: Cosmic Architecture and Kinematics** projects these solid-state mechanics to the macroscopic scale, redefining the Big Bang as a topological phase rupture, resolving the Hubble Tension, and mechanically eliminating the need for Dark Energy and Dark Matter—ultimately proving the universe operates as a closed, perpetual macro-oscillator that resets the cosmic thermodynamic clock.

Part I

Foundations of the Dual-Phase Vacuum: The Mechanical Origin of the Dark Sector, Mass, and Light

Chapter 1

Introduction

1.1 The Limits of the Continuous Manifold

For over a century, General Relativity has successfully modeled the macroscopic universe by treating the vacuum as a continuous, smooth manifold. However, this assumption encounters fundamental limitations when extrapolated to the quantum limit or the Cosmic Horizon, often yielding non-physical singularities.

While the standard cosmological model (Λ–CDM) is observationally robust, it requires the introduction of phenomenological components—Dark Energy (roughly 69%) and Dark Matter (roughly 26%)—which dominate the cosmic energy budget yet lack a definitive micro-structural definition. Furthermore, persistent tensions in the Hubble constant (H_0) and the ongoing challenge of unifying gravity with quantum mechanics suggest that purely continuous, purely geometric frameworks may be operational approximations of a deeper, discrete mechanical reality. While approaches like Loop Quantum Gravity and Superfluid Vacuum Theory [1, 2] have attempted to quantize space, they often remain mathematically abstract without yielding the specific macroscopic density ratios observed in astrophysics.

1.2 The Spacetime Gravitational Floor (SGF)

This paper proposes a paradigm shift from continuous geometry to discrete continuum mechanics, introducing Tension Field Theory (TFT). We postulate that the vacuum is not an empty void, but a high-stiffness, dual-phase material structure termed the Spacetime Gravitational Floor (SGF). Rather than relying on arbitrary parameter fitting, we derive the properties of this medium directly from the rigorous, classical geometry of sphere packing.

By modeling the observable vacuum as a Face–Centered Cubic (FCC) lattice, we demonstrate that the "Dark Sector" is simply the physical manifestation of the universe's baseline geometric architecture. Specifically, Dark Energy is reinterpreted as the volumetric packing fraction of the solid lattice phase (roughly 74%), representing the stored elastic potential of the field. Dark Matter is reinterpreted as the visco-elastic damping of the interstitial condensate phase (roughly 26%), representing the hydrodynamic impedance to motion through the geometric voids.

1.3 Objectives of Part I

To support this framework, we define a strict dual-scale architecture. The foundational "Hard Floor" is the Tension Substrate—a Simple Cubic (SC) lattice defined at the irreducible substrate

scale associated with the absolute structural limit ($\ell_S \approx 10^{-35}$ m). Emerging from this substrate at the characteristic microscopic boundary is the "Soft Floor"—a Face–Centered Cubic (FCC) lattice of resonant nodes ($r_D \approx 10^{-26}$ m) that acts as the elastic carrier for transverse waves (light).

**Note: ℓ_S is numerically identical to the Planck Length (ℓ_P) but recovered mechanically from the limit of vacuum strain saturation ($\alpha_G = 1$). See Appendix A.*

In this first installment of the Tension Field Theory trilogy, we establish the exact mechanical constitution of this vacuum. We will derive the cosmic energy budget directly from the Kepler Conjecture, mechanize the origins of mass, light, and time, resolve the invisibility of the Dark Sector via acoustic impedance mismatch, and calculate the strict mechanical origins of the fundamental constants (h, c_E, and μ_D). This structural derivation provides the necessary foundation to integrate macroscopic gravity and cosmic evolution in Part II and Part III.

Chapter 2

Foundational Framework

2.1 The Zeroth Law: The Foundational Tension Field

We begin with the fundamental premise: a conserved and contiguous scalar tension field forms the absolute substrate of all physical reality. All observable manifestations—spacetime, mass, energy, and motion—emerge from its dynamics and return into it, conserving total energy. Its total content remains invariant across all physical transformations, from quantum fluctuations to cosmological evolution.

2.2 The Mechanical Postulates

To translate this foundational law into observable physics, we define the following mechanisms that govern the mechanical architecture of the unified field:

Postulate I: The Absolute Reference Frame (The Hard Floor SC Phase)
At the lowest limit of physical existence lies the spatially contiguous Tension Substrate—an indivisible, zero-entropy, topologically locked Simple Cubic (SC) state that provides the absolute reference frame for all physical mechanics. The Hard Floor is ultrastiff relative to the active FCC vacuum and possesses no ordinary propagating active-phase degrees of freedom. It can nevertheless retain localized static longitudinal strain records generated by the loading of the observable Soft Floor.

The Hard Floor is therefore not treated as an ordinary elastic medium having a finite acoustic spectrum. It supplies the fixed reference structure, saturation boundary, and static topological memory against which the active FCC phase deforms and evolves.

Note: While the discrete Substrate constitutes an absolute reference frame, Tension Field Theory recovers near-Lorentzian kinematics as an emergent Soft Floor measurement degeneracy: both the observer's apparatus and the propagating signal are covariantly deformed by the same active-vacuum mechanics (developed in Chapter 7 and in Section 11.4.3). Because transverse electromagnetic propagation occurs strictly on the FCC Soft Floor rather than the Substrate, direct background sensitivity remains negligible at ordinary optical energies, leaving any extreme-energy deviations as higher-order empirical constraints.

Postulate II: Space and Time The substrate constitutes an absolute vacuum and an infinite, latent coordinate space defined by zero phase evolution ($\partial\varphi/\partial t = 0$, where φ is the fundamental torsional phase angle of the lattice) and zero tension gradient ($\nabla\tau = 0$, where τ is the scalar volumetric tension).

- **Active Space** emerges strictly as the topological unfolding of substrate tension in response to phase variations.

  Mechanically, Active Space is first defined by the characteristic coordinate length (x_φ) generated by the discrete phase topology of the lattice nodes:

$$x_\varphi = \frac{\Delta\varphi}{|\nabla\varphi|}. \tag{2.1}$$

  The physical path length experienced by a propagating excitation is then described by the strain-weighted path functional (D_τ). This functional integrates the latent coordinate path against the localized tension-gradient penalty, normalized by the absolute yield tension of the Hard Floor (τ_{S}) and scaled by the fundamental active-vacuum node radius (r_{D}):

$$D_\tau = \int \left(1 + \frac{r_{\mathrm{D}}}{\tau_{\mathrm{S}}}|\nabla\tau(\mathbf{x})|\right) \mathrm{d}\ell. \tag{2.2}$$

  For a one-dimensional path from a to b, this reduces to:

$$D_\tau(a,b) = \int_a^b \left(1 + \frac{r_{\mathrm{D}}}{\tau_{\mathrm{S}}}|\nabla\tau(x)|\right) \mathrm{d}x. \tag{2.3}$$

  Here τ_{S} is the volumetric yield-pressure scale of the Hard Floor,

$$[\tau_{\mathrm{S}}] = \mathrm{Pa}, \tag{2.4}$$

  so that $r_{\mathrm{D}}|\nabla\tau|/\tau_{\mathrm{S}}$ is dimensionless.

- **Active Time** arises from the physical oscillation of the fundamental nodes within the observable space, functioning as an emergent mechanical interval that is strictly bifurcated by the topology of the field. For propagating energy (unbound waves), it functions as Coordinate Time (t)—the local reconfiguration interval ($\Delta t = \delta x/c_{\mathrm{P}}$, where c_{P} is the dynamic wave propagation speed) required for a state transfer across a locally deformed lattice region (δx). In a perfect, unstrained active space, this dynamic propagation delay minimizes to an absolute baseline constant, dictated by the fundamental coherence scale (r_{D}) and maximum propagation potential (c_{E}) of the lattice (defined in Postulates III and IV). Conversely, for localized mass (a bound topological defect), Active Time manifests as Proper Time (t_{p})—the emergent internal clock defined strictly by the accumulation of stationary, integer 360° volumetric phase cycles (n) required to maintain localized structural equilibrium against the active vacuum.

  Temporal Scaling Limits:
  $\Delta t = \delta x/c_{\mathrm{P}}$ (where $\delta x \gg r_{\mathrm{D}}$): **Macroscopic Coordinate Time** (the lattice delay of a wave crossing a gravitational field).
  $\mathrm{d}t = r_{\mathrm{D}}/c_{\mathrm{E}}$: **Fundamental Coordinate Time** (the lattice delay of a wave crossing a perfect vacuum node).
  $t_{\mathrm{p}} = n\left(\frac{h}{E_0}\right)$: **Proper Time** (the internal clock of a localized defect, defined by its cycle count and rest energy).

Postulate III: Observable Vacuum (The Elastic Soft Floor FCC Lattice)

Active Space manifests as the observable vacuum: a contiguous Face-Centered Cubic (FCC) lattice of resonant nodes forming the dynamic Soft Floor above the phase-locked Hard Floor Substrate. The active vacuum is a dual-phase visco-elastic medium composed of a solid FCC nodal scaffold and a connected interstitial condensate.

The FCC scaffold supplies the microscopic contact structure, finite transverse restoring action, and baseline surface inertia of the active vacuum. Its bonded node network transmits mechanical disturbances from one local configuration to the next. The interstitial condensate supplies the continuous pressure-bearing phase of the active vacuum, redistributing through the FCC interstitial network under differential loading and constraining local volumetric change. In coherent wave propagation it moves with the scaffold without relative flow; under differential motion it can redistribute relative to the scaffold and produce a conservative inertial reaction.

The transition from the Hard Floor to the active FCC phase occurs at the characteristic node scale, denoted by r_{D}. This geometric threshold enables finite elastic deformation, dynamic phase freedom ($\Delta\varphi \neq 0$), transverse coherent propagation, localized topological structure, and observable quantum action (h).

Postulate IV: The Invariant Elastic Capacity and Dynamic Propagation (c_{E} versus c_{P})
The invariant elastic capacity c_{E} is distinguished from the locally completed propagation speed c_{P}.

- c_{E} **(Invariant Elastic Capacity):** The unstrained transverse propagation capacity of the active FCC vacuum and the maximum specific energy scale appearing in ($E = mc_{\mathrm{E}}^2$). It is a structural invariant defined by the baseline surface tension and surface inertia of the lattice ($c_{\mathrm{E}}^2 = \tau_{\mathrm{D}}/\mu_{\mathrm{D}}$).
- c_{P} **(Completed Dynamic Propagation):** The actual transmission speed of a coherent transverse disturbance. It depends on the completed endpoint transfer through the dynamically loaded FCC contact network, governed by the effective surface inertia of the transfer coordinate ($c_{\mathrm{P}}^2 = \tau_{\mathrm{D}}/\mu_{\mathrm{eff}}$).

Light represents the minimal 2D transverse shear ripple of the active vacuum. Its transmission speed, and the corresponding flow of time, are strictly governed by the local effective surface inertia (μ_{eff}) of the underlying medium:

- **The Hard Floor ($\mu_{\mathrm{eff}} \to 0$):** The bare Simple Cubic substrate possesses zero intrinsic inertial density. This allows for the instantaneous longitudinal stress transfer ($c_{\mathrm{S}} \to \infty$) required for quantum entanglement and static gravitational fields.
- **The Unstrained Soft Floor ($\alpha_{\mathrm{G}} = 0$):** In the perfect active vacuum, inertia normalizes to the baseline lattice constant ($\mu_{\mathrm{eff}} = \mu_{\mathrm{D}}$). This allows the transverse wave speed to reach the invariant structural limit ($c_{\mathrm{P}} = c_{\mathrm{E}}$).
- **The Gravitationally Loaded Soft Floor ($0 < \alpha_{\mathrm{G}} < 1$):** In high-density regions (gravity wells), the active vacuum is subjected to macroscopic topological strain (α_{G}). This amplifies the local inertial density ($\mu_{\mathrm{eff}} > \mu_{\mathrm{D}}$), imposing two distinct mechanical impedances on the field:
  - *Gravitational Refraction (Waves):* The amplified inertia strictly slows the dynamic propagation speed of transverse waves ($c_{\mathrm{P}} < c_{\mathrm{E}}$), manifesting macroscopically as the delay of Coordinate Time (t).

  - *Phase Damping (Mass):* The macroscopic strain consumes a fraction of the vacuum's elastic capacity. This physically slows the internal stationary phase rotation of localized topological defects, expanding the duration of their emergent Proper Time (t_{p}).

- **Active-Side Saturation Limit ($\alpha_{\mathrm{G}} \to 1^{-}$):** The effective active-coordinate inertia diverges ($\mu_{\mathrm{eff}} \to \infty$), and $c_{\mathrm{P}} \to 0$. This limit marks the causal termination of the active FCC transfer coordinate; it does not represent a continuous softening of the underlying absolute Hard Floor.

(Note: The formal definition of the gravitational strain fraction α_{G} is developed in Section 10.3, and the explicit continuum derivation of c_{P} via the serial endpoint-transfer closure is derived in Section 10.4).

Postulate V: Inertia, Mass, and Motion

- **Inertia (Kinematic Resistance)**

  Inertia arises from the conservative hydrodynamic coupling between a localized topological defect—specifically, a phase, torsional, radial, or mixed defect supported by an FCC r_{D} node and its connected contact neighborhood—and the surrounding interstitial condensate. When the defect translates or reconfigures, it induces a relative-flow field within the condensate. The reversible kinetic energy stored in this flow generates the defect's baseline added inertia. This baseline coupling is strictly conservative; dissipative resistance, irreversible damping, and energy transfer emerge only when the condensate response develops a nonzero phase lag.

- **Mass (Structural Coefficient)**

  Mass is the fundamental topological loading coefficient of a localized defect. It is an invariant structural property whose inertial manifestation is the conservative hydrodynamic added inertia determined by the defect topology, boundary-mode geometry, phase participation, and condensate response. Evaluated in its rest configuration, it sets the invariant rest-energy scale of the localized field state and serves as the common scalar coefficient governing its inertial and gravitational loading.

- **Motion (State Transfer)**

  Motion originates from the mechanical tendency of the active field to minimize localized structural strain and restore equilibrium through directionally ordered Sequential Discrete Reconfiguration, subject to conservation of the excitation's topological state. The phase gradient encodes the momentum orientation of the localized excitation and determines the direction of this state transfer. Spatial gradients of the surrounding lattice tension potential, $-\nabla\varphi_{\tau}$, modify the directional transfer sequence and thereby produce acceleration and trajectory change.

2.3 The Fundamental Definitions

From the mechanical architecture established in the postulates, we derive the fundamental identities of physical interaction:

Dimensional Nomenclature of the Tension Field:

To distinguish the surface, volumetric, and mode-resolved manifestations of the active vacuum, TFT uses the following dimensional hierarchy:

- τ: **Volumetric Tension or Energy Density**

  The three-dimensional internal energy density of a localized or extended state:

$$\tau = \rho c_{\mathrm{E}}^2, \qquad [\tau] = \mathrm{N\,m^{-2}} = \mathrm{J\,m^{-3}}. \tag{2.5}$$

- τ_{D}: **Surface Contact Tension**

  The two-dimensional restorative coefficient of the active FCC contact interface:

$$[\tau_{\mathrm{D}}] = \mathrm{N\,m^{-1}} = \mathrm{J\,m^{-2}}. \tag{2.6}$$

- μ_{D}: **Baseline Surface Inertia**

  The surface inertia associated with the unstrained FCC transfer coordinate:

$$[\mu_{\mathrm{D}}] = \mathrm{kg\,m^{-2}}. \tag{2.7}$$

- $K_{\mathrm{sh}}^{(\mathrm{micro})}$: **Microscopic Shear Coefficient**

  The primitive-cell volumetric tangent coefficient of the coherent FCC branch:

$$\left[K_{\mathrm{sh}}^{(\mathrm{micro})}\right] = \mathrm{Pa}. \tag{2.8}$$

- $\rho_{\mathrm{IC}}^{(\mathrm{imp})}$: **Mode-Resolved Impedance Density**

  The equivalent volumetric density sampled by a localized defect-flow mode:

$$\rho_{\mathrm{IC}}^{(\mathrm{imp})} = \mu_{\mathrm{D}} \iota_V^{(\mathrm{def})}, \qquad \left[\rho_{\mathrm{IC}}^{(\mathrm{imp})}\right] = \mathrm{kg\,m^{-3}}. \tag{2.9}$$

Definition I: Energy (Volumetric Tension and Phase Evolution)

Energy is the fundamental integrated volumetric tension carried by a physical state. For an arbitrary spatial domain $\mathcal{V}$, the total energy is

$$E = \int_{\mathcal{V}} \tau(\mathbf{x}, t)\, \mathrm{d}V. \tag{2.10}$$

For a spatially uniform state, this reduces to the macroscopic scalar product:

$$E = \tau V. \tag{2.11}$$

For a coherent phase eigenmode possessing a well-defined total energy, the temporal phase-evolution relation is

$$E = \hbar \frac{\partial \varphi}{\partial t}. \tag{2.12}$$

The macroscopic integral tension representation and the microscopic phase-evolution representation describe the mechanical and dynamical forms of the exact same mode energy.

(Note: The formal quantization of this identity, including the derivation of the local FCC lattice Hamiltonian and the division between transverse kinetic and elastic strain contributions, is detailed in Appendix Z.)

Definition II: Fundamental Force (Gradient of the Tension Potential)

All physical interactions are macroscopic manifestations of the tension field seeking to restore the FCC contact network to its equilibrium state. Mechanically, the observed "force" is the restorative vector field generated by the vacuum's tendency to minimize localized phase defects and structural strain.

Mathematically, this restorative force is the negative spatial gradient of the mechanical potential energy of the relevant field configuration:

$$\mathbf{F} = -\nabla U. \tag{2.13}$$

For a localized body or field domain whose potential energy is represented by volumetric tension,

$$U = \int_{\mathcal{V}} \tau(\mathbf{x})\, \mathrm{d}V, \tag{2.14}$$

and therefore the tension-driven restorative force is

$$\mathbf{F}_\tau = -\nabla \int_{\mathcal{V}} \tau(\mathbf{x})\, \mathrm{d}V. \tag{2.15}$$

When the defect's potential depends on an internal topological phase coordinate φ, the phase-mediated resistance is formally evaluated via the chain rule:

$$\mathbf{F}_\varphi = -\frac{\partial U}{\partial \varphi} \nabla \varphi. \tag{2.16}$$

The tension-gradient and phase-gradient forms are therefore related through the state-dependent potential $U(\tau, \varphi)$; they are not assumed to be universally identical term by term.

Definition III: Matter (Localized Topological Defect)

Matter is a persistent, localized, topologically nontrivial configuration of the active FCC vacuum. It manifests mechanically as a stable topological defect having a phase, torsional, radial, or mixed boundary mode, supported by a fundamental FCC node and sustained by the restoring action of its connected contact neighborhood. In resonant particle sectors, the defect may be realized dynamically as a self-sustaining standing-wave or phase-knot mode of the FCC contact network.

For fundamental massive particles, inertial mass arises from the conservative hydrodynamic added inertia of the interstitial vacuum condensate and is identified exactly with the topological loading coefficient:

$$m_{\mathrm{i}} = M_{\mathrm{top}} = \rho_{\mathrm{IC}}^{(\mathrm{imp})} V_{\mathrm{imp}} f_\varphi(\Delta\varphi). \tag{2.17}$$

Where:

- $\rho_{\mathrm{IC}}^{(\mathrm{imp})}$: The equivalent mode-resolved condensate impedance density, obtained as a volumetric projection of the FCC baseline surface inertia μ_{D}.
- V_{imp}: The mode-weighted condensate participation volume associated with the selected defect motion.
- $f_\varphi(\Delta\varphi) \geq 0$: The phase-participation function, specifying the nonnegative fraction of the available defect impedance activated by the localized phase structure.

The microscopic defect-impedance projection, including the construction of $\rho_{\mathrm{IC}}^{(\mathrm{imp})}$ and V_{imp}, and the constitutive role of $f_\varphi(\Delta\varphi)$, is developed in Appendix E. The conditional thin-layer reduction involving V_{eff} and the selected branch closure $f_\varphi(\Delta\varphi) = \sin(\Delta\varphi)$ is developed in Appendix F.

Definition IV: Charge (Lattice Chirality)
Electric Charge is the Topological Chirality (handedness) of the resonant node, representing a persistent stress vortex. Its polarity is defined by the direction of the lattice torsion with the discrete Chiral Integer (χ):

- **Positive ($\chi = +1$):** Right-Handed Torsion (Compression).
- **Negative ($\chi = -1$):** Left-Handed Torsion (Rarefaction).
- **Neutral ($\chi = 0$):** Zero Torsion (Symmetric Oscillation).

Definition V: Information (The Topological Strain Record)

Information is the permanent, mechanical ledger of the universe. It is defined as a discrete topological footprint: the specific, static longitudinal strain configuration encoded within the ultra-dense Simple Cubic (SC) Substrate (The Hard Floor).

Mechanically, as Energy dynamically propagates across the active FCC Soft Floor, it exerts a localized downward mechanical stress upon the substrate, registering as a discrete longitudinal strain defect.

For any dynamic state—whether a propagating wave (Photon) or a localized resonant knot (Matter)—the total information content N is fundamentally defined as the ratio of the Carrier's total dynamic energy (E_{carrier}) to the static strain energy of a single continuous record (E_{record}). The reduced mathematical normalization of this ratio is branch-dependent based on the topology of the state:

- **The Kinematic (Wave) Identity:**

$$N_\gamma = \frac{1}{\alpha_{\text{G},\gamma}} = \frac{1}{2\pi}\left(\frac{\lambda}{\ell_{\text{S}}}\right)^2 \tag{2.18}$$

- **The Inertial (Matter) Identity:**

$$N_{\text{m}} = \frac{2\pi}{\alpha_{\text{G},m}} = 2\pi\left(\frac{m_{\text{S}}}{m_{\text{i}}}\right)^2 \tag{2.19}$$

Where:

- N_γ, N_{m}: The total count of discrete longitudinal strain bits (formally derived in Appendix AB) anchoring the dynamic Soft Floor state to the static Hard Floor Substrate.
- λ: The macroscopic wavelength of the propagating Soft Floor carrier (Photon).
- $m_{\text{i}} = M_{\text{top}}$: The localized invariant inertial loading of the Soft Floor carrier (Matter).
- $\ell_{\text{S}}, m_{\text{S}}$: The fundamental Lattice Spacing and Mass Potential of the Substrate (See Appendix A).
- $\alpha_{\text{G},\gamma}, \alpha_{\text{G},m}$: The corresponding dimensionless gravitational strain of the carrier state.

Chapter 3

The Dual-Scale Architecture of the Vacuum

3.1 The Coherence Boundary and the Kinematic Ceiling

As established in Postulate III, the active Spacetime Gravitational Floor (SGF) is a visco-elastic medium with a finite structural capacity. To resolve the singularity paradoxes inherent in continuous field theories, Tension Field Theory (TFT) postulates an absolute microscopic Coherence Boundary. This boundary is defined by the characteristic radius of the fundamental Face-Centered Cubic (FCC) lattice node (r_{D}), representing the smallest scale at which a transverse excitation can be coherently sustained before localized lattice saturation occurs.

3.1.1 Multi-Parameter Global Calibration of the FCC Node (r_{D})

The active Spacetime Gravitational Floor cannot be dimensionlessly derived; its geometric scale (r_{D}) must be globally calibrated against the physical extremes of the observable universe. The framework must simultaneously satisfy two empirical Standard Model boundaries:

- **The Low-Energy Anchor (Resting State):** The structural capacity of the vacuum must physically accommodate the 246.22 GeV Vacuum Expectation Value (VEV) without localized fracture.
- **The High-Energy Consistency Check:** The physical Nyquist limit of the calibrated geometry should yield a wave-fracture scale compatible with the broad electroweak vacuum-instability range (1.0×10^{10} to 1.0×10^{12} GeV).

The fundamental node radius is calibrated by equating the mass-equivalent electroweak VEV scale to the physical hydrodynamic capacity of the Interstitial Condensate (ρ_{IC}), defined in Appendix C, occupying the total Interstitial Volume (V_{IC}), detailed in Section 6.2, of a single Face-Centered Cubic cell ($\approx 25.95\%$ of the cell volume). By defining the 3D vacuum fluid density from the linear gravitational mass-density scale of the lattice (c_{E}^2/G), projected volumetrically through the macroscopic SI calibration convention ($\iota_{\mathrm{V}} \equiv 1\ \mathrm{m}^{-1}$), we formulate a calibrated geometric matching condition.

The complete step-by-step calibration calculation is provided in Appendix H. This calibration should not be read as a parameter-free derivation of r_{D} from the Standard Model; rather, it

establishes the empirical active-vacuum scale used throughout the TFT framework. Solving the calibrated matching condition yields:

$$r_{\mathrm{D}} \approx 7.4504 \times 10^{-27} \text{ m}. \tag{3.1}$$

In subsequent sections, this fundamental dimension r_{D} governs the mechanical manifestations of the active vacuum. (Note: Because the coefficient 7.45 falls above the logarithmic midpoint of a base-10 scale ($\sqrt{10} \approx 3.16$), the fundamental geometric grain size is strictly classified as an order-of-magnitude scale of $r_{\mathrm{D}} \sim 10^{-26}$ m in all subsequent expressions of the FCC node size).

3.1.2 Post-Calibration Consistency Check Against the Kinematic Ceiling ($E_{\max}$)

To confirm this geometric calibration is physically valid, the calibrated node radius is evaluated against the absolute Kinematic Ceiling ($E_{\max}$). Because a transverse wave knot cannot physically propagate through a lattice node smaller than its own physical diameter ($\lambda_{\min} = 2r_{\mathrm{D}}$), this limit represents the absolute energy required to compress a singular photon's spatial wavelength to the physical diameter of the node, triggering structural lattice failure.

Utilizing the internal kinematic equation for a localized photon-like excitation ($E = hc_{\mathrm{E}}/\lambda$), the fracture limit of the calibrated SGF evaluates to:

$$E_{\max} = \frac{hc_{\mathrm{E}}}{2r_{\mathrm{D}}} \tag{3.2}$$

Using the invariant constant $hc_{\mathrm{E}} \approx 1.2398 \times 10^{-15}$ GeV $\cdot$ m:

$$E_{\max} = \frac{1.2398 \times 10^{-15} \text{ GeV} \cdot \text{m}}{2(7.4504 \times 10^{-27} \text{ m})} \approx 8.3203 \times 10^{10} \text{ GeV} \tag{3.3}$$

The resulting value lies within the broad electroweak vacuum-instability range often quoted in Standard Model extrapolations. Because r_{D} has already been empirically calibrated using the electroweak VEV scale, this agreement should be interpreted as a post-calibration consistency check rather than as an independent prediction. The result shows that the calibrated FCC Soft Floor scale is not immediately incompatible with the expected high-energy structural instability window.

Composite vs. Fundamental Saturation:
It is critical to distinguish this geometric ceiling from the observed energies of Ultra-High-Energy Cosmic Rays (UHECRs) [3, 4]. A UHECR is a macroscopic composite structure (a proton) that distributes its immense kinetic energy across millions of resonant nodes via a hydrodynamic shock-wave. The limit $E_{\max}$ defines the absolute Nyquist yield threshold strictly for a *single, fundamental transverse wave* (such as a single photon).

3.2 The Scale Hierarchy and the Cosmic Boundary

While the microscopic boundary ($2r_{\mathrm{D}}$) is calibrated to the empirical limits of the Standard Model, the macroscopic boundary of the universe is governed by the structural dissipation of the active vacuum. Tension Field Theory utilizes these two absolute limits to define the total scale hierarchy of the local cosmic domain.

3.2.1 The Kinematic Boundary (R_{U})

Because the active Spacetime Gravitational Floor is a visco-elastic medium, transverse shear waves cannot propagate infinitely. Their kinetic energy is continuously subjected to a fundamental, macroscopic temporal Vacuum Damping Rate (Γ_{D}).

Observational cosmology measures this visco-elastic damping directly as the Hubble parameter ($H_0 \equiv \Gamma_{\mathrm{D}}$). Using the SH0ES collaboration baseline of $H_0 \approx 73.0$ km/s/Mpc, the absolute kinematic limit of macroscopic wave coherence is calculated. Standard cosmology identifies this distance as the Cosmic Horizon. In Tension Field Theory, this boundary is mechanically defined as the Viscous Cosmic Horizon.

The Viscous Cosmic Horizon (R_{U}) is the characteristic coordinate distance at which the visco-elastic damping of the lattice attenuates a propagating wave by a factor of $1/e$ (draining approximately 63.2% of its initial kinematic energy):

$$R_{\mathrm{U}} = \frac{c_{\mathrm{E}}}{\Gamma_{\mathrm{D}}} = \frac{c_{\mathrm{E}}}{H_0} \approx 1.2665 \times 10^{26} \text{ m} \tag{3.4}$$

3.2.2 The Kinematic Lattice Index (N_{D})

The macroscopic limit of coherence (R_{U}) and the microscopic limit of coherence ($2r_{\mathrm{D}}$) establish the absolute mechanical phase boundaries of the active vacuum. These bounds are synthesized into a single, fundamental dimensionless invariant: the Kinematic Lattice Index (N_{D}).

$$N_{\mathrm{D}} = \frac{R_{\mathrm{U}}}{2r_{\mathrm{D}}} = \frac{1.2665 \times 10^{26} \text{ m}}{2(7.4504 \times 10^{-27} \text{ m})} \approx 8.4995 \times 10^{51} \tag{3.5}$$

Physical Meaning:
N_{D} represents the characteristic maximum number of discrete lattice nodes a transverse excitation can traverse before visco-elastic damping reduces its kinematic energy below the $1/e$ macroscopic coherence threshold. Because N_{D} is a pure dimensionless ratio bounded by fundamental geometry and empirical observation, it is an absolute structural property of the visco-elastic continuum.

3.2.3 The Quantum-Cosmic Consistency Identity

This dimensionless scale ratio mathematically bridges the microscopic and macroscopic boundaries of the universe. Rather than treating these limits as isolated phenomenological parameters, Tension Field Theory demonstrates they form a strict Scale-Invariant Identity. Projecting the macroscopic temporal damping (Γ_{D}) across the total geometric lattice count (N_{D}) yields the exact mathematical equivalence of the quantum vacuum's energetic yield limit:

$$E_{\max} \equiv h\Gamma_{\mathrm{D}} N_{\mathrm{D}} \tag{3.6}$$

Rather than an independent derivation, this identity serves as a rigorous structural consistency check. It demonstrates that the scale kinematics of the FCC vacuum commute perfectly across extremes: the localized ultraviolet structural cutoff ($E_{\max}$) is strictly equivalent to the infrared cosmic decay rate (Γ_{D}) integrated across the absolute spatial depth of the lattice. (The formal proof of this strain unification is detailed in Appendix H).

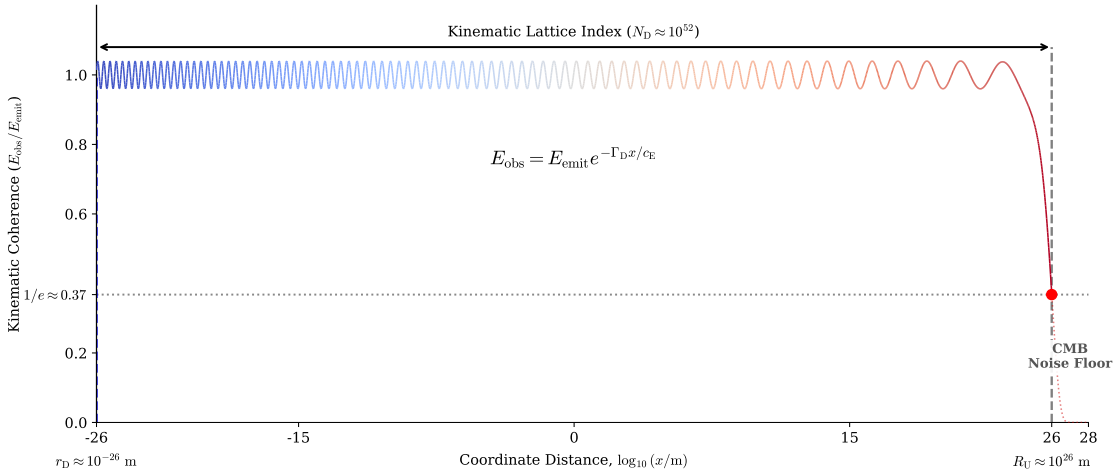

Figure 3.1: **The Scale Hierarchy of the Active Vacuum.** The observable universe exists within a finite structural envelope spanning approximately 52 orders of magnitude ($N_D \approx 10^{52}$). It is bounded on the micro-scale by the lattice resolution limit ($r_D \approx 10^{-26}$ m), where quantum saturation triggers a phase transition, and on the macro-scale by the Viscous Cosmic Horizon ($R_U \approx 10^{26}$ m), where lattice damping (Γ_D) exponentially attenuates the wave's kinematic energy by a factor of $1/e \approx 0.37$.
Wave Kinematics: The visual represents a propagating transverse wave undergoing continuous visco-elastic damping. The vertical amplitude strictly follows the exponential decay equation (E_{obs}), while topological conservation of the wave packet causes the horizontal wavelength to continuously elongate, generating the cosmological redshift ($1 + z$). Beyond R_U, the wave sheds its remaining energy into the ambient 2.725 K Cosmic Microwave Background [5] (thermal exhaust).

3.3 The Constitution of the SC Phase Hard Floor Substrate

As established in Postulate I, the Latent Substrate forms the spatially contiguous mechanical foundation of the field. It possesses a topologically locked Simple Cubic (SC) structure at the irreducible substrate scale (ℓ_S) and provides the absolute structural reference from which the active vacuum is defined. Its mechanical constitution is specified by the following limiting properties.
The Irreducible Node Spacing: The Substrate Lattice Spacing (ℓ_S) defines the smallest structural interval admitted by the Hard Floor. The corresponding maximum substrate force scale is

$$F_S = \frac{c_E^4}{G}. \tag{3.7}$$

Distributed over the substrate cell area, this defines the finite volumetric yield-pressure scale

$$\tau_S = \frac{F_S}{\ell_S^2} = \frac{c_E^4}{G\ell_S^2}. \tag{3.8}$$

Thus, τ_S specifies the limiting stress capacity of the Hard Floor.
Latent State Energy: At the irreducible substrate scale, the structural energy associated with one fundamental cell is

$$E_S = F_S \ell_S = \frac{c_E^4 \ell_S}{G}. \tag{3.9}$$

The Hard Floor therefore retains latent structural capacity while its intrinsic inertial response approaches

$$\mu_{\mathrm{S}} \to 0. \tag{3.10}$$

The corresponding substrate density characterizes the structural content of this latent configuration rather than the ordinary inertial dynamics of the active vacuum.

Phase Locking and Longitudinal Connectivity: The unperturbed Hard Floor defines the equilibrium phase reference of the field. The convention

$$\varphi_{\mathrm{S}} = 0 \tag{3.11}$$

fixes this reference, while the physical condition of internal phase locking is

$$\Delta\varphi = 0. \tag{3.12}$$

In its homogeneous equilibrium condition,

$$\frac{\partial\varphi}{\partial t} = 0, \qquad \nabla\tau = 0. \tag{3.13}$$

The incremental rigidity of the phase-locked substrate is denoted by K_{S}. At the irreducible structural limit,

$$K_{\mathrm{S}} \to \infty. \tag{3.14}$$

The distinction between τ_{S} and K_{S} is fundamental: τ_{S} is the finite limiting stress capacity of the Hard Floor, whereas $K_{\mathrm{S}} \to \infty$ expresses its vanishing incremental deformability in the phase-locked limit.

Together with

$$\mu_{\mathrm{S}} \to 0, \tag{3.15}$$

this locked constitution provides longitudinal constraint connectivity represented by

$$c_{\mathrm{S}} \to \infty. \tag{3.16}$$

The limit $c_{\mathrm{S}} \to \infty$ denotes zero-delay longitudinal constraint equilibration through the connected Hard Floor, rather than an independently propagating finite-energy mode. Localized loading may nevertheless leave a static longitudinal strain configuration in the substrate. Such a configuration is a persistent deformation of the structural record, not a continuing propagating excitation.

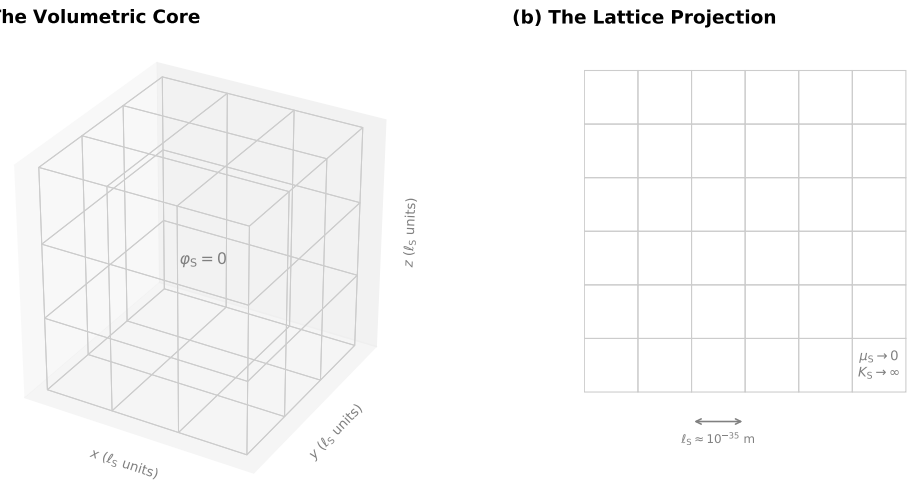

Figure 3.2: **The Latent Substrate ($\tau = \tau_S$).** The fundamental substrate architecture is a topologically locked Simple Cubic (SC) lattice at the irreducible scale ($\ell_S \approx 10^{-35}\,\mathrm{m}$). **(a) The Volumetric Core (Equilibrium Phase):** A three-dimensional representation of the equilibrium Hard Floor. The convention ($\varphi_S = 0$) establishes the substrate phase reference, while ($\Delta\varphi = 0$) specifies internal phase locking. The maximum substrate force scale is ($F_S = c_E^4/G$), corresponding to the finite yield-pressure scale ($\tau_S = F_S/\ell_S^2$). **(b) The Lattice Projection (Reference Frame):** A two-dimensional representation of the absolute structural reference, characterized by the limiting rigidity ($K_S \to \infty$) and vanishing intrinsic inertial response ($\mu_S \to 0$). The associated limit ($c_S \to \infty$) represents longitudinal constraint equilibration through the connected phase-locked Hard Floor.

The Three Topological States of the Field

The contiguous field admits three topological states distinguished by their structural organization, phase freedom, and mechanical response.

State 0: The Latent Substrate (Equilibrium; $\Delta\varphi = 0,\ \nabla\tau = 0$): State 0 denotes the Hard Floor defined above in its unperturbed equilibrium condition. It is the persistent phase-locked SC foundation of the field and supplies the absolute structural reference and static longitudinal record. Because State 0 constitutes the foundational substrate rather than an alternative coarse structure occupying the same scale, the Hard Floor remains structurally present beneath the active and saturated configurations defined below.

State I: The Active Vacuum (Expansion/Elastic; $0 \le \alpha_G < 1$): At the characteristic active-vacuum scale (r_D), the persistent Hard Floor supports a dynamic Face-Centered Cubic (FCC) organization of resonant nodes and a connected interstitial condensate. The FCC scaffold possesses the finite surface-tension scale (τ_D) and finite inertial response required for active elastic dynamics.

Unlike the phase-locked Hard Floor, State I possesses finite phase freedom: local phase differences and temporal phase evolution are mechanically permitted. This active freedom enables elastic deformation, transverse coherent propagation, localized topological defects, and interstitial inertial response. The full State-I constitutive domain is

$$0 \le \alpha_G < 1, \tag{3.17}$$

from the unstrained active vacuum through gravitationally loaded configurations below saturation.

State II: The Saturated Core (Compression/Saturation; $\Delta\varphi = 0,\ \alpha_G = 1$): State II is reached when gravitational loading exhausts the available reconfiguration capacity of the ac-

tive FCC organization. At saturation, the active FCC degrees of freedom can no longer sustain their interstitial and phase freedom. The active organization collapses to the substrate-limited SC structural condition and becomes locally phase locked.

The loss of interstitial freedom eliminates the active oscillation and state transfer supported by State I, mechanically arresting the corresponding local dynamical evolution.

Although State 0 and State II both possess phase-locked SC character, they represent different mechanical conditions: **State 0 is the equilibrium foundational substrate, whereas State II is the compressed, saturated configuration produced from State I.**

Table 3.1: Summary of the SC Phase Substrate Constants (See Appendix A for the mechanical definitions of these values)

Property	**Symbol**	**Mathematical Relation**	**Mechanical Definition**
Reference Phase	φ_{S}	0	Equilibrium phase-reference convention of the Hard Floor
Phase Locking	$\Delta\varphi$	0	Internal phase-locked condition of the unperturbed substrate
Coherence	Ψ_{S}	$\sqrt{n_0}\cdot e^{i0} \quad (n_0 = \ell_{\mathrm{S}}^{-3})$	Uniform equilibrium coherence of the phase-locked substrate
Lattice Spacing	ℓ_{S}	$\sqrt{\hbar G/c_{\mathrm{E}}^3}$	Irreducible structural interval of the SC Hard Floor
Structural Mass Moment	J_{S}	$\rho_{\mathrm{S}}\ell_{\mathrm{S}}^4$	Substrate realization of the conserved structural mass moment underlying $\hbar$ and G
Bond Force	F_{S}	c_{E}^4/G	Maximum substrate force scale
Yield Pressure	τ_{S}	$F_{\mathrm{S}}/\ell_{\mathrm{S}}^2$	Finite limiting volumetric stress capacity of the Hard Floor
Latent Energy	E_{S}	$F_{\mathrm{S}}\ell_{\mathrm{S}}$	Latent structural energy associated with one substrate cell
Incremental Rigidity	K_{S}	$\to\infty$	Vanishing incremental deformability of the phase-locked substrate
Active Wave Mode	—	None	No ordinary independently propagating active-phase mode in the Hard Floor
Intrinsic Inertial Response	μ_{S}	$\to 0$	Vanishing intrinsic inertial response of the bare Hard Floor
Equilibrium Entropy	S_{S}	0	Perfect geometric order of the unperturbed substrate
Longitudinal Connectivity	c_{S}	$\to\infty$	Zero-delay longitudinal constraint equilibration through the connected phase-locked substrate
Absolute Substrate Index	N_{S}	$R_{\mathrm{Res}}/\ell_{\mathrm{S}}$	Total dimensionless radial node count ($\approx 3.827\times10^{69}$). Derived in the Unified Phase Map Summary.

3.3.1 The Master Geometric Scaling Law

To transition from State 0 (The Latent Substrate) to State I (The Active Vacuum), the universe cannot simply fracture across scales; it must strictly conserve its fundamental mechanical action.

As introduced in the Substrate Constants table (Section 3.1) and formally established in Appendix B, the absolute topology-normalized Scale-Invariant Mass Moment of the vacuum is defined as $\hat{J} \equiv J_i/\mathcal{F}_i$. Because the latent geometric form factor is $\mathcal{F}_{\mathrm{S}} = 1.0$, the raw structural mass moment of the Hard Floor ($J_{\mathrm{S}} = \rho_{\mathrm{S}}\ell_{\mathrm{S}}^4$) serves as the Substrate realization of this topology-normalized invariant. This invariant represents the irreducible, intrinsic structural mass capacity of the field—the absolute mechanical anchor for Quantum Action ($\hbar$) prior to the emergence of kinematic mass. Because the vacuum is a contiguous elastic medium, this fundamental topology-normalized action must be conserved across all phase bounds.

To conserve this mechanical action while maintaining a constant transverse wave speed (c_{E}), the localized density of the vacuum (ρ) must geometrically dilute as a strict function of the inverse-fourth power of the radius (r). This geometric projection is governed by the Master Geometric Scaling Law:

$$\rho(r) = \mathcal{F}_i \cdot \rho_{\mathrm{S}} \left(\frac{\ell_{\mathrm{S}}}{r} \right)^4 \tag{3.18}$$

Where:

- ρ_{S}: The absolute Substrate Density ($\approx 5.1550 \times 10^{96}$ kg/m^3).
- ℓ_{S}: The 1D Substrate Lattice Spacing ($\approx 1.6162 \times 10^{-35}$ m).
- r: The radial topological scale of the localized node.
- $\mathcal{F}_i$: The Topological Form Factor, which accounts for the specific volumetric geometry of the localized phase state ($\mathcal{F}_{\mathrm{D}} = 1.5$ for the spherical nodes of the active Soft Floor).

(See Appendix B for the strict mathematical derivation of this scaling law, the geometric proof of the Form Factor, and the Topological Boundary Equation).

This equation acts as the universal gear ratio of Tension Field Theory. It proves that the emergent density of the observable cosmos is not an arbitrary parameter, but a strict, deterministic projection of the underlying Hard Floor.

When this scaling law is evaluated at the FCC Node Radius ($r = r_{\mathrm{D}} \approx 10^{-26}$ m), it dictates the exact mechanical density of the observable Spacetime Gravitational Floor, setting the stage for the active vacuum.

3.4 The Constitution of the FCC Phase Soft Floor Active Vacuum

While the Substrate, or Hard Floor, provides the absolute boundary conditions of the theory, the observable cosmos exists on the active Spacetime Gravitational Floor (SGF). As established in Postulate 2.2, Tension Field Theory (TFT) models this Soft Floor not as a fundamentally smooth geometric manifold, but as a dual-phase Face–Centered Cubic (FCC) medium produced by symmetry breaking at the calibrated FCC Node Radius,

$$r_{\mathrm{D}} \approx 7.45 \times 10^{-27}\,\mathrm{m}. \tag{3.19}$$

At this scale, the active SGF acquires finite contact stiffness, scaffold surface inertia, condensate pressure response, localized condensate impedance, and separately defined dissipative response

channels. The FCC configuration is selected as the cubic close-packed branch of the active vacuum because it combines twelve-neighbor coordination, a connected interstitial network, and direct structural compatibility with the saturated Simple Cubic phase. The FCC geometry establishes cubic material symmetry; exact isotropy of the leading long-wavelength elastic response additionally requires a constitutive relation between the normal and tangential contact coefficients.

For equal spherical nodes, as derived in Chapter 6, the FCC packing fraction is

$$\beta_{\mathrm{geo}} = \frac{\pi}{3\sqrt{2}} \approx 0.74048. \tag{3.20}$$

The complementary interstitial fraction is

$$\beta_{\mathrm{IC}} = 1 - \beta_{\mathrm{geo}} \approx 0.25952. \tag{3.21}$$

These quantities are geometric volume fractions of the active FCC structure. They partition the Soft Floor into two inseparable constitutive phases.

- **The Solid FCC Scaffold** ($\beta_{\mathrm{geo}} \approx 74.048\%$)
  - **Geometry:** The spherical FCC nodes occupy the fraction β_{geo} of each periodic cell and form a twelve-connected load-bearing scaffold. The nodes are not treated as perfectly rigid bodies; their interfaces possess finite normal, tangential, rotational, and phase-contact responses.
  - **Constitutive Role:** The FCC scaffold supplies the microscopic contact stiffness, baseline surface-tension scale, and restoring action of coherent transverse propagation. The node density ρ_{D}, derived in Appendix C, is the intrinsic operational material density assigned to the solid nodal phase. The corresponding primitive-cell FCC scaffold inertia density is
    $$\rho_{\mathrm{sh}}^{(\mathrm{micro},0)} = \beta_{\mathrm{geo}}\rho_{\mathrm{D}}. \tag{3.22}$$
    The factor β_{geo} arises because the nodal mass is averaged over the complete FCC primitive-cell volume; it does not represent a reduction of the intrinsic nodal density ρ_{D}.
  - **Mechanical Communication:** Neighboring nodes transmit deformation through the objective FCC contact network. This network supplies coherent transverse elastic communication. Gravitational loading acts on this baseline carrier through the separate endpoint-transfer constraint developed in Appendix J.

- **The Interstitial Condensate** ($\beta_{\mathrm{IC}} \approx 25.952\%$)
  - **Geometry:** The complementary fraction β_{IC} forms the contiguous tetrahedral–octahedral interstitial network between the FCC nodes. This connected region is occupied by the fluid-like interstitial condensate.
  - **Coherent Constitutive Role:** In the conservative coherent branch, the condensate is entrained with the FCC scaffold without relative condensate flow and supplies the incremental pressure response required by the selected volume constraint. Entrainment fixes the relative kinematics of the two phases but does not, at the present constitutive order, establish an independently additive condensate contribution to the primitive-cell scaffold inertia.

– **Localized Constitutive Role:** A localized topological defect can produce condensate motion relative to the surrounding scaffold. The resulting conservative relative-flow field generates a mode-resolved hydrodynamic added inertia of the localized defect coordinate. Viscous impedance, irreversible heating, and vacuum damping arise only when a dissipative phase lag or other nonconservative response is introduced separately.

– **Status of the Projected Density:** The quantity historically denoted by ρ_{IC} in the calibrated particle calculations is not yet established as an independently derived intrinsic equilibrium density of the condensate. Under the presently adopted empirical projection,

$$\rho_{\mathrm{IC}}^{(\mathrm{emp})} = \mu_{\mathrm{D}} \iota_{\mathrm{V}}^{(\mathrm{emp})}, \qquad \iota_{\mathrm{V}}^{(\mathrm{emp})} = 1\,\mathrm{m}^{-1}. \tag{3.23}$$

This is an equivalent projected defect-impedance density. The microscopic mode-resolved replacement is

$$\rho_{\mathrm{IC}}^{(\mathrm{imp})} = \mu_{\mathrm{D}} \iota_{\mathrm{V}}^{(\mathrm{def})}, \tag{3.24}$$

where $\iota_{\mathrm{V}}^{(\mathrm{def})}$ is determined by the localized defect-flow boundary-value problem developed in Appendix E.

3.4.1 Leading Constitutive Closure of the Active FCC Vacuum

Let $\mathbf{u}(\mathbf{x}, t)$ denote the FCC scaffold displacement and let $\mathbf{v}_{\mathrm{IC}}(\mathbf{x}, t)$ denote the condensate velocity. Their relative velocity is

$$\mathbf{v}_{\mathrm{rel}} = \mathbf{v}_{\mathrm{IC}} - \dot{\mathbf{u}}. \tag{3.25}$$

For the conservative coherent branch,

$$\mathbf{v}_{\mathrm{rel}} = \mathbf{0}. \tag{3.26}$$

Equation (3.26) does not require the condensate to remain absolutely stationary. It states that the condensate and the FCC scaffold move together at the retained coherent order. Relative condensate flow is reserved for localized defect impedance, dissipative phase lag, or another explicitly non-entrained sector. The entrainment condition alone does not establish an independently additive condensate kinetic density.

The nearest-neighbor FCC contact system homogenizes to a cubic elastic continuum. Cubic symmetry alone does not guarantee exact isotropy. Within the leading objective contact model, exact long-wavelength isotropy requires equality of the normal and tangential contact coefficients:

$$\kappa_{\mathrm{n}} = \kappa_{\mathrm{t}} \equiv \kappa_{\mathrm{c}}. \tag{3.27}$$

Under this constitutive closure, the unstrained primitive-cell scaffold tangent shear coefficient satisfies

$$K_{\mathrm{sh}}^{(\mathrm{micro},0)} = \rho_{\mathrm{sh}}^{(\mathrm{micro},0)} c_{\mathrm{E}}^2 = \beta_{\mathrm{geo}} \rho_{\mathrm{D}} c_{\mathrm{E}}^2. \tag{3.28}$$

Here $K_{\mathrm{sh}}^{(\mathrm{micro},0)}$ is the unstrained primitive-cell tangent shear modulus of the FCC scaffold, homogenized over the complete primitive-cell volume. It is a constitutive stiffness and is not itself a static shear stress, a gravitational-wave stress, a measure of local gravitational loading, or a localized defect impedance coefficient.

The microscopic scaffold coefficient must not be identified directly with an effective macroscopic gravitational-wave response coefficient. Such an identification requires an explicit collective-mode projection and coarse-graining construction of the type developed conditionally in Appendix N.

The condensate supplies the incremental pressure response associated with the selected coherent volume constraint, while the FCC contact system supplies the finite transverse restoring coefficient. Under this coherent constitutive reduction, the translational acoustic sector contains two finite-frequency transverse polarizations and no independent finite-frequency longitudinal volumetric polarization. This statement applies only to the incremental coherent FCC branch. It does not eliminate static longitudinal tension, quasistatic condensate pressure, localized defect-induced pressure and redistribution fields, or finite background compaction toward the FCC–SC phase transition.

The complete objective FCC contact action, primitive-cell scaffold inertia normalization, homogenized cubic tensor, isotropy condition, and microscopic transverse normalization are derived in Appendix D. The coherent condensate constraint, localized relative-flow sector, and mode-resolved impedance projection are developed in Appendix E.

The Mechanical Stage

The Soft Floor is neither a pure crystal nor a pure fluid. It is a coupled dual-phase medium whose solid and condensate constituents perform distinct but dynamically connected mechanical functions. The FCC scaffold provides the contact structure and finite transverse restoring action. The condensate is entrained without relative flow in coherent propagation, enforces the incremental volume constraint through its pressure response, and develops relative flow around localized topological defects. Conservative relative flow produces hydrodynamic added inertia of the localized defect coordinate, whereas viscous or phase-lagged relative flow produces damping and irreversible energy transfer.

The geometric partition alone does not determine every constitutive coefficient. The FCC arrangement fixes the packing fractions and cubic neighbor geometry, while the contact law, condensate constraint, defect topology, phase participation, and gravitational endpoint constraint determine the realized mechanical response. The subsequent chapters apply this architecture to quantized action, particle mass, gravity, optical propagation, structural saturation, and the dark-sector response.

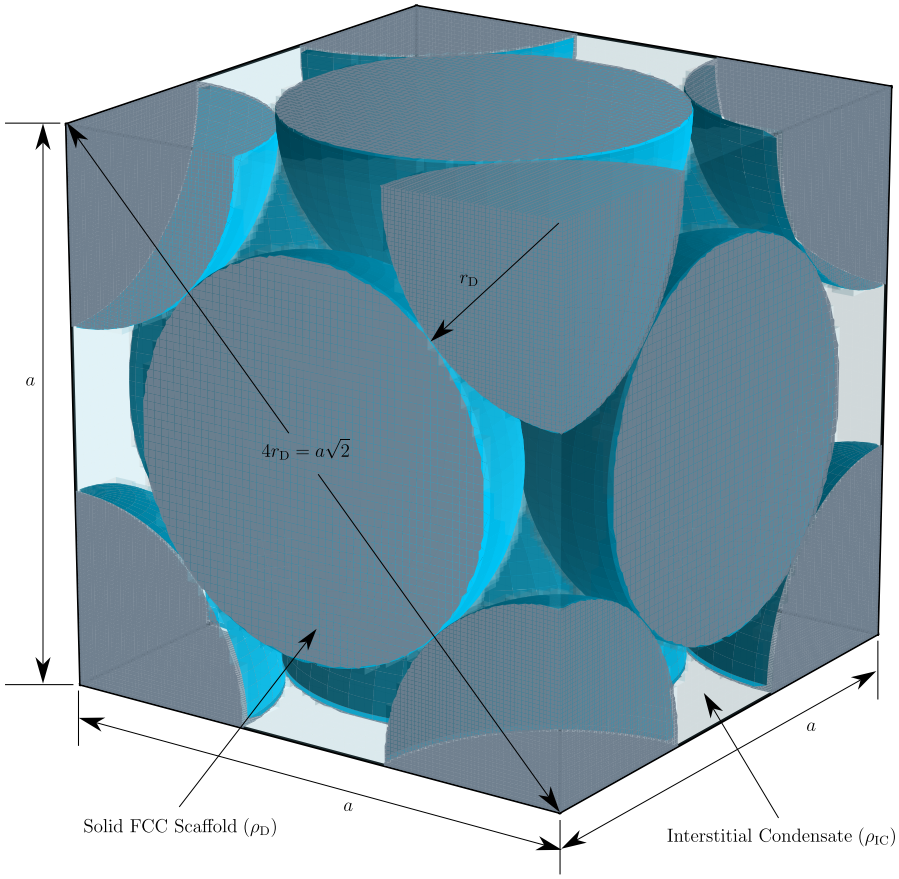

Figure 3.3: **The Active Vacuum Phase: Soft Floor FCC Architecture.** The active vacuum is represented as a Face–Centered Cubic structure at the calibrated FCC Node Radius $r_D \approx 7.45 \times 10^{-27}\,\mathrm{m}$. Equal-node FCC packing partitions each periodic cell into the solid nodal fraction $\beta_{geo} = \pi/(3\sqrt{2}) \approx 0.74048$ and the connected interstitial fraction $\beta_{IC} = 1 - \beta_{geo} \approx 0.25952$. The solid nodal phase has intrinsic operational density $\rho_D \approx 1.71 \times 10^{62}\,\mathrm{kg\,m^{-3}}$ and supplies the FCC contact structure and baseline surface-tension scale τ_D. Its primitive-cell scaffold inertia normalization is $\rho_{sh}^{(micro,0)} = \beta_{geo}\rho_D$, with baseline microscopic scaffold tangent shear coefficient $K_{sh}^{(micro,0)} = \beta_{geo}\rho_D c_E^2$. The interstitial condensate occupies the connected void network, is entrained without relative flow in the conservative coherent branch, and supplies the incremental pressure response of the selected volume constraint. This entrainment does not independently establish an additive condensate kinetic density. The currently calibrated value $\rho_{IC}^{(emp)} \approx 1.81 \times 10^{53}\,\mathrm{kg\,m^{-3}}$ is an empirical equivalent defect-impedance density obtained from $\rho_{IC}^{(emp)} = \mu_D \iota_V^{(emp)}$ with $\iota_V^{(emp)} = 1\,\mathrm{m^{-1}}$; it is not an independently derived intrinsic equilibrium condensate density and remains conditional until the microscopic defect-flow boundary-value problem determines the mode-resolved projection.

Table 3.2: Summary of FCC Phase Active Vacuum Constants and Constitutive Coefficients. See Appendix C, Appendix D, Appendix E, and Appendix S for the corresponding derivations and constitutive status.

Property	**Symbol**	**Mathematical Relation**	**Mechanical Definition**
Phase Freedom	$\varphi(t)$	$\Delta\varphi$ permitted	Dynamic phase freedom of the active Soft Floor; local phase differences and temporal phase evolution are mechanically permitted
Geometry	—	FCC	Cubic close-packed active-phase architecture
FCC Node Radius	r_{D}	$hc_{\mathrm{E}}/(2E_{\mathrm{D}})$	Fundamental geometric resolution scale of the SGF
Kinematic Lattice Index	N_{D}	$R_{\mathrm{U}}/(2r_{\mathrm{D}})$	Total dimensionless radial node count, approximately 8.508×10^{51}
Structural Mass Moment	J_{D}	$\rho_{\mathrm{D}} r_{\mathrm{D}}^4$	Lattice structural mass moment entering the TFT cross-scale construction
Yield Pressure Scale	$\tau_{\mathrm{D,bulk}}$	$c_{\mathrm{E}}^4/(Gr_{\mathrm{D}}^2)$	Finite active-phase saturation and yield-pressure scale; distinct from the tangent incompressibility parameter B_{IC}
Surface-Tension Scale	τ_{D}	$c_{\mathrm{E}}^4/(Gr_{\mathrm{D}})$	Baseline active-FCC surface-tension and contact-restoring scale
Surface Inertia	μ_{D}	$c_{\mathrm{E}}^2/(Gr_{\mathrm{D}})$	Baseline FCC scaffold surface-inertia coefficient
Primitive-Cell Scaffold Inertia	$\rho_{\mathrm{sh}}^{(\mathrm{micro},0)}$	$\beta_{\mathrm{geo}}\rho_{\mathrm{D}}$	Solid nodal mass averaged over the complete FCC primitive-cell volume; no independently additive condensate inertia is implied
Primitive-Cell Scaffold Shear	$K_{\mathrm{sh}}^{(\mathrm{micro},0)}$	$\rho_{\mathrm{sh}}^{(\mathrm{micro},0)} c_{\mathrm{E}}^2$	Unstrained primitive-cell tangent shear modulus of the FCC scaffold
Impedance Acceleration	a_{D}	$c_{\mathrm{E}}^2/R_{\mathrm{U}} = c_{\mathrm{E}}\Gamma_{\mathrm{D}}$	Cosmic vacuum-impedance acceleration scale
Damping Rate	Γ_{D}	$c_{\mathrm{E}}/R_{\mathrm{U}}$	Vacuum damping rate used in the cosmological redshift sector
Wave-Speed Limit	c_{E}	$\sqrt{\tau_{\mathrm{D}}/\mu_{\mathrm{D}}}$	Gravity-neutral transverse transfer-speed limit of the active FCC carrier

Continued on next page

Table 3.2 – *Continued from previous page*

Property	**Symbol**	**Mathematical Relation**	**Mechanical Definition**
Empirical Defect-Impedance Density	$\rho_{\mathrm{IC}}^{(\mathrm{emp})}$	$\mu_{\mathrm{D}}\iota_{\mathrm{V}}^{(\mathrm{emp})}$	Equivalent defect-impedance density under the empirical projection $\iota_{\mathrm{V}}^{(\mathrm{emp})} = 1\,\mathrm{m}^{-1}$; not an independently derived intrinsic equilibrium condensate density
Mode-Resolved Defect-Impedance Density	$\rho_{\mathrm{IC}}^{(\mathrm{imp})}$	$\mu_{\mathrm{D}}\iota_{\mathrm{V}}^{(\mathrm{def})}$	Equivalent volumetric inertia projection associated with a specified localized relative-flow mode
Quantum Mass	$M_{\mathrm{D,Q}}$	$\rho_{\mathrm{D}} r_{\mathrm{D}}^3$	Three-dimensional localized inertia scale of a single quantum node
Defect Impedance Coefficient	$K_{\mathrm{D}}^{(\mathrm{def})}$	$4\pi r_{\mathrm{D}}^2 \mu_{\mathrm{D}} \iota_{\mathrm{V}}^{(\mathrm{def})} \mathcal{G}_{\mathrm{imp}}$	Mode-resolved thin-layer conservative defect-loading coefficient; the historical universal form requires additional projection and geometry closures
Operational Node Density	ρ_{D}	$1.5\,\rho_{\mathrm{Q}}$	Intrinsic operational mass density assigned to the active FCC nodal phase
Gravitational Yield Density	$\rho_{\mathrm{D,G}}$	$c_{\mathrm{E}}^2/(G r_{\mathrm{D}}^2)$	Structural density scale associated with the active-phase yield limit
Quantum Energy Limit	$E_{\mathrm{D,Q}}$	$hc_{\mathrm{E}}/(2r_{\mathrm{D}})$	Kinematic saturation scale associated with the phase-transition trigger
Gravitational Energy Limit	$E_{\mathrm{D,G}}$	$\mu_{\mathrm{D}} c_{\mathrm{E}}^2 r_{\mathrm{D}}^2$	Structural gravitational yield-energy scale
Node Saturation Mass	$M_{\mathrm{D,G}}$	$c_{\mathrm{E}}^2 r_{\mathrm{D}}/G$	Local mass scale associated with structural locking of an active node

Note: The vacuum-impedance acceleration is $a_{\mathrm{D}} = c_{\mathrm{E}}\Gamma_{\mathrm{D}} = c_{\mathrm{E}}^2/R_{\mathrm{U}}$, as developed in Appendix L. The galactic low-acceleration comparison scale used in the TFT response law is $a_{\mathrm{gal}} = a_{\mathrm{D}}/(2\pi)$. The damping rate Γ_{D} is developed in Appendix AQ. The quantities $\rho_{\mathrm{IC}}^{(\mathrm{emp})}$ and $K_{\mathrm{D}}^{(\mathrm{def})}$ describe projected localized defect response and must not be interpreted as independently established intrinsic condensate density or universal defect coupling without the corresponding microscopic projection and geometry closures.

Chapter 4

Lattice Constraints and Quantization

The discrete architecture of the SGF imposes strict mechanical limits on physical action. "Quantum Mechanics" is defined here as the stress-strain constitutive law of the vacuum lattice.

4.1 The Resolution Limit

The FCC Node Radius (r_{D}) constitutes the physical resolution limit of the vacuum.

- **Constraint:** Position is physically undefined below the lattice spacing ($x < r_{\mathrm{D}}$).
- **Mechanism:** Attempting to localize energy below this scale induces lattice shear rather than coordinate precision, converting positional information into vibrational noise (Uncertainty).

4.2 Quantization of Action (Origin of h)

Energy quantization in Tension Field Theory is modeled by treating the Soft Floor lattice as a stiff resonator that restricts non-resonant vibrational modes.

- **Mechanism:** The contiguous lattice accepts energy transfer in discrete, whole-cycle packets sufficient to activate the full harmonic rotation of a node.
- **Definition:** The Planck constant (h) is therefore represented mechanically as the *Action of Existence*—the rotational momentum required to complete one cycle of a single Soft Floor node.

As established in Appendix B, TFT demonstrates that the observable action is a consistent geometric realization of the topology-normalized Scale-Invariant Mass Moment. This absolute conserved quantity across all phase layers is denoted $\hat{J} = J_i/\mathcal{F}_i$. For the Soft Floor node, the raw structural mass moment ($J_{\mathrm{D}} = \rho_{\mathrm{D}} r_{\mathrm{D}}^4$) includes a spherical compression form factor of $\mathcal{F}_{\mathrm{D}} = 1.5 = \frac{3}{2}$.

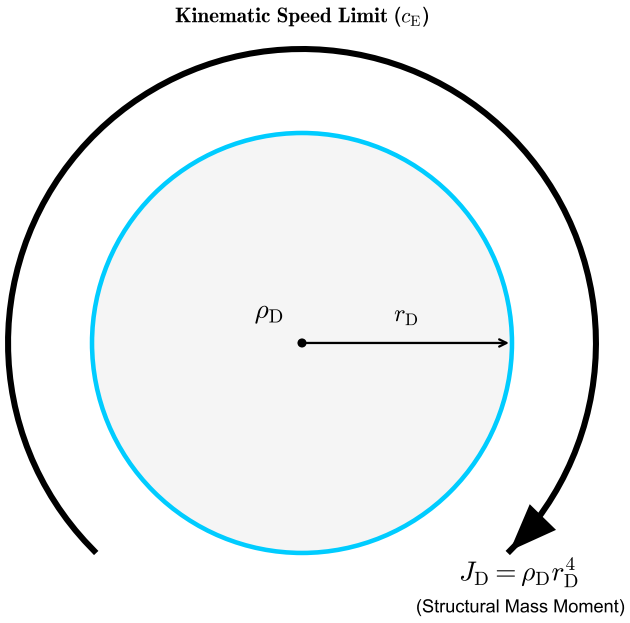

Evaluating the strict kinematic product of the node's geometry, its raw mass moment, and the transverse speed limit (c_{E}) yields:

$$h = \frac{4}{3}\pi \cdot J_{\mathrm{D}} \cdot c_{\mathrm{E}} \tag{4.1}$$

By substituting the Soft Floor raw structural mass moment, ($J_{\mathrm{D}} = \frac{3}{2}\hat{J}$), the spherical volume and compression factors mathematically cancel to explicitly recover the fundamental 2π rotational phase structure:

$$h = \frac{4}{3}\pi \left(\frac{3}{2}\hat{J}\right) c_{\mathrm{E}} \implies h = 2\pi \cdot \hat{J} \cdot c_{\mathrm{E}} \tag{4.2}$$

yielding the observable quantum of action $h \approx 6.6261 \times 10^{-34}$ J · s.

$$h = \frac{4\pi}{3} \cdot J_{\mathrm{D}} \cdot c_{\mathrm{E}}$$

Figure 4.1: **The Mechanical Kinematics of the Quantum of Action (h).** This schematic illustrates the internal rotational architecture of the localized Soft Floor node. As depicted, the fundamental action (h) is initially formulated as the direct product of the node's raw Structural Mass Moment (J_{D}), the transverse kinematic speed limit (c_{E}), and its spherical geometry ($\frac{4}{3}\pi$). As derived in the text, substituting the absolute topology-normalized mass moment ($\hat{J}$) mathematically cancels these volumetric and compression factors to yield a pure 2π phase state.

The Geometric Requirement of Integer Cycles ($S = nh$)

To maintain structural stability, the contiguous Face–Centered Cubic (FCC) lattice cannot sustain partial geometric phase rotations. A localized topological defect must complete a full 360° volumetric rotation (2π radians) to successfully return the surrounding vacuum nodes to their neutral, relaxed baseline; a partial cycle leaves the lattice permanently deformed under unsustainable

elastic strain.

This establishes a strict boundary condition on the accumulated macroscopic action (S) of any mechanical event within the medium. If the continuous phase angle of the rotation is φ, the total action is defined as $S = \hbar\varphi$. Because the physical lattice requires complete rotations, the phase angle must strictly equal integer multiples of 2π ($\varphi = n \cdot 2\pi$, where $n = 1, 2, 3, \ldots$). Substituting this geometric requirement yields:

$$S = \hbar(n \cdot 2\pi) = nh \tag{4.3}$$

In standard quantum mechanics, $S = nh$ represents the abstract Bohr-Sommerfeld quantization postulate. In Tension Field Theory, it is the mandatory solid-state condition for structural equilibrium. Energy and action are strictly quantized because topological defects must complete full, integer rotations (n) to preserve the macroscopic geometric harmony of the crystal lattice.

The Physical Translation of the De Broglie Wave

This internal quantization directly generates the macroscopic momentum vector. In standard quantum mechanics, the instantaneous phase of a propagating plane wave is defined as $\varphi(\mathbf{x}, t) = \mathbf{k}\cdot\mathbf{x} - \omega t$, where the spatial gradient of the phase yields the wave vector ($\nabla\varphi = \mathbf{k}$).

TFT physicalizes this relationship. Because the central node must rotate in discrete, quantized cycles (h) against the lattice resistance, it induces a discrete spatial phase gradient ($\nabla\varphi$) in the surrounding medium. Therefore, the standard quantum momentum relation (the De Broglie equation) is not a probabilistic abstraction, but a strict continuum mechanics identity defining the physical push of the phase gradient:

$$\mathbf{p} = \hbar\mathbf{k} \quad \equiv \quad \mathbf{p} = \hbar(\nabla\varphi) \tag{4.4}$$

Momentum is the mechanical projection of the node's internal action ($\hbar$) propagating across the spatial phase gradient ($\nabla\varphi$) of the contiguous vacuum.

4.3 The Mechanical Origin of the Pilot Wave

The lattice architecture mechanically resolves the Wave-Particle paradox by separating the Topological Node from the Elastic Response of the Field.

- **Mechanism:** The Resonant Node (Particle) generates elastic shear waves in the surrounding Soft Floor.
- **Result:** These waves reflect off the lattice geometry, creating a local pressure gradient that steers the node's trajectory. The particle is guided by the hydrodynamic wake of its own vibration, which is elaborated upon in Part II (Section 14.1).

Chapter 5

The Mechanical Origin of Mass

5.1 The Singularity Paradox

The current synthesis of physics does not provide a common microscopic account of particle localization, inertial mass, and gravitational loading. Quantum field theory represents particles as quantized excitation states of underlying fields, whereas classical General Relativity permits singular limits in which localized mass–energy is associated with divergent density or curvature. These descriptions are operationally successful, but they do not identify a shared mechanical origin for what a fundamental particle physically is.

Tension Field Theory (TFT) replaces the point-particle with a finite localized excitation of the active FCC vacuum. A particle is not an independent object inserted into space, but a persistent, topologically nontrivial defect supported by an FCC node and its connected contact network. Because the particle state has a finite localization scale, finite boundary deformation, and finite condensate participation, TFT does not require an infinitely dense material core. Its experimentally point-like behavior is interpreted as a limited external interaction footprint rather than evidence for a literal zero-radius object.

5.2 The Surface State Topology

Building on the Spacetime Gravitational Floor architecture and Definition 2.3, TFT identifies matter as a localized topological defect of the active vacuum itself.

The support structure and the defect must be distinguished:

- **The Core (The Support Node):** The FCC node,

$$r_{\mathrm{D}} \approx 7.4504 \times 10^{-27}\,\mathrm{m}, \tag{5.1}$$

  provides the phase-coherent structural support for the localized excitation. It possesses finite contact stiffness, surface inertia, and objective boundary degrees of freedom through which the defect couples to neighboring nodes.

- **The Defect (The Matter):** Matter exists as a localized phase, torsional, radial, or mixed deformation concentrated on the 2D nodal boundary and its connected contact network.

The physical particle is therefore not identical to the underlying node. The node belongs to the universal vacuum scaffold, whereas the particle is the persistent nontrivial state carried by that scaffold.

5.3 The Three Faces of Mass

In Tension Field Theory, the word "mass" describes three operational manifestations of one localized topological state. They are distinct mechanical projections of the same topological loading coefficient, M_{top}.

- **Static Mass (Gravitational Loading):** In equilibrium, the defect imposes a persistent structural load on the surrounding Spacetime Gravitational Floor. This loading establishes the static tension field through which the defect acts as a gravitational source.
- **Dynamic Mass (Particle Identity):** The identity of a fundamental particle is determined by its complete localized dynamical state: topological class, phase structure, resonance sector, and deformation amplitude.
- **Kinematic Mass (Inertial Response):** When the defect is accelerated or reconfigured, it induces condensate motion relative to the FCC scaffold. The reversible kinetic energy stored in this relative-flow field produces conservative hydrodynamic added inertia.

Within the equivalence closure developed in the gravitational sector, these manifestations are identified through the same scalar loading coefficient:

$$m_{\text{i}} = m_{\text{g}} = M_{\text{top}}. \tag{5.2}$$

5.4 The Mechanism of Kinematic Mass: Conservative Added Inertia

As established in Definition 2.3, a fundamental massive particle does not possess mass as an intrinsic material substance confined inside a core. Its inertial mass is the effective kinetic coefficient generated when the localized defect induces condensate motion relative to the surrounding FCC scaffold.

The two phases of the active vacuum perform complementary mechanical functions:

- **The FCC Nodal Scaffold:** Supplies the contact stiffness and restoring action that sustain the localized defect. Within the reduced radial breathing-mode ansatz, the corresponding characteristic support-node frequency is

$$f_{\text{m}} = \frac{c_{\text{E}}}{4r_{\text{D}}}. \tag{5.3}$$

  The doubled radial transit provides a kinematic correspondence with the TFT fermion-cycle construction, but does not by itself constitute a complete derivation of spin-1/2.

- **The Interstitial Condensate:** Supplies the external hydrodynamic response (added inertia) when the defect translates or reconfigures.

The mode-weighted boundary and condensate-volume construction developed in Appendix E identifies the inertial coefficient with the topological loading coefficient:

$$m_{\text{i}} \equiv M_{\text{top}} = \rho_{\text{IC}}^{(\text{imp})} V_{\text{imp}} f_{\varphi}(\Delta\varphi). \tag{5.4}$$

Appendix E derives this coefficient from the reversible kinetic energy of the defect-induced condensate relative-flow field; the particle-specific boundary-value solutions remain to be determined for individual defect sectors. The formal translational limit recovers:

$$\mathbf{F}_{\mathrm{ext}} = m_{\mathrm{i}}\mathbf{a}. \tag{5.5}$$

Conclusion:
A fundamental particle possesses no independent material mass substance. It is a localized topological defect sustained by the FCC scaffold and conservatively loaded by the surrounding interstitial condensate. The scaffold supplies the restoring structure of the defect, while the condensate supplies the reversible added inertia encountered during translation or reconfiguration. Inertial mass is therefore an interaction property of the complete defect–vacuum system rather than a viscous impedance coefficient.

5.5 Reduced Thin-Layer Mass Law

For a defect represented by a thin active layer of radial amplitude r_{amp} surrounding a node of radius r_{D}, the mass law reduces to:

$$m_{\mathrm{i}} = K_{\mathrm{D}}^{(\mathrm{def})} r_{\mathrm{amp}} f_{\varphi}(\Delta\varphi) \left[1 + \mathcal{O}\left(\frac{r_{\mathrm{amp}}}{r_{\mathrm{D}}}\right)\right], \tag{5.6}$$

where

$$K_{\mathrm{D}}^{(\mathrm{def})} = 4\pi r_{\mathrm{D}}^2 \mu_{\mathrm{D}} \iota_V^{(\mathrm{def})} \mathcal{G}_{\mathrm{imp}}. \tag{5.7}$$

The historical branch-level relation

$$m_{\mathrm{i}} = \rho_{\mathrm{IC}} V_{\mathrm{eff}} \sin(\Delta\varphi) \tag{5.8}$$

is recovered only under $\rho_{\mathrm{IC}}^{(\mathrm{imp})} = \rho_{\mathrm{IC}}$, $\mathcal{G}_{\mathrm{imp}} = 1$, $V_{\mathrm{eff}} = 4\pi r_{\mathrm{D}}^2 r_{\mathrm{amp}}$, and $f_{\varphi}(\Delta\varphi) = \sin(\Delta\varphi)$ on the selected nonnegative phase branch.

5.6 Conservative Inertia versus Dissipative Resistance

The coefficient m_{i} arises from reversible kinetic energy stored in the defect-induced condensate flow and therefore persists in the conservative limit. Viscous phase lag may produce damping, heating, or irreversible energy transfer, but it does not define the baseline inertial mass.

5.7 The Amplitude Hierarchy: Node Radius versus Defect Amplitude

Because all fundamental particles are supported by FCC nodes of the same calibrated structural radius ($r_{\mathrm{D}} \approx 7.4504 \times 10^{-27}\,\mathrm{m}$), the observed mass hierarchy is not interpreted as a hierarchy of different material core sizes.

In the general defect law, the mass hierarchy may depend on deformation amplitude, phase participation, boundary-mode geometry, and condensate impedance projection. Under the common calibration closures adopted below, this dependence reduces at leading order to an amplitude hierarchy:

$$\iota_V^{(\mathrm{def})} = 1\,\mathrm{m}^{-1}, \qquad \mathcal{G}_{\mathrm{imp}} = 1, \qquad f_{\varphi}(\Delta\varphi) = 1. \tag{5.9}$$

Under this radial thin-layer calibration, the leading relation reduces to:

$$r_{\mathrm{amp}} \simeq \frac{m_{\mathrm{i}}}{K_{\mathrm{D}}}. \tag{5.10}$$

Within the current rest-energy identification, the calibrated topological loading determines the corresponding rest-energy and proper-time scales:

$$E_0 = m_{\mathrm{i}} c_{\mathrm{E}}^2, \qquad t_{\mathrm{p}} = \frac{h}{E_0}. \tag{5.11}$$

- **Top Quark (The "Shout"):** Under the current calibration, $r_{\mathrm{amp(t)}} \approx 0.3283\, r_{\mathrm{D}}$. While it satisfies the geometric bound ($r_{\mathrm{amp}} < r_{\mathrm{D}}$), it acts as a high-amplitude "shout," producing a comparatively large condensate participation volume and added inertial loading. Because it is not asymptotically small, nonlinear boundary geometry and finite-deformation corrections may be significant.

- **Electron (The "Whisper"):** The calibrated electron amplitude is $r_{\mathrm{amp(e)}} \approx 7.23{\times}10^{-33}\,\mathrm{m} \ll r_{\mathrm{D}}$. Operating as a low-amplitude "whisper," it produces a much smaller calibrated condensate participation volume and lies deeply within the controlled linear thin-layer regime.

- **Standard Model Reinterpretation:** TFT does not interpret the experimentally point-like behavior of the electron as evidence for a literal zero-radius material core. The universal FCC support node retains the radius r_{D}, while the externally activated deformation amplitude r_{amp} is extremely small relative to both the node scale and present experimental resolution, giving the localized state an effectively point-like external interaction footprint at presently accessible resolution. *(See Appendix F for the complete numerical calibration).*

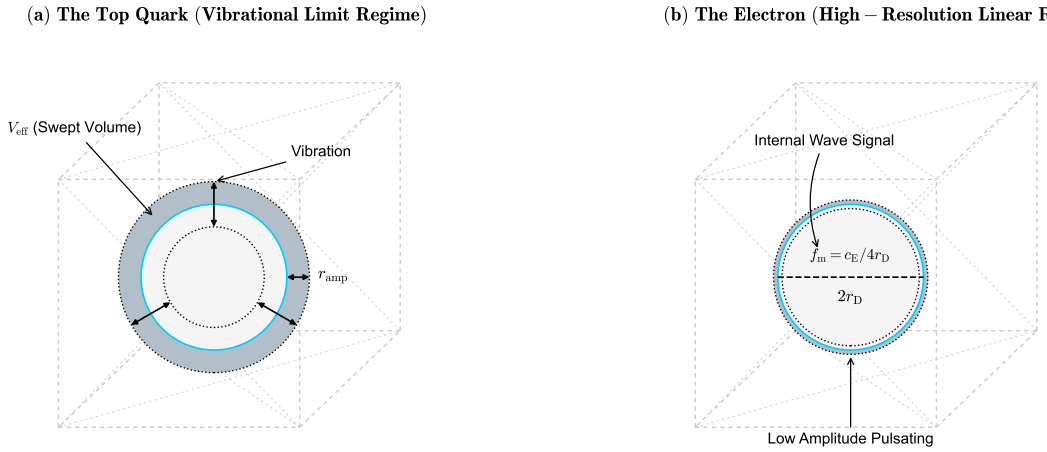

Figure 5.1: **Conditional Particle-Mass Calibration through Boundary Displacement.** Fundamental particles are represented as different localized topological states supported by FCC nodes of the common structural radius $r_{\text{D}} \approx 7.45 \times 10^{-27}$ m and characteristic resonance $f_{\text{m}} = c_{\text{E}}/(4r_{\text{D}})$. In the reduced thin-layer branch, the defect-induced condensate participation volume is approximated by $V_{\text{eff}} \approx 4\pi r_{\text{D}}^2 r_{\text{amp}}$, giving $m_{\text{i}} \approx \rho_{\text{IC}} V_{\text{eff}}$ when $\mathcal{G}_{\text{imp}} = 1$ and the selected phase-participation factor equals unity. **(a) Top Quark:** The current calibration gives $r_{\text{amp(t)}} \approx 0.3283\, r_{\text{D}}$. This is a high-amplitude estimate for which nonlinear defect geometry and condensate-flow corrections may be important. **(b) Electron:** The calibrated amplitude satisfies $r_{\text{amp(e)}} \ll r_{\text{D}}$ and lies within the controlled linear thin-layer regime. The plotted amplitudes remain conditional on the empirical projection $\iota_V = 1\ \text{m}^{-1}$, the unit geometry-factor approximation, and the selected phase branch.

5.8 Topological Stability, Creation, and Annihilation

A massive particle persists because its localized defect cannot be removed by a smooth deformation that preserves the surrounding vacuum topology.

- **Creation (Topological Locking):** A massive defect forms when a propagating lattice excitation closes into a persistent localized configuration characterized by a nontrivial protected invariant or phase class. The FCC contact network supplies the restoring action required to sustain the localized state.
- **Annihilation (Topological Unwinding):** Matter and antimatter are represented by defects carrying opposite topological orientation (chiral charge, χ). When inverse configurations overlap $\big(\chi + (-\chi) = 0\big)$, the combined state may unwind into the topologically trivial vacuum sector, releasing its stored structural and kinetic energy into coherent propagating excitations, including photons.

Annihilation is therefore not produced by the cancellation of positive and negative inertial mass (the kinetic coefficient remains nonnegative); what cancels is the signed topological quantity that protects the localized state.

5.9 The Resolution of Wave-Particle Duality

Quantum mechanics describes both wave-like propagation and localized interaction outcomes, but does not assign them a substrate-level mechanical decomposition. Tension Field Theory interprets these behaviors as two mechanical aspects of one localized topological state rather than as a physical transformation between a wave and a material point.

- **The Wave Nature (Internal Kinematics):** Internally, a particle is a phase-coherent topological excitation. Because the SGF nodes are permanently bonded, they cannot move independently; the phase-twist must be mechanically transferred from node to node. As it propagates, this coherent state transfer naturally exhibits classical wave behaviors (interference, diffraction, phase accumulation).
- **The Particle Nature (Localized Topology and Added Inertia):** Externally, this trapped wave must physically interact with its environment. As the internal phase-twist cycles, it forces the physical boundary of the node to radially pulse, inducing condensate motion and generating conservative added inertia ($m_{\mathrm{i}} = M_{\mathrm{top}}$). When this defect strikes a detector, its localized topology and finite inertial loading transfer energy and momentum through a discrete interaction event.

Conclusion:
The excitation never becomes a solid microscopic ball. Its wave character describes the coherent propagation and internal evolution of the defect state, while its particle character describes the localized topology and finite added inertial loading through which that state couples to a detector.

Chapter 6

Geometric Basis of the Cosmic Energy Budget

6.1 The Principle of Maximal Stability

In Section 2.1 (The Zeroth Law), the cosmos was defined as a contiguous tension substrate. In Section 3.4, the active phase of this substrate was represented by a close-packed lattice of finite nodes.

Tension Field Theory postulates that the active vacuum settles into a maximally coordinated, mechanically stable ground state. This requirement determines the geometric partition between the nodal lattice phase and the connected interstitial phase. The additional conditions under which this geometric partition corresponds to the cosmological energy budget are stated separately below.

6.2 The Kepler Conjecture and Lattice Packing

The structural packing limit is governed by the Kepler Conjecture [6], which establishes that no arrangement of equal-sized spheres in three-dimensional Euclidean space exceeds the density of a close-packed lattice.

Both Face-Centered Cubic (FCC) and Hexagonal Close-Packed (HCP) structures achieve this maximum density and coordination number 12. Maximum packing therefore restricts the active vacuum to the close-packed family but does not, by itself, uniquely select FCC.

For an FCC lattice with node radius r_{D}, the conventional cubic cell contains the equivalent of four complete spheres. Its nodal volume is

$$V_{\mathrm{nodes}} = 4\left(\frac{4}{3}\pi r_{\mathrm{D}}^3\right) = \frac{16}{3}\pi r_{\mathrm{D}}^3. \tag{6.1}$$

The FCC edge length is

$$a = 2\sqrt{2}\, r_{\mathrm{D}}, \tag{6.2}$$

so the unit-cell volume is

$$V_{\mathrm{cell}} = a^3 = 16\sqrt{2}\, r_{\mathrm{D}}^3. \tag{6.3}$$

6.3 The Vacuum Packing Fraction

The FCC nodal packing fraction is therefore

$$\begin{aligned}\beta_{\mathrm{geo}} &= \frac{V_{\mathrm{nodes}}}{V_{\mathrm{cell}}} \\ &= \frac{\frac{16}{3}\pi r_{\mathrm{D}}^3}{16\sqrt{2}\, r_{\mathrm{D}}^3} \\ &= \frac{\pi}{3\sqrt{2}} = \frac{\pi}{\sqrt{18}}.\end{aligned} \tag{6.4}$$

Numerically,

$$\beta_{\mathrm{geo}} \approx 0.74048. \tag{6.5}$$

The complementary interstitial fraction is

$$\beta_{\mathrm{IC}} = 1 - \beta_{\mathrm{geo}} \approx 0.25952. \tag{6.6}$$

These values are exact geometric volume fractions of the ideal FCC architecture. Their interpretation as energy fractions requires the constitutive closure introduced below.

6.4 Dynamic Selection of the FCC Lattice

Maximum packing alone leaves FCC and HCP geometrically degenerate. TFT adopts the FCC branch as its active close-packed ground state, constrained by the following symmetry and dynamical requirements:

- **Cubic Symmetry:** HCP contains a distinguished crystallographic axis, whereas FCC belongs to the cubic O_h symmetry class. FCC therefore provides the more suitable discrete foundation for an emergent vacuum having no preferred macroscopic direction.
- **Isotropic Contact Closure:** The twelve equivalent FCC nearest-neighbor directions generate a cubic long-wavelength elastic tensor. Exact leading-order isotropy is obtained only when the normal and tangential contact coefficients satisfy

  $$\kappa_{\mathrm{n}} = \kappa_{\mathrm{t}}. \tag{6.7}$$

  The objective contact construction and homogenization establishing this condition are developed in Appendix D.
- **Compatibility with the Saturated Phase:** The FCC active phase and the Simple Cubic Hard Floor both possess cubic symmetry. This motivates a mechanically compatible saturation transition between them, although the complete microscopic transformation pathway and activation barrier remain to be derived from the parent lattice potential.

The FCC structure is therefore the TFT-selected close-packed phase. Its selection is a constitutive ground-state choice constrained by packing, cubic symmetry, contact isotropy, and compatibility with the phase-locked substrate; it is not a uniqueness theorem derived from packing geometry alone.

6.5 Identification of the Cosmological Sectors

The commonly stated cosmological budget consists approximately of a dominant dark-energy sector, a secondary dark-matter sector, and a smaller baryonic sector. TFT interprets these sectors as distinct structural allocations and dynamical responses of the two-phase State-I FCC vacuum.

The exact FCC packing fractions determine the unperturbed geometric partition,

$$\beta_{\mathrm{geo}} \approx 0.74048, \qquad \beta_{\mathrm{IC}} \approx 0.25952. \tag{6.8}$$

Their interpretation as normalized structural-energy fractions requires the uniform structural-capacity closure introduced below. The complete phase-resolved tensor construction is developed in Appendix Q.

The TFT correspondence is:

- **Structural Nodal Sector:** The close-packed FCC nodal scaffold occupies

  $$\beta_{\mathrm{geo}} \approx 0.74048 \tag{6.9}$$

  of the ideal cell volume. This is the unperturbed structural allocation of the bonded State-I framework. Under the TFT defect-conversion closure, a fraction β_{b} of this allocation is converted into localized baryonic defects, leaving the smooth structural fraction

  $$\beta_{\Lambda,\mathrm{eff}} = \beta_{\mathrm{geo}} - \beta_{\mathrm{b}}. \tag{6.10}$$

  TFT associates this remaining nodal sector with the effective source contribution conventionally attributed to dark energy. Under the isotropic structural-tension closure, its tensor representation has

  $$w_{\mathrm{D}}^{(\mathrm{eff})} = -1. \tag{6.11}$$

  The corresponding negative effective pressure represents positive isotropic tensile prestress in the State-I solid rather than a fundamental negative-pressure fluid. The tensor derivation is developed in Appendix Q, while the corresponding redshift and apparent-acceleration phenomenology is developed in Appendices AQ and AS.

- **Interstitial Condensate Sector:** The connected interstitial phase occupies

  $$\beta_{\mathrm{IC}} = 1 - \beta_{\mathrm{geo}} \approx 0.25952. \tag{6.12}$$

  This value specifies the homogeneous structural allocation of the interstitial phase. Its dark-matter-like behavior does not follow from the geometric fraction alone, but from the dynamical condensate response generated around matter and extended through the interstitial network.

- **Baryonic Defect Sector:** Baryonic matter consists of localized topological defects of the active FCC vacuum, as defined in Definition 2.3. These defects are sustained by the FCC contact network and conservatively loaded by the interstitial condensate.

  The localized defect structure, its conservative condensate added inertia, and the local defect–condensate boundary response form one coupled mechanical state. They are therefore represented within the baryonic sector and are not counted as independent additive energy reservoirs.

Under the TFT defect-conversion closure, the structural energy assigned to baryonic defects is drawn from the unperturbed nodal-sector allocation:

$$\beta_{\Lambda,\mathrm{eff}} = \beta_{\mathrm{geo}} - \beta_{\mathrm{b}}. \tag{6.13}$$

For the adopted approximate baryonic fraction

$$\beta_{\mathrm{b}} \approx 0.05, \tag{6.14}$$

this gives

$$\beta_{\Lambda,\mathrm{eff}} \approx 0.74048 - 0.05 \approx 0.69048. \tag{6.15}$$

This subtraction is an energy-allocation closure. The local condensate participation that generates conservative defect inertia is already contained in the complete coupled baryonic state and is not added again as an independent interstitial contribution. Only the extended condensate response outside the localized defect domain is retained separately as part of the dynamical interstitial sector.

The energetic conversion and the geometric accommodation of baryonic defects are distinct. The subtraction

$$\beta_{\mathrm{geo}} - \beta_{\mathrm{b}} \tag{6.16}$$

identifies the structural allocation from which the defect energy is drawn. The octahedral-site construction developed in Appendix AT derives the inscribed-spherical volume fraction $\beta_{\mathrm{oct}} \approx 0.0526$, interpreted in TFT as the upper isotropic accommodation limit for condensed macroscopic defect states within the FCC interstitial architecture.

6.5.1 Structural Volumetric Energy Closure

The FCC packing fractions specify the geometric partition of the dual-phase State-I vacuum:

$$\beta_{\mathrm{geo}} = \frac{V_{\mathrm{D}}}{V_{\mathrm{cell}}}, \qquad \beta_{\mathrm{IC}} = \frac{V_{\mathrm{IC}}}{V_{\mathrm{cell}}}, \tag{6.17}$$

with

$$\beta_{\mathrm{geo}} + \beta_{\mathrm{IC}} = 1. \tag{6.18}$$

The cosmological background budget is a structural quantity rather than an operational inertial-density budget. TFT therefore characterizes the complete unperturbed FCC cell by the structural reference density ρ_{G} and its corresponding volumetric structural tension

$$\tau_{\mathrm{G}} = \rho_{\mathrm{G}} c_{\mathrm{E}}^2. \tag{6.19}$$

Here, τ_{G} is the coarse-grained structural capacity per unit volume of the complete dual-phase cell. It is not identified with the operational nodal density ρ_{D}, the nodal surface tension τ_{D}, or the mode-resolved condensate impedance density $\rho_{\mathrm{IC}}^{(\mathrm{imp})}$.

The conversion of the exact FCC volume fractions into normalized structural-energy fractions requires the uniform structural-capacity closure. In the local orthonormal State-I frame,

$$T_{\hat{0}\hat{0}}^{(\mathrm{D},0)} = T_{\hat{0}\hat{0}}^{(\mathrm{IC},0)} = \tau_{\mathrm{G}}. \tag{6.20}$$

This equality applies to the reference energy-density component only. It does not require the nodal and interstitial phases to possess equal operational densities, constitutive responses, momentum currents, or spatial stresses.

The total structural energy assigned to one reference FCC cell is

$$E_{\mathrm{G}}^{(\mathrm{cell})} = \tau_{\mathrm{G}} V_{\mathrm{cell}}. \tag{6.21}$$

The nodal and interstitial sectors partition this structural capacity as

$$E_{\mathrm{D}}^{(\mathrm{G})} = \beta_{\mathrm{geo}} \tau_{\mathrm{G}} V_{\mathrm{cell}}, \tag{6.22}$$

and

$$E_{\mathrm{IC}}^{(\mathrm{G})} = \beta_{\mathrm{IC}} \tau_{\mathrm{G}} V_{\mathrm{cell}}. \tag{6.23}$$

Therefore,

$$E_{\mathrm{D}}^{(\mathrm{G})} + E_{\mathrm{IC}}^{(\mathrm{G})} = E_{\mathrm{G}}^{(\mathrm{cell})}. \tag{6.24}$$

Following baryonic-defect conversion, the complete normalized structural-energy ledger is

$$(\beta_{\mathrm{geo}} - \beta_{\mathrm{b}}) + \beta_{\mathrm{IC}} + \beta_{\mathrm{b}} = 1. \tag{6.25}$$

The corresponding unperturbed TFT structural fractions are

$$\Omega_{\mathrm{D}}^{(\mathrm{TFT},0)} = \beta_{\mathrm{geo}}, \qquad \Omega_{\mathrm{IC}}^{(\mathrm{TFT},0)} = \beta_{\mathrm{IC}}. \tag{6.26}$$

These are normalized TFT structural fractions. Their comparison with conventional critical-density parameters requires the cosmological normalization bridge developed in Part III; the exact FCC packing fractions alone do not establish equality with the conventional Ω parameters.

The phase-resolved tensor realization of this structural partition is summarized in Section 11.3.4 and developed fully in Appendix Q.

6.5.2 Dynamical Distinction between the Vacuum Components

Although the nodal and interstitial sectors belong to the same contiguous State-I FCC vacuum, their mechanical responses are different:

- **Structural Nodal Response:** The close-packed FCC nodes and their bonded contact network form the connected restoring framework of the active vacuum. Their geometry strongly suppresses ordinary volumetric accumulation. Additional loading therefore requires elastic strain, defect formation, or transition out of the active FCC phase.

- **Interstitial Condensate Response:** The condensate occupies the connected void network and participates dynamically in defect-induced motion. A localized baryonic defect activates a mode-dependent condensate response characterized by conservative hydrodynamic impedance and added inertia.

  The localized condensate contribution belongs to the complete baryonic defect state. The extended response outside the localized defect domain is treated separately and is proposed as the TFT mechanism for the effective galactic contribution conventionally attributed to dark matter.

  Any viscous phase lag, irreversible transport, heating, or persistent condensate redistribution belongs to a separate dissipative sector and does not define the baseline inertial or galactic-loading mechanism.

The corresponding galactic response law and its relation to rotation curves and gravitational lensing are developed in Appendix L.

Conclusion: The ideal FCC State-I vacuum possesses the non-arbitrary geometric partition

$$\beta_{\mathrm{geo}} \approx 0.74048, \qquad \beta_{\mathrm{IC}} \approx 0.25952. \tag{6.27}$$

Under the uniform structural-capacity closure, these exact volume fractions define the normalized unperturbed nodal and interstitial structural-energy allocations. Under the defect-conversion closure, a fraction β_{b} of the nodal allocation is converted into localized coupled baryonic defects, leaving

$$\beta_{\Lambda,\mathrm{eff}} = \beta_{\mathrm{geo}} - \beta_{\mathrm{b}}. \tag{6.28}$$

The homogeneous interstitial allocation remains distinct from its extended dynamical response, which supplies the effective galactic loading developed in Appendix L. The universe is therefore not mechanically empty; its observable sectors arise from different configurations and dynamical responses of one contiguous state I active vacuum.

Chapter 7

The Origin of Inertia, Light, and Motion

7.1 The Tension Cell: Potential vs. Kinetic

We identify the fundamental unit of the vacuum as the Tension Cell. As established in Section 3.2, its structural evolution from the latent substrate to the active lattice defines the laws of motion:

- **The Latent Cell (State 0 / Hard Floor):** A perfect cube of length ℓ_S (Substrate Lattice Spacing). It represents the absolute geometric limit. It possesses pure potential tension but, lacking geometric expansion, possesses zero intrinsic inertial density ($\mu_S \to 0$).
- **The Manifest Cell (State I / Soft Floor):** A resonant sphere operating at the FCC Node Radius (r_D). Here, the potential tension is geometrically captured and converted into the mass-equivalent surface inertia (μ_D) of the active Soft Floor.

7.2 Inertia as the Speed Regulator

Motion is regulated by the resistance of the medium. In TFT, inertia (μ_{eff}) acts as the mechanical "brake" on propagation speed (c_P).

To quantify this resistance, we first define the theoretical gravitational energy capacity (E_G) of an active FCC lattice node:

$$E_G \approx \mu_D \cdot c_E^2 \cdot r_D^2 \tag{7.1}$$

This relationship establishes that the baseline surface inertia (μ_D) is an intrinsic structural property of the vacuum lattice. Consequently, following the standard mechanical wave relation ($c_P = \sqrt{\tau_D/\mu_{\text{eff}}}$), the absolute speed of light is inversely determined by the local effective inertial density of the medium.

7.3 The Two Regimes of Propagation

This architecture creates a universe with two distinct communication channels, defined strictly by the mechanical moduli of the vacuum phases:

A. The Entanglement Regime (Hard Floor / Longitudinal)

- **Mechanism:** Longitudinal Stress Transmission (State Transfer).

- **Modulus:** The Latent Substrate is perfectly rigid and incompressible ($\tau_S \to \infty$).
- **Dynamics:** Operating with zero intrinsic inertial density ($\mu_S \to 0$), longitudinal stress transmits instantaneously across the lattice ($c_S \to \infty$).
- **Physics:** This allows for Instantaneous Stress Transfer (Entanglement) and the instantaneous equilibration of the Gravitational Tension field, without transferring transverse energy.

B. The Relativistic Regime (The Elastic Soft Floor / Transverse)

- **Mechanism:** Transverse Shear Deformation (Energy Propagation).
- **Modulus:** The Active Vacuum (FCC Lattice) possesses finite shear stiffness (τ_D).
- **Dynamics:** The "swollen" state of the dynamic nodes creates local structural stiffness (τ_D) and node interface inertial density (μ_D). The vibration of these nodes creates a shear wave whose propagation speed is strictly dictated by the surface inertia (μ_D), enforcing a finite kinematic limit ($c_{shear} = c_E$).
- **Physics:** This is Light. It carries physical information and transverse energy, but is strictly speed-limited by the surface tension and inertial density of the active FCC lattice.

7.4 The Kinematic Velocity Budget

Because the lattice possesses a finite stiffness (τ_D) and inertia (μ_D), there is a strict mechanical ceiling on the total kinematic capacity a node can support. This manifests as a Fixed Velocity Budget (c_E) that is partitioned between Internal Resonance (Mass/Proper Time) and External Translation (Spatial Motion).

We define the microscopic kinematic identity, which follows from the orthogonal decomposition of lattice displacement into translational and resonant components:

$$c_E^2 = v_{ext}^2 + v_{int}^2 \tag{7.2}$$

In this framework, acceleration is experienced as a kinematic rotation: as a particle gains spatial velocity, the force-driven phase-twist rotates the node's total velocity vector from the internal resonant axis toward the spatial axis.

- $v_{ext} = c_E \cos(\Delta\varphi)$ **(Spatial Velocity):** The component of lattice capacity dedicated to moving the topological knot (localized phase defect) through the contiguous medium. As $\Delta\varphi \to 0$, $v_{ext} \to c_E$.
- $v_{int} = c_E \sin(\Delta\varphi)$ **(Proper Time):** The component of lattice capacity dedicated to the internal resonant oscillation of the node. As $\Delta\varphi \to 0$, $v_{int} \to 0$ (As the node undergoes kinematic rotation toward the spatial axis, its invariant total capacity, c_E, is re-oriented entirely into spatial translation, mechanically arresting the internal oscillation that governs proper time).

Boundary Limit: Because v_{int} represents real mechanical oscillation against the lattice restorative force, its square cannot be negative ($v_{int}^2 \geq 0$). Therefore, v_{ext} is physically capped by the lattice shear limit c_E. Exceeding this limit would require the node to possess a non-physical (imaginary) displacement amplitude, which is a structural impossibility in a solid-state medium.

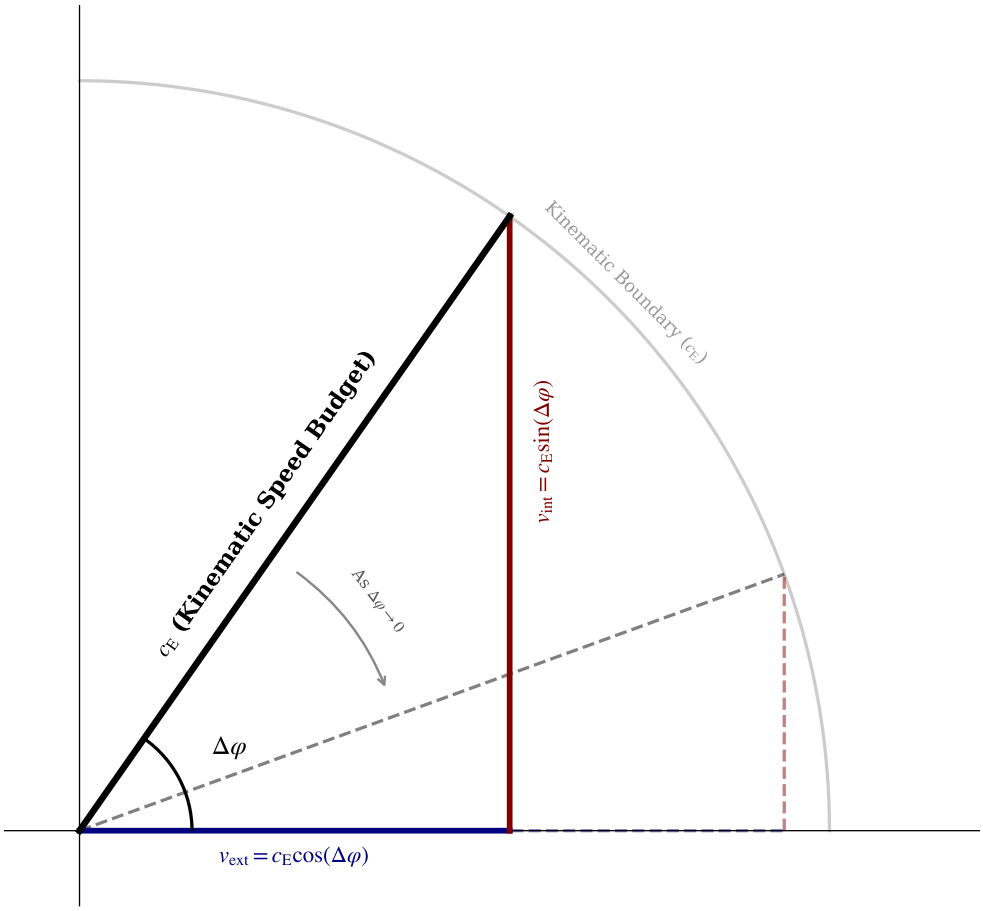

Figure 7.1: **The Kinematic Budget Triangle.** A geometric representation of the invariant kinematic budget (c_E). Because the total structural speed capacity (the hypotenuse) is strictly conserved by the medium, any increase in external spatial velocity (v_{ext}) mechanically requires a proportional decrease in internal radial velocity (v_{int}).

7.5 The Two Mechanical States (Light and Mass)

The Light State (Coherence):

- **Phase:** Adjacent nodes vibrate in near-perfect phase ($\Delta\varphi \approx 0$).
- **Dynamics:** Near-zero phase-dissonance ensures node displacement is dominantly elastic.
- **Budget:** The internal cost (v_{int}) is zero. The entire kinematic budget is available for transmission.
- **Result:** The wave propagates at the maximum shear limit ($v_{ext} = c_E$). Light exhibits no internal resonant duty cycle and therefore experiences no proper-time evolution.

The Mass State (Dissonance):

- **Phase:** The node is a topological knot (localized phase defect) with a significant phase-angle relative to the background lattice ($\Delta\varphi > 0$).

- **Dynamics:** This dissonance forces the node to perform work against the vacuum condensate, generating hydrodynamic impedance that manifests macroscopically as inertia.
- **Budget:** This internal resonance consumes a portion of the c_{E} budget.
- **Result:** The remaining capacity for spatial motion is reduced ($v_{\mathrm{ext}} < c_{\mathrm{E}}$). The particle moves slower than light because it is structurally locked into local oscillation.

7.5.1 The Mechanical Emergence of the Lorentz Factor

Time dilation is a mechanical capacity partition. As v_{ext} consumes the displacement bandwidth, the frequency of internal oscillation (v_{int}) must drop. The structural bonds are stretched toward their elastic limit, leaving less capacity for internal restorative relaxation.

By rearranging the kinematic identity, we obtain $v_{\mathrm{int}} = \sqrt{c_{\mathrm{E}}^2 - v_{\mathrm{ext}}^2}$. The Lorentz factor ($\gamma$) naturally emerges as the ratio between the total lattice velocity budget and the remaining internal resonant capacity:

$$\gamma = \frac{c_{\mathrm{E}}}{v_{\mathrm{int}}} = \frac{1}{\sqrt{1 - \frac{v_{\mathrm{ext}}^2}{c_{\mathrm{E}}^2}}} \tag{7.3}$$

7.5.2 The Mechanical Origin of Length Contraction

Just as time dilation is the mechanical reduction of internal resonant frequency, relativistic length contraction in TFT is the physical spatial deformation of the topological defect.

In standard relativity, length contraction is often treated as a geometric projection or a symmetric observer illusion. In Tension Field Theory, it is a harsh, asymmetric physical reality. Because the particle is a standing mechanical wave propagating through an active vacuum with an absolute finite shear limit (c_{E}), increasing spatial velocity (v_{ext}) forces the forward-propagating phase-fronts of the particle to physically compress.

The underlying Face-Centered Cubic (FCC) lattice grid (r_{D}) remains perfectly rigid and completely invariant; space itself does not shrink. Instead, it is the physical particle (the topological knot) that structurally flattens in the direction of travel. The degree of spatial flattening is dictated exactly by the remaining internal kinematic budget:

$$L = L_0 \cdot \left(\frac{v_{\mathrm{int}}}{c_{\mathrm{E}}} \right) = \frac{L_0}{\gamma} \tag{7.4}$$

Macroscopic Implication: The 2D Limit
This mechanical compression scales to macroscopic objects. The structural bonds holding a physical ruler together are transverse shear waves propagating through the lattice at c_{E}. As the ruler accelerates, the forward-moving binding signals have less and less kinematic headroom to outpace the back of the ruler. At the absolute theoretical limit ($v_{\mathrm{ext}} \to c_{\mathrm{E}}$), the internal budget drops to zero ($v_{\mathrm{int}} = 0$). The atoms geometrically cannot maintain their longitudinal separation. The proper length of the ruler physically becomes zero, crushing the 3D structure entirely into a 2D plane. Length contraction is therefore the physical signature of an object exhausting its internal capacity to maintain 3D structural bonds.

7.6 Force Transfer Efficiency (Impedance Matching)

The incident elastic force (F_{E}) is the temporal rate of momentum transfer driven by a Phase Twist ($-\nabla\varphi$) propagating across the contiguous lattice at wave speed c_{E}. The ability of this transverse wave to do physical work on a particle depends strictly on the Mechanical Impedance Match between the propagating wave-front and the 3D topological defect.

The effective force delivered to a massive particle is governed by the volumetric overlap between the incident phase-twist and the internal resonance of the defect. As the particle's internal resonant bandwidth (v_{int}) shrinks due to spatial motion, its structural receptivity to the lattice force-wave diminishes. The coupling efficiency follows the ratio of the available internal resonance to the total lattice budget:

$$F_{\mathrm{eff}} = F_{\mathrm{E}} \cdot \left(\frac{v_{\mathrm{int}}}{c_{\mathrm{E}}} \right) = \frac{F_{\mathrm{E}}}{\gamma} \tag{7.5}$$

- **At Rest ($v_{\mathrm{ext}} = 0, \gamma = 1$):** Coupling is perfect ($F_{\mathrm{eff}} = F_{\mathrm{E}}$). This is the Newtonian Limit.
- **Approaching the Shear Limit ($v_{\mathrm{ext}} \to c_{\mathrm{E}}, \gamma \to \infty$):** Coupling efficiency collapses to zero as the internal resonance (v_{int}) vanishes. This is the Saturation Limit.
- **At the Absolute Limit ($v_{\mathrm{ext}} = c_{\mathrm{E}}, v_{\mathrm{int}} = 0$):** The Kinematic Untying. If the internal resonance is entirely consumed, the phase dissonance ($\Delta\varphi$) required to maintain the 3D topological knot drops to zero. The structural defect physically unravels into a 2D planar wave, losing its matter identity and converting entirely into propagating transverse light.

Conclusion: The Saturated Vacuum and Mass Invariance
The "relativistic" increase in energy required for acceleration is strictly a Mechanical Impedance Mismatch. As $v_{\mathrm{ext}} \to c_{\mathrm{E}}$, the force-transfer mechanism becomes asymptotically inefficient because the particle has no remaining resonant capacity to absorb the incident elastic force (F_{E}).

Crucially, the electron's mass (m_0) remains an invariant structural defect throughout its acceleration. The universe does not require mass to become infinite to enforce a speed limit; it simply requires the impedance of the medium to reach a saturation point. The relativistic limit is not a property of the particle, but the mechanical saturation of force-coupling in a finite-speed medium. The particle cannot be accelerated to c_{E} because the lattice loses its physical grip on the mass; however, if the limit is theoretically reached, the mass structurally ceases to exist, untying into pure radiant energy.

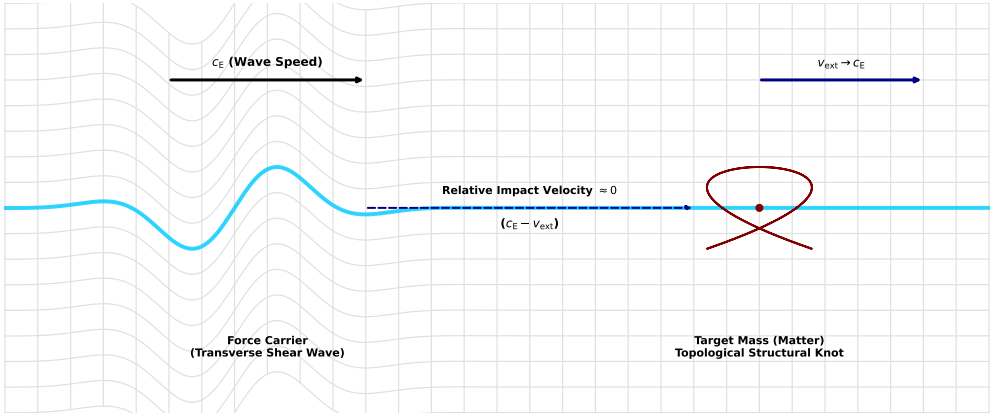

Figure 7.2: **Mechanical Limit of Relativistic Force Transfer.** A kinematic visualization demonstrating the mechanical failure of relativistic force transfer. Because the force carrier (the transverse shear wave) propagates through the condensate at a fixed absolute limit (c_{E}), its ability to transfer momentum diminishes as the target mass's spatial velocity (v_{ext}) increases. As the target approaches c_{E}, the carrier geometrically cannot catch the mass, causing the effective push of the vacuum (F_{eff}) to asymptotically drop to zero.

7.6.1 The Mechanical Derivation of $E = mc_{\mathrm{E}}^2$

In standard relativity, mass-energy equivalence is an algebraic consequence of Lorentz invariance. In Tension Field Theory, it emerges as a strict mechanical necessity of the Kinematic Budget ($c_{\mathrm{E}}^2 = v_{\mathrm{ext}}^2 + v_{\mathrm{int}}^2$). Because mass is defined as a topological knot of trapped phase dissonance, forcing a mass to the structural shear limit ($v_{\mathrm{ext}} \to c_{\mathrm{E}}$) mechanically demands that its internal resonance vanishes ($v_{\mathrm{int}} \to 0$). At this absolute boundary, the 3D knot physically unties. The invariant mass identity ceases to exist, and 100% of the localized structural tension used to maintain the defect is liberated as a 2D planar transverse wave. The equation $E = m_0 c_{\mathrm{E}}^2$ is therefore the exact mechanical conversion metric, dictating that the energy of the resulting light wave perfectly equals the latent structural tension of the unspooled node. The strict invariance of the c_{E} velocity budget guarantees absolute mass-energy conservation throughout this phase transition.

7.7 The Impedance Mismatch of the Dark Sector

The mechanical model of the active SGF naturally explains the invisibility of the dark sector by distinguishing between the solid and condensate phases of the vacuum:

- **Light (Solid Phase):** Propagates exclusively through the FCC solid surface. Solids possess Shear Stiffness ($\tau_{\mathrm{D}} > 0$), which is the requisite mechanical property for supporting transverse electromagnetic waves (photons).
- **Dark Matter (Condensate Phase):** Resides in the Vacuum Condensate (Liquid Voids). Liquids possess a Bulk Modulus (allowing them to conduct longitudinal sound/gravity) but effectively exhibit zero Shear Stiffness ($\tau_{\mathrm{D}} \approx 0$).

The Boundary Barrier: Because the vacuum condensate cannot support shear stress, transverse light waves cannot penetrate the interstitial voids. The photons are mechanically forced to bypass or reflect off these regions entirely.

Conclusion: The Mechanical Origin of Transparency

Dark matter is "invisible" not because it is composed of exotic phantom particles, but because there exists an Infinite Impedance Mismatch for shear waves between the solid lattice (the light carrier) and the interstitial condensate (the mass reservoir).

Chapter 8

Conclusion: The Vertical Unity and Falsifiability

Because Tension Field Theory (TFT) defines the universe as a mechanical continuum rather than an abstract geometry, its predictions are fundamentally structural and strictly testable. TFT fundamentally rejects the existence of phenomenological "placeholder" particles to balance the cosmic energy budget, relying instead on the inherent visco-elastic properties of the Spacetime Gravitational Floor (SGF).

8.1 The Governing Equations of the Spacetime Gravitational Floor

As rigorously derived throughout Part I and summarized in the Consolidated Equations appendix, the fundamental properties of space, time, and mass are not abstract parameters. They are the strict mechanical properties of the SGF. Tension Field Theory formally replaces the continuous geometry of the standard model with five exact continuum mechanics equations.

1. The Active Space Strain-Weighted Path Functional:

$$D_\tau(a,b) = \int_a^b \left(1 + \frac{r_{\mathrm{D}}}{\tau_{\mathrm{S}}}|\nabla\tau(x)|\right) \mathrm{d}x. \tag{8.1}$$

Mechanical Translation: Distance is not treated as a bare coordinate abstraction. In TFT, the physically experienced path length is the latent coordinate interval weighted by the local tension-gradient penalty of the active vacuum. In an unstrained region, where $|\nabla\tau| \to 0$, the expression reduces to ordinary coordinate distance. In a strained region, the accumulated path length increases according to the local tension gradient, producing the mechanical basis for propagation delay, refractive bending, and later effective metric behavior.

2. The Master Geometric Scaling Law (The Fractal Vacuum Architecture):

$$\rho(r) = \mathcal{F}_i \cdot \rho_{\mathrm{S}} \left(\frac{\ell_{\mathrm{S}}}{r}\right)^4 \tag{8.2}$$

Mechanical Translation: The energy density of the universe is not arbitrary. It scales fractally based strictly on the geometric phase factor ($\mathcal{F}_i$) linking the absolute latent density of the Hard Floor (ρ_{S}) to the active dimension of the observable domain.

3. The Kinematic Velocity Budget (Replacing Geometric Time Dilation):

$$c_{\mathrm{E}}^2 = v_{\mathrm{ext}}^2 + v_{\mathrm{int}}^2 \quad \Longrightarrow \quad \gamma = \frac{c_{\mathrm{E}}}{v_{\mathrm{int}}} \tag{8.3}$$

Mechanical Translation: Relativistic time dilation is not the warping of an abstract temporal dimension. It is the strict mechanical consequence of a zero-sum kinematic velocity budget, where increasing spatial translation (v_{ext}) forces a corresponding drop in the internal resonant frequency (v_{int}) of the node. The Lorentz factor (γ) is simply the algebraic ratio of the absolute lattice capacity (c_{E}) to the remaining internal proper time.

4. The Dynamic Propagation Velocity (Replacing the Invariance of c):

$$c_{\mathrm{P}} = \sqrt{\frac{\tau_{\mathrm{D}}}{\mu_{\mathrm{eff}}}} \tag{8.4}$$

Mechanical Translation: The speed of light is not an axiomatic geometric constant; it is the variable, dynamic propagation velocity of a transverse mechanical wave. It is strictly derived from the restorative surface tension (τ_{D}) and the localized effective inertia (μ_{eff}) of the active vacuum lattice. The "universal constancy" of c postulated by relativity is merely a localized measurement artifact, arising because the observer's physical clock is governed by the exact same visco-elastic inertial limits as the propagating light wave *(The full macroscopic derivation of this covariant scaling artifact is resolved in Section 11.4.3).*

5. The Quantization of Action (The Mechanical Origin of h):

$$h = 2\pi \cdot \hat{J} \cdot c_{\mathrm{E}} \tag{8.5}$$

Mechanical Translation: Planck's constant is not an unexplained mathematical limit. It is the strict macroscopic projection of the absolute topology-normalized Scale-Invariant Mass Moment ($\hat{J} \equiv J_{\mathrm{D}}/\mathcal{F}_{\mathrm{D}}$), defining the exact structural yield energy required to mechanically snap a lattice node into the adjacent cell, yielding the observable quantum of action $h \approx 6.626 \times 10^{-34}$ J·s.

8.2 Strict Falsification Criteria

The mechanical framework of Part I is immediately falsified if any of the following experimental outcomes are confirmed:

- **Isolation of a Dark Matter Particle:** TFT defines Dark Matter exclusively as the hydrodynamic impedance of the interstitial vacuum condensate (roughly 26% void volume). If a discrete, independent Dark Matter particle (such as a WIMP or axion) is physically isolated and confirmed in a detector, the TFT vacuum condensate-impedance postulate is falsified.
- **Dynamic Dark Energy (Quintessence):** TFT derives Dark Energy as the static volumetric packing fraction of the FCC solid lattice phase (exactly $\pi/\sqrt{18}$, or roughly 74.04%).[6] If observational cosmology definitively proves that Dark Energy is a dynamic, evolving scalar field (quintessence) rather than a fixed geometric property of the vacuum state, the Kepler Conjecture structural derivation is falsified.
- **Divergence of the Nucleon Mechanical Radius:** As derived in Appendix G, TFT strictly predicts that while the electric charge distribution halo of a proton may measure 0.84 fm [7], its mechanical structural radius (governing inertia and gravitational coupling) must converge

exactly on 0.88 fm to conserve the absolute topology-normalized Scale-Invariant Mass Moment ($\hat{J}$). If future high-precision gravitational or inertial scattering experiments definitively rule out the 0.88 fm structural boundary, the scale-invariant fractal architecture of the theory is falsified.

8.3 Diagnostic Comparison of Core Phenomena

To clarify the specific mechanical departures from standard Λ–CDM cosmology, the core phenomena of the observable vacuum are contrasted below.

Table 8.1: Diagnostic Map: Standard Model Λ–CDM vs. TFT Lattice Mechanics

Phenomenon	**Standard Model (Λ–CDM)**	**TFT Resolution (Lattice Mechanics)**
Active Vacuum	An abstract, empty spatial manifold.	**The SGF Continuum:** A dual-phase material structure comprising a high-stiffness Solid FCC lattice and an Interstitial Condensate phase.
Dark Energy	A mysterious expansive scalar field (Λ).	**Static Elastic Potential:** The reinterpreted volumetric packing fraction (74.04%) of the Solid FCC lattice phase.
Dark Matter	Undiscovered, non-interacting particles.	**Hydrodynamic Impedance:** The reinterpreted viscous response of the interstitial condensate phase (25.96%) within geometric voids.
Mass / Inertia	Property acquired via the Higgs mechanism.	**Hydrodynamic Resistance:** The work performed by a resonant node (topological defect) vibrating against the interstitial condensate.
Speed of Light (c_{E})	An arbitrary geometric constant.	**Elastic Shear Limit:** The absolute shear-wave limit of the FCC lattice ($c_{\mathrm{E}} = \sqrt{\tau_{\mathrm{D}}/\mu_{\mathrm{D}}}$).
Action (h)	Unexplained quantum constant.	**The Structural Yield Limit:** The minimum mechanical energy required to "snap" a node into its adjacent lattice shell.
Force	Mediated by abstract gauge bosons.	**Mechanical Phase-Twist:** The propagation of a torsional strain gradient ($-\nabla\varphi$) through the contiguous SGF medium.
Speed Budget	An observational limit ($v < c$).	**Kinematic Capacity:** A strict zero-sum partition of displacement bandwidth between internal resonance (v_{int}) and spatial translation (v_{ext}).
Force Efficiency	Assumed 100% until $v \approx c$.	**Impedance Matching:** The volumetric overlap efficiency ($1/\gamma$) between a phase-twist and the internal resonance of a defect.

Summary: The Vertical Unity of the Vacuum

In this first installment, we established the mechanical constitution of the vacuum, modeling spacetime not as an empty geometric void, but as a structured, dual-phase continuum. By introducing the Spacetime Gravitational Floor (SGF), we provide a discrete mechanical foundation intended to resolve the phenomenological gaps between macroscopic gravity and quantum mechanics.

A central result of this structural approach is the geometric derivation of the cosmic energy budget. Utilizing the Kepler Conjecture, the framework naturally partitions the universe into a roughly 74% solid elastic phase (Dark Energy) and a roughly 26% condensed interstitial phase (Dark Matter) without invoking unobserved exotic particles. Within this Face–Centered Cubic (FCC) architecture, light is defined deterministically as the transverse shear wave of the solid lattice, while mass emerges as the hydrodynamic impedance of a topological defect vibrating against the interstitial condensate.

Furthermore, we demonstrated that the Latent Substrate (the SC Hard Floor at 10^{-35} m) and the Active Vacuum (the FCC Soft Floor at 10^{-26} m) function as coupled geometric phases. This establishes a vertical symmetry across scales: the mechanical laws governing the rigid Substrate are replicated at the Soft Floor, and again at the scale of the Nucleon (10^{-15} m). Rather than operating under disparate physical regimes, the macroscopic and microscopic domains are unified by a single structural geometry (See Appendix G: The Fractal Architecture for the cross-scale consistency of Action (h) and Coupling (G) normalizations across these three scales). We also derived that the Standard Model particles are not "point-like" abstractions, but are mechanical solutions of the soft floor lattice (See Appendix F).

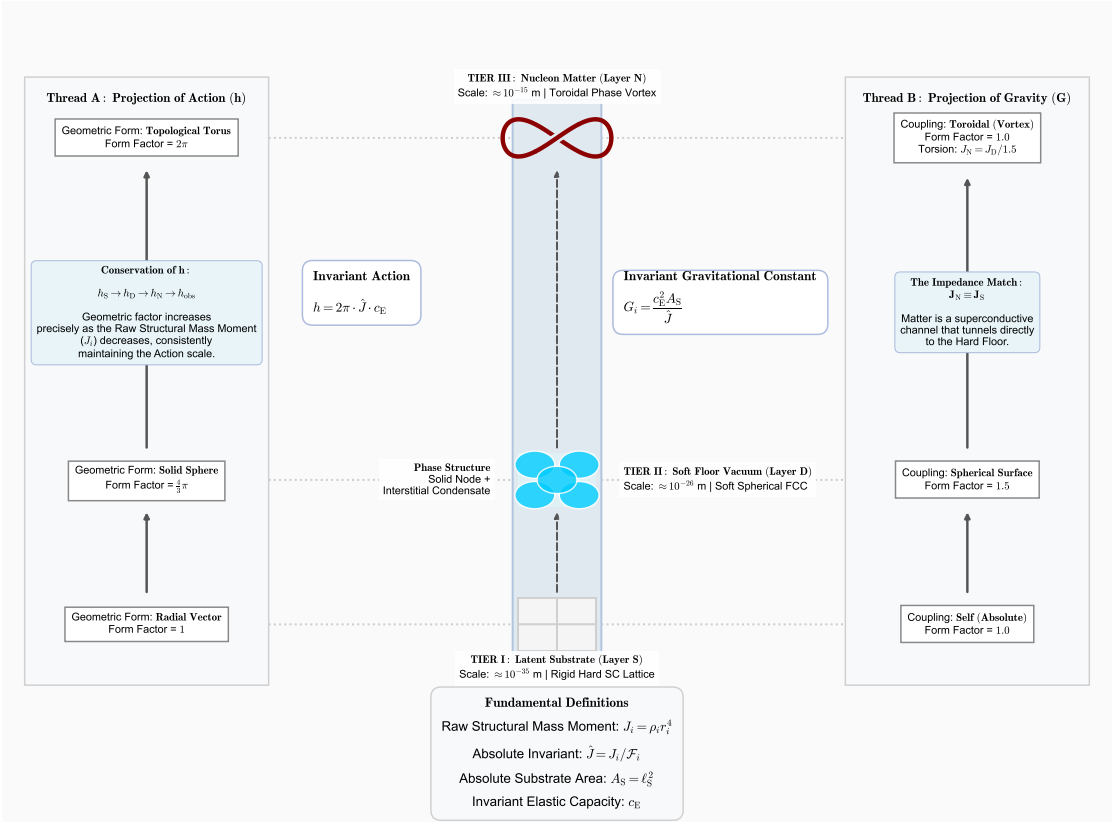

Figure 8.1: **The Unified Vertical Fractal Architecture.** A mechanical projection of the scale-invariant architecture of the universe under Tension Field Theory (TFT). The fundamental constants, Action (h) and Gravity (G), are not mathematical abstractions but geometric projections emerging from a single, absolute topology-normalized Scale-Invariant Mass Moment ($\hat{J} \equiv J_i/\mathcal{F}_i$). As the structural hierarchy projects upward from the fundamental Hard Substrate (Layer S), through the Soft Vacuum (Layer D), and finally to localized Matter (Layer N), the phase-dependent form factor ($\mathcal{F}_i$) changes with topology, and the corresponding raw structural moment changes according to $J_i = \mathcal{F}_i \hat{J}$, while the normalized ratio $J_i/\mathcal{F}_i = \hat{J}$ remains invariant. Therefore, the hierarchy strictly conserves the reduced action capacity ($\hbar$), while h represents its complete-cycle realization. Conversely, the Nucleon achieves an approximate impedance match with the absolute Substrate ($J_N \approx J_S$), revealing matter as a localized superconductive channel bridging the observable vacuum directly to the latent Hard Floor.

Having defined the mechanical origins of mass and light, and mapped the structural consistency of the fundamental constants (h, G, and c_E), we now possess the structural vocabulary required to analyze macroscopic tension. In Part II, we apply this dual-scale architecture to derive the mechanical nature of gravitational curvature, the structural failure of the vacuum at black hole event horizons, and the deterministic hydrodynamics of quantum mechanics.

END OF PART I

Part II

The Mechanics of Gravity, Black Holes, and the Quantum Structure of the Vacuum and the Atom

Chapter 9

Introduction

9.1 The Limits of the Abstract Metric

For the past century, physics has relied on two highly successful but fundamentally distinct frameworks: General Relativity, which models gravity as the geometric curvature of a continuous spacetime manifold, and Quantum Mechanics, which models matter via probabilistic wavefunctions. While observationally robust, this disconnect presents a critical mechanical limitation at extreme boundary conditions.

By treating space purely as mathematical geometry, standard models encounter non-physical infinities, such as gravitational singularities, the information paradox, and the profound discrepancy in the vacuum energy density. The challenge of reconciling the deterministic macroscopic universe with the probabilistic quantum realm suggests these standard models serve as highly accurate operational approximations of a deeper, unified mechanical reality.

9.2 The Restorative Lattice Postulate

Building upon the constitution of the Spacetime Gravitational Floor (SGF) established in Part I, this paper demonstrates that gravity and quantum mechanics are strictly the macroscopic and microscopic mechanical responses of a single, contiguous elastic lattice.

- **Macroscopic Gravity:** Rather than the bending of empty geometry, TFT treats gravity as the physical Restorative Tension of the active vacuum lattice. Gravitational phenomena arise from mechanical strain in the Soft Floor as the vacuum attempts to minimize topological defects and return to the flat equilibrium of the underlying Hard Floor. What General Relativity describes as metric curvature is recovered in TFT only as an effective observational representation of strain-induced refractive propagation through the active vacuum.
- **Microscopic Quantum Dynamics:** Concurrently, this framework replaces abstract quantum probability with the deterministic vacuum condensate hydrodynamics of the active Face–Centered Cubic (FCC) lattice, demonstrating that particle motion is strictly guided by the physical pilot wave of its own structural vibration.

9.3 The Phase Transition of Spacetime

Tension Field Theory (TFT) addresses mathematical singularities by introducing the finite structural yield limits of the vacuum medium. We redefine the Black Hole not as a point of infinite

density, but as a macroscopic phase transition of the fundamental Substrate.

- **The Event Horizon:** Conceptually, the Event Horizon represents the physical phase boundary where the active vacuum (FCC lattice) structurally saturates and transitions into the static substrate (Simple Cubic lattice), mechanically arresting the flow of time.

9.4 Objectives of Part II

In this second installment of the Tension Field Theory trilogy, we apply the structural mechanics of the vacuum to derive the fundamental dynamics of the observable universe. We will:

- **Define the Mechanism of Gravity:** Establish gravity as a restorative tension gradient, deriving the Equivalence Principle and explaining galactic rotation curves via the mechanical Cosmic Impedance (a_{D}) of the vacuum.
- **Resolve the Singularity and Information Paradox:** Demonstrate that Black Holes are crystallographic phase transitions (FCC $\rightarrow$ SC) that topologically lock and preserve information within a static volumetric core.
- **Mechanize Quantum Dynamics:** Replace abstract quantum probability with deterministic lattice hydrodynamics, deriving Heisenberg's Uncertainty Principle and quantum entanglement as strict geometric functions of the lattice's elasticity and vertical topology.
- **Unify the Fundamental Forces:** Prove that the Strong, Weak, Electromagnetic, and Gravitational interactions are not independent phenomena, but strictly the 1D, 2D, 3D, and bulk volumetric geometric projections of a single topology normalized Scale-Invariant Mass Moment ($\hat{J}$).

Chapter 10

The Foundations of Restorative Gravity

"Tensio Condensatur, Spatiotemporis Emergit, Gravitas Integrata"

General Relativity represents gravity through the geometric curvature of a continuous spacetime manifold. Tension Field Theory proposes a deeper mechanical ontology in which the same observable gravitational behavior emerges from restorative strain within the active vacuum lattice. It is the restorative bulk response of a highly elastic discrete lattice seeking to relax a localized structural phase defect and restore the active vacuum toward its equilibrium state.

10.1 The First Law: Manifestation of Gravity (Restorative Tension)

Gravity is the restorative tension of the Spacetime Lattice acting to suppress energetic vibration.

- **Definition:** It is the mechanical response of the vacuum substrate attempting to minimize localized geometric strain—whether from permanent topological defects (invariant mass) or propagating transverse waves (effective mass)—to return to the flat equilibrium state of the Hard Floor.
- **Mechanism:** It manifests as a radial tension gradient, pulling inertial mass from regions of high static potential (unperturbed vacuum) toward regions of lower potential (matter-induced sinks).

10.1.1 The Gravitational Constant (G): Universal Substrate Coupling

In TFT, the gravitational constant G is interpreted as the cross-scale coupling coefficient between the Latent Substrate, the active Soft Floor, and localized matter. Appendix B establishes the topology-normalized Scale-Invariant Mass Moment ($\hat{J}$),

$$\hat{J} \equiv \frac{J_i}{\mathcal{F}_i} \tag{10.1}$$

where $J_i = \rho_i r_i^4$ is the raw structural mass moment and $\mathcal{F}_i$ accounts for the geometry of the corresponding structural layer.

Using the Substrate reference area

$$A_{\mathrm{S}} = \ell_{\mathrm{S}}^2, \tag{10.2}$$

the gravitational coupling is directly governed by this absolute invariant:

$$G = \frac{c_{\mathrm{E}}^2 A_{\mathrm{S}}}{\hat{J}}. \tag{10.3}$$

Because the absolute topology-normalized invariant ($\hat{J}$) is conserved, the coupling remains constant across the structural hierarchy:

$$G_{\mathrm{S}} = G_{\mathrm{D}} = G_{\mathrm{N}} \approx 6.6743 \times 10^{-11}\ \mathrm{m^3\,kg^{-1}\,s^{-2}}. \tag{10.4}$$

The Soft Floor moment J_{D} characterizes the active vacuum medium through which restorative tension is transmitted, while the nucleon moment J_{N} represents the localized matter-side coupling. The nucleon is used in Figure 10.1 because its vortical form factor is unity ($\mathcal{F}_{\mathrm{N}} = 1.0$), meaning its raw structural mass moment aligns exactly with the invariant ($J_{\mathrm{N}} = \hat{J}$), and approximately matches the Substrate realization,

$$J_{\mathrm{N}} \approx J_{\mathrm{S}}. \tag{10.5}$$

This relation is a cross-scale consistency representation of the empirical gravitational constant, not an independent parameter-free prediction of its numerical value, because the Substrate scale is normalized through the Planck-scale combination containing G.

See Appendix B and Appendix G for the derivation of the topology-normalized conservation law and its cross-scale gravitational-coupling validation.

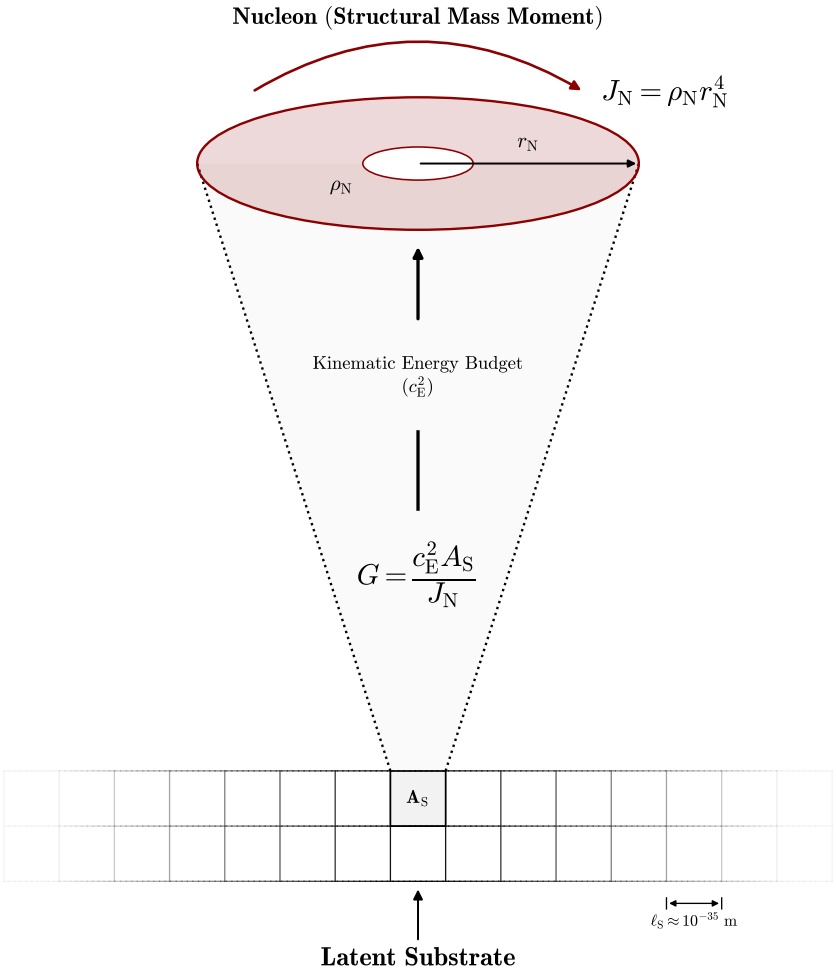

Figure 10.1: **Cross-Scale Representation of the Gravitational Constant (G).** The schematic illustrates the matter-side coupling between the Latent Substrate and a localized nucleon. The coupling is represented by the Substrate area A_S, the elastic capacity c_E^2, and the nucleon Structural Mass Moment J_N. The nucleon is used because its vortical form factor is unity ($\mathcal{F}_N = 1.0$) and $J_N \approx J_S$, producing an approximate structural impedance match between localized matter and the Hard Floor. The Soft Floor remains the active carrier of the restorative tension field.

10.2 Gravitational Acceleration from the Conserved Tension Gradient

Consider a spherical source of mass M and physical radius R_s. At an exterior radial coordinate $R > R_s$, no additional localized mass-loading is present between the source and the chosen spherical surface. The source-generated tension field must therefore transmit the same total radial restorative influence through every concentric spherical surface.

To express this mechanically, define the **specific tension potential**

$$\Phi_\tau(R) \equiv \frac{\tau_{\mathrm{M}}(R)}{\mu_{\mathrm{D}}}.$$

Here, $\tau_{\mathrm{M}}(R)$ is the signed mass-induced surface-tension potential of the Soft Floor, with units of N/m, and μ_{D} is the baseline Soft Floor surface inertia, with units of kg/m^2. Therefore,

$$[\Phi_\tau] = \frac{\mathrm{N/m}}{\mathrm{kg/m^2}} = \mathrm{m^2/s^2}.$$

Thus, Φ_τ has the dimensions of gravitational potential per unit inertial loading.

Outside the spherical source, conservation of the radial tension-gradient flux requires the total flux through every concentric spherical surface to remain constant:

$$\oint \nabla\Phi_\tau \cdot \mathrm{d}\mathbf{A} = 4\pi GM.$$

For spherical symmetry, the gradient is purely radial and has the same magnitude at every point on a sphere of radius R. The flux relation therefore reduces to

$$4\pi R^2 \frac{\mathrm{d}\Phi_\tau}{\mathrm{d}R} = 4\pi GM.$$

Hence,

$$\frac{\mathrm{d}\Phi_\tau}{\mathrm{d}R} = \frac{GM}{R^2}.$$

The inverse-square dependence is therefore not independently assumed. It follows from conservation of the source-generated restorative flux across spherical surfaces whose area increases as R^2.

Taking the unstrained vacuum at infinity as the zero-potential reference,

$$\Phi_\tau(\infty) = 0,$$

integration gives

$$\Phi_\tau(R) = -\frac{GM}{R}.$$

The negative sign identifies the source region as a local tension-potential deficit relative to the unstrained Soft Floor.

The corresponding mechanical surface-tension potential is

$$\tau_{\mathrm{M}}(R) = \mu_{\mathrm{D}}\Phi_\tau(R) = -\frac{GM\mu_{\mathrm{D}}}{R}.$$

Its spatial gradient has units of pressure:

$$[\nabla\tau_{\mathrm{M}}] = \frac{\mathrm{N/m}}{\mathrm{m}} = \mathrm{N/m^2},$$

and represents the radial restorative stress of the active Soft Floor.

The source-generated gravitational acceleration field is obtained by normalizing this stress gradient by the baseline Soft Floor surface inertia:

$$\mathbf{g}(R) = -\frac{1}{\mu_{\mathrm{D}}}\nabla\tau_{\mathrm{M}} = -\nabla\Phi_\tau.$$

For spherical symmetry,

$$\nabla\Phi_\tau = \frac{\mathrm{d}\Phi_\tau}{\mathrm{d}R}\hat{\mathbf{r}},$$

so the acceleration field becomes

$$\mathbf{g}(R) = -\frac{GM}{R^2}\hat{\mathbf{r}}.$$

Here, $\hat{\mathbf{r}}$ is the outward radial unit vector. The negative sign therefore indicates that the restorative acceleration points inward, toward the source. From this point onward, all quantities denoted by g represent positive inward acceleration magnitudes unless a vector direction is written explicitly.

The inward acceleration magnitude is

$$g(R) = \frac{GM}{R^2}.$$

This result governs the active FCC exterior field of any spherically symmetric source. In this formulation, μ_D is not the inertial mass of the falling body. It is the baseline constitutive surface inertia of the Soft Floor that converts the mechanical surface-tension potential (τ_M) into the specific tension potential (Φ_τ). The inertial loading of the test body enters separately through the topological mass identity developed in the following section.

10.3 Structural Gravitational Coupling (α_G)

The structural gravitational coupling (α_G) is defined as the active gravitational strain induced by localized mass-energy on the Soft Floor. It rigorously quantifies the ratio between the local mass-induced tension (τ_L) and the invariant Soft Floor stiffness (τ_D):

$$\alpha_\mathrm{G} = \frac{\tau_\mathrm{L}}{\tau_\mathrm{D}} = \frac{\left(\frac{GM\mu_\mathrm{D}}{r}\right)}{\mu_\mathrm{D}c_\mathrm{E}^2} = \frac{GM}{rc_\mathrm{E}^2} \tag{10.6}$$

This dimensionless ratio governs the kinematics of the Soft Floor, determining exactly how strongly a local mass couples to the active Face–Centered Cubic (FCC) lattice.

The Quantum Unification of α_G

In standard quantum mechanics, the gravitational coupling of a proton is treated as a fixed, fundamental constant: $\alpha_\mathrm{G} = \frac{Gm_\mathrm{p}^2}{\hbar c_\mathrm{E}}$. Tension Field Theory (TFT) proves this is not a separate physical constant, but simply the macroscopic Soft Floor strain equation evaluated at the quantum limit.

If we evaluate the TFT strain equation for a single proton ($M = m_\mathrm{p}$) at the geometric boundary of its mass-energy (its reduced Compton wavelength, $r = \frac{\hbar}{m_\mathrm{p}c_\mathrm{E}}$), the equations perfectly unify:

$$\alpha_\mathrm{G} = \frac{Gm_\mathrm{p}}{\left(\frac{\hbar}{m_\mathrm{p}c_\mathrm{E}}\right)c_\mathrm{E}^2} = \frac{Gm_\mathrm{p}^2}{\hbar c_\mathrm{E}} \tag{10.7}$$

Result: Standard quantum gravitational coupling is simply the local structural strain of the Soft Floor exerted by a particle.

The Saturation Phase Transition ($\alpha_G = 1$)

Because α_G represents the physical mechanical strain of the Soft Floor, it is bounded by an absolute geometric limit. When $\alpha_G = 1$, the local mass has consumed 100% of the available Soft Floor tension capacity. The system becomes gravitationally saturated, forcing a structural phase transition.

At the macroscopic scale ($r \gg \ell_S$), reaching $\alpha_G = 1$ dictates that the local load density (ρ_L) has reached the scale-dependent convergence density ($\rho_{QG}(r)$, derived in Appendix S). For a macroscopic stellar collapse, this corresponds to $\rho_{QG} \approx 10^{70}$ kg/m^3, defining the Event Horizon of a black hole. At this boundary, the active FCC Soft Floor structurally yields, geometrically locking into the rigid Simple Cubic (SC) Substrate and uncovering the fundamental lattice parameters (derived in Appendix A).

10.4 Discrete Soft-Floor Endpoint-Transfer Closure

As established in Postulate 2.2, motion and coherent wave propagation in the active Soft Floor proceed through sequential discrete reconfiguration. A transferable phase or strain state is released from one local FCC configuration and reconstructed at a nearest-neighbor configuration while continuity of the surrounding lattice is preserved.

Each active Soft Floor node remains vertically constrained to its phase-locked Hard Floor address through a Tension Column. The Tension Column supplies the local gravitational loading condition; it is not the nearest-neighbor propagation channel. State transfer proceeds through the bonded FCC Soft Floor network.

The dimensionless gravitational strain defined in Section 10.3 is

$$\alpha_G = \frac{\tau_L}{\tau_D}, \tag{10.8}$$

where τ_L is the local gravitational loading and τ_D is the active Soft Floor tension capacity. The active FCC phase occupies the constitutive domain

$$0 \leq \alpha_G < 1. \tag{10.9}$$

The corresponding residual capacity available for local reconfiguration is

$$1 - \alpha_G. \tag{10.10}$$

The gravity-neutral FCC contact action, objective bond kinematics, and long-wavelength transverse homogenization are developed in Appendix D. The work-conjugate gravitational endpoint construction and its effective-inertia reduction are developed in Appendix J.

10.4.1 Serial Endpoint Transfer

A completed nearest-neighbor transfer from an FCC node i to an adjacent node j requires two serial operations:

1. the source configuration must release the transferable state into the connecting FCC channel;
2. the target configuration must accept the incoming state and restore local lattice closure.

The normalized source-release and target-acceptance capacities are respectively

$$1-\alpha_{\mathrm{G}}^{(i)} \qquad \text{and} \qquad 1-\alpha_{\mathrm{G}}^{(j)}. \tag{10.11}$$

Because the target acts on the state already admitted by the source, the completed-transfer factor is the serial product

$$\mathcal{C}_{ij}=\left[1-\alpha_{\mathrm{G}}^{(i)}\right]\left[1-\alpha_{\mathrm{G}}^{(j)}\right]. \tag{10.12}$$

The corresponding effective propagation speed across the selected nearest-neighbor connection is

$$\frac{c_{\mathrm{P}}^{(i\to j)}}{c_{\mathrm{E}}}=\mathcal{C}_{ij}, \tag{10.13}$$

where c_{E} is the completed-transfer speed of the unstrained active Soft Floor.

The multiplicative form is not a probability rule. It is a reduced constitutive closure expressing source release followed by target acceptance. Its exact nonuniform endpoint decomposition, continuum-validity condition, and work-conjugate construction are given in Appendix J.

For a locally uniform gravitational strain, the two endpoint factors coincide and the propagation law reduces to

$$c_{\mathrm{P}}=c_{\mathrm{E}}\left(1-\alpha_{\mathrm{G}}\right)^{2}. \tag{10.14}$$

The quadratic factor therefore has a direct discrete interpretation:

$$\text{source release capacity} \times \text{target acceptance capacity}. \tag{10.15}$$

10.4.2 Strain-Induced Refraction and Effective Inertia

The local propagation index of the coherent transverse branch is defined by

$$n_{\tau}=\frac{c_{\mathrm{E}}}{c_{\mathrm{P}}}. \tag{10.16}$$

Using Equation (10.14),

$$n_{\tau}=\frac{1}{\left(1-\alpha_{\mathrm{G}}\right)^{2}}. \tag{10.17}$$

In the weak-field limit,

$$\alpha_{\mathrm{G}}\ll 1, \tag{10.18}$$

the index becomes

$$n_{\tau}=1+2\alpha_{\mathrm{G}}+3\alpha_{\mathrm{G}}^{2}+\mathcal{O}\left(\alpha_{\mathrm{G}}^{3}\right). \tag{10.19}$$

The leading coefficient 2 is the continuum manifestation of the two endpoint constraints required to complete one nearest-neighbor state transfer.

Appendix D establishes the baseline transverse stiffness–inertia relation of the unstrained FCC phase,

$$c_{\mathrm{E}}^{2}=\frac{\tau_{\mathrm{D}}}{\mu_{\mathrm{D}}}. \tag{10.20}$$

Within the active gravitational specialization, the leading surface shear tension remains at its baseline value while the endpoint constraint is represented through an effective dynamic surface inertia. The equivalent inertial representation of Equation (10.14) is therefore

$$\mu_{\mathrm{eff}}=\frac{\mu_{\mathrm{D}}}{\left(1-\alpha_{\mathrm{G}}\right)^{4}}. \tag{10.21}$$

This is not an independent second law. It is the stiffness–inertia representation of the same serial endpoint-transfer closure. The detailed referred-inertia derivation is given in Appendix J.

The index n_τ describes gravitational refraction of the coherent transverse branch through the locally strained FCC network. Internal phase mismatch may modify excitation amplitude, polarization, defect coupling, or mode participation, but it does not introduce an additional universal multiplicative factor into c_{P} unless such a correction is separately obtained from the microscopic eigenvalue problem.

10.4.3 Constitutive Limits and Saturation

In the unstrained active vacuum,

$$\alpha_{\mathrm{G}} = 0, \tag{10.22}$$

and the endpoint closure gives

$$c_{\mathrm{P}} = c_{\mathrm{E}}, \qquad n_\tau = 1, \qquad \mu_{\mathrm{eff}} = \mu_{\mathrm{D}}. \tag{10.23}$$

As the active FCC phase approaches saturation,

$$\alpha_{\mathrm{G}} \to 1^{-}, \tag{10.24}$$

the completed-transfer capacity vanishes:

$$c_{\mathrm{P}} \to 0. \tag{10.25}$$

At the same limit,

$$n_\tau \to \infty, \qquad \mu_{\mathrm{eff}} \to \infty. \tag{10.26}$$

This limit represents mechanical arrest of active FCC reconfiguration through divergent constrained inertia. It does not represent the continuous disappearance of the baseline Soft Floor shear tension.

The closure applies only while both endpoints remain in the active FCC phase:

$$0 \le \alpha_{\mathrm{G}}^{(i)} < 1, \qquad 0 \le \alpha_{\mathrm{G}}^{(j)} < 1. \tag{10.27}$$

At saturation, the local structure undergoes the FCC-to-SC phase transition. The active endpoint-transfer law is therefore not analytically continued into the phase-locked SC substrate or across a sharp FCC-to-SC boundary.

The present section summarizes the gravitational propagation closure required by the main-body theory. Its gravity-neutral mechanical foundation is developed in Appendix D, while its work-conjugate endpoint construction, nonuniform correction, referred-inertia derivation, and microscopic completion criterion are developed in Appendix J.

10.5 The Mechanical Equivalence Principle: Topological Mass Identity

Standard physics treats the equivalence of inertial mass and gravitational mass as an empirical fact. TFT does not treat this equality as a coincidence between two independently existing quantities. Instead, TFT derives it from a deeper mechanical identity: inertial mass and gravitational mass are two operational projections of the same coupled topological loading of the Spacetime Gravitational Floor (SGF).

In TFT, motion is not the continuous sliding of an object through empty space. Motion is a discrete structural reconfiguration of the active lattice. A localized mass defect must transfer its phase state from one FCC lattice node to the next, while remaining coupled to the interstitial condensate and to the surrounding restorative tension field.

10.5.1 The Mechanism of Inertia: Tying and Untying

- **The Step (Reconfiguration):** To move, a localized particle must physically untie its three-dimensional topological phase-knot from FCC lattice node A and simultaneously retie it onto adjacent FCC lattice node B. This transfer occurs across the shared two-dimensional interface of the active lattice and is guided by the local phase gradient.
- **The Drive (Restorative Gravity):** The vacuum substrate naturally seeks flat equilibrium. A localized topological defect creates a structural tension deficit in the Soft Floor. The surrounding SGF responds by exerting a restorative tension gradient that pulls on the defect to reduce that deficit.
- **The Cost (Inertia):** The same topological knot resists reconfiguration. A more strongly coupled phase structure displaces more interstitial condensate and therefore produces greater hydrodynamic impedance against motion. Inertia is this resistance to discrete reconfiguration through the condensate.

10.5.2 The Topological Loading Identity

Let m_T denote the coupled topological loading of a localized defect. Physically, m_T is the condensate impedance displaced by the defect's phase structure. It is determined by the interstitial condensate density (ρ_{IC}), the effective displacement volume of the defect (V_{eff}), and the phase-coupling efficiency ($\sin(\Delta\varphi)$):

$$m_T = \rho_{\text{IC}} V_{\text{eff}} \sin(\Delta\varphi) \tag{10.28}$$

This same structural quantity has two observational projections:

- **Inertial Mass:** When the defect resists reconfiguration through the interstitial condensate, the topological loading is observed as inertia:

$$m_{\text{inertial}} = m_T \tag{10.29}$$

- **Gravitational Mass:** When the external Soft Floor tension potential acts on the same defect, the topological loading dictates the coupling strength to the restorative tension:

$$m_{\text{gravitational}} = m_T \tag{10.30}$$

Therefore, TFT does not require nature to separately tune inertial mass and gravitational mass to equality. They are not two independent masses. They are the identical SGF loading viewed through two different mechanical operations: resistance to reconfiguration and coupling to restorative tension.

10.5.3 Universal Free Fall as the Test-Body Limit

The gravitational force on a localized defect is the external restorative tension-field acceleration $(-\nabla\Phi_\tau)$ multiplied by the topological loading:

$$F_{\text{gravity}} = -m_T \nabla\Phi_\tau \tag{10.31}$$

The inertial resistance of that defect is also m_T. Therefore, the acceleration is obtained by dividing the restorative force by the inertial resistance:

$$a = \frac{F_{\text{gravity}}}{m_{\text{inertial}}} \tag{10.32}$$

$$a = -\nabla\Phi_\tau \tag{10.33}$$

The topological loading m_T cancels identically. A body with larger topological loading experiences a proportionally stronger restorative pull, but it also possesses proportionally greater resistance to reconfiguration.

Thus, in the test-body limit, the acceleration depends only on the external Soft Floor tension-potential gradient, independent of composition, density, or internal phase complexity. This is the TFT mechanical origin of the observed universality of free fall. For a spherical source, the external tension potential reduces to the usual radial form, giving the familiar inverse-square acceleration. In TFT interpretation, this is not action-at-a-distance through empty geometry; it is the local restorative response of the active SGF tension field.

10.5.4 Extension to Self-Gravitating Bodies

For composite and self-gravitating systems, this identity remains valid, but the comparison is no longer a simple point-defect calculation. The relevant quantity becomes the integrated topological loading of the full strain configuration.

- A **weak test particle** is a localized phase defect.
- A **planet** is a composite defect aggregate whose own tension field modestly contributes to its internal equilibrium.
- A **neutron star** is a highly compressed Soft Floor strain state whose internal phase condition is governed by its own restorative tension.
- A **black hole** is the saturation limit, where the active FCC Soft Floor phase-converts into the SC substrate (See Section 12.2) while the inertial loading remains carried by the live FCC/SC phase boundary.

In all cases, the same SGF strain-loading maintains both ledgers: the inertial ledger measuring resistance to reconfiguration, and the restorative-tension ledger measuring gravitational coupling. Therefore, TFT's equivalence principle is fundamentally a topological mass identity. Universal free fall is its weak-field test-body limit; self-gravitating behavior is its integrated strong-field extension.

10.6 Bound-Orbit Strain Coupling and Perihelion Precession

The equivalence-principle derivation above establishes why all localized mass defects experience the same radial acceleration in the Newtonian limit. However, a bound orbit is not merely radial free fall. A planet is a three-dimensional topological defect aggregate moving tangentially through the radial strain field established by the central mass.

This produces a distinct conservative correction to the Newtonian bound-orbit acceleration. The correction is not a dark-matter impedance effect and not an optical propagation delay. It is a local bound-orbit strain effect caused by the coupling between the radial Soft Floor strain potential and the tangential transport of the orbiting mass defect.

For a central mass M, the radial Soft Floor strain potential per unit mass is

$$\Phi_\tau(r) = -\frac{GM}{r}. \tag{10.34}$$

A bound orbiting mass moving with tangential speed $v_\perp$ consumes a dimensionless fraction of the Soft Floor kinematic capacity,

$$\frac{v_\perp^2}{c_{\mathrm{E}}^2}. \tag{10.35}$$

Therefore, the leading conservative specific orbital strain-potential coupling is

$$\Phi_{\mathrm{orb}} = \Phi_\tau \frac{v_\perp^2}{c_{\mathrm{E}}^2}. \tag{10.36}$$

For the weak-field spherical bound-orbit problem, the specific orbital angular momentum is conserved:

$$\ell_{\mathrm{orb}} = r v_\perp. \tag{10.37}$$

After imposing this bound-orbit reduction, the orbital strain potential becomes

$$\Phi_{\mathrm{orb}}^{(\mathrm{red})} = -\frac{GM\ell_{\mathrm{orb}}^2}{c_{\mathrm{E}}^2 r^3}. \tag{10.38}$$

This reduced potential is not a fully general velocity-dependent field potential for arbitrary motion. It is the reduced central-orbit strain potential obtained after applying angular-momentum conservation to a weak-field, spherical, conservative bound orbit.

The radial derivative of this cubic reduced strain-potential term produces the additional inward bound-orbit correction

$$g_{\mathrm{orb}} = 3 g_{\mathrm{b}} \frac{v_\perp^2}{c_{\mathrm{E}}^2}, \tag{10.39}$$

where

$$g_{\mathrm{b}} = \frac{GM}{r^2}. \tag{10.40}$$

Thus, the inward acceleration magnitude for a weak-field massive bound orbit becomes

$$g_{\mathrm{bound}} = g_{\mathrm{b}} + g_{\mathrm{orb}} = \frac{GM}{r^2} + \frac{3GM\ell_{\mathrm{orb}}^2}{c_{\mathrm{E}}^2 r^4}. \tag{10.41}$$

This correction leads directly to the weak-field post-Newtonian orbital equation

$$\frac{\mathrm{d}^2 u}{\mathrm{d}\varphi^2} + u = \frac{GM}{\ell_{\mathrm{orb}}^2} + \frac{3GM}{c_{\mathrm{E}}^2} u^2, \tag{10.42}$$

where $u = 1/r$. This is the same reduced orbital equation obtained in General Relativity for the weak-field perihelion correction.

Therefore, TFT recovers the standard perihelion advance

$$\Delta\varphi = \frac{6\pi GM}{a(1-e^2)c_{\mathrm{E}}^2}. \tag{10.43}$$

The complete mechanical derivation is provided in Appendix K.

In TFT interpretation, the non-closing orbit is not caused fundamentally by spacetime curvature. It is the cumulative orbital phase advance generated by the conservative cubic reduced Soft Floor strain potential of a bound topological defect moving through a radially pre-stressed lattice.

10.7 The Galactic Rotation Solution: Cosmic Impedance

Observed galactic rotation curves commonly exhibit orbital accelerations greater than those generated by the measured baryonic mass under an isolated inverse-square law. Standard cosmology attributes this discrepancy primarily to non-baryonic dark matter, while modified-dynamics approaches introduce a characteristic low-acceleration scale [8]. Tension Field Theory instead attributes the excess acceleration to the coherent reactive response of the Vacuum Interstitial Condensate within the active FCC Soft Floor.

A baryonic tension gradient phase-loads the surrounding condensate. In high-acceleration regions, the extended condensate response is suppressed and the gravitational field is dominated by the directly transmitted baryonic contribution. In the low-acceleration galactic regime, the condensate remains coherently coupled to the source and contributes an additional restorative acceleration. This response is inductive rather than dissipative and therefore does not require continuous orbital-energy loss.

Let $g_b(R)$ denote the spherical-equivalent baryonic acceleration, and let the geometry-corrected radial field be

$$g_{b,\Pi}(R) = \Pi(R) g_b(R), \tag{10.44}$$

where $\Pi(R)$ is the scalar geometric transmission factor defined in Appendix M.

Appendix L derives the fundamental Lattice Impedance Acceleration,

$$a_{\mathrm{D}} = \frac{c_{\mathrm{E}}^2}{R_{\mathrm{U}}} = c_{\mathrm{E}}\Gamma_{\mathrm{D}}, \tag{10.45}$$

and defines the corresponding galactic acceleration scale as

$$a_{\mathrm{gal}} = \frac{a_{\mathrm{D}}}{2\pi}. \tag{10.46}$$

Within the coherent galactic regime, where the screening function approaches unity, the acceleration law becomes

$$g_{\mathrm{obs}}(R) \approx g_{b,\Pi}(R) + \sqrt{a_{\mathrm{gal}} g_{b,\Pi}(R)}. \tag{10.47}$$

The first term is the directly transmitted baryonic restorative field. The second term is the inductive response of the Vacuum Interstitial Condensate.

In the high-acceleration inner region,

$$g_{b,\Pi} \gg g_*, \tag{10.48}$$

the coherent condensate response is screened and

$$g_{\rm obs} \approx g_{b,\Pi}. \tag{10.49}$$

In the coherent outer-galactic region,

$$g_{b,\Pi} \ll g_*, \qquad R \ll R_{\rm c}, \tag{10.50}$$

the screening function approaches unity. When the field also satisfies

$$g_{b,\Pi} \ll a_{\rm gal}, \tag{10.51}$$

the condensate term dominates:

$$g_{\rm obs}(R) \approx \sqrt{a_{\rm gal} g_{b,\Pi}(R)}. \tag{10.52}$$

For an exterior baryonic field proportional to R^{-2}, this induced contribution scales as R^{-1}, producing an approximately constant orbital speed and the Baryonic Tully–Fisher relation.

See Appendix L for the derivation of $a_{\rm D}$, the definition of $a_{\rm gal}$, and the finite-coherence screening law.

10.8 The Master Acceleration Equation

The galactic rotation solution describes the coherent large-scale response of the Vacuum Interstitial Condensate. Astrophysical systems, however, may also contain nonspherical source geometries, finite coherence boundaries, and trajectory-dependent corrections for precision bound orbits. TFT therefore separates the environmental source field from the additional correction associated with the tangential motion of a massive bound body.

The gravitational response is organized into two levels:

1. the **environmental acceleration field**, determined by the directly transmitted baryonic field, geometric transmission, and condensate-coherence screening;

2. the **precision bound-orbit correction**, applicable to a massive body moving tangentially through a weak radial strain field.

10.8.1 Environmental Acceleration Field

The geometry-corrected baryonic acceleration is

$$g_{b,\Pi}(R) = \Pi(R) g_b(R). \tag{10.53}$$

The environmental weak-field acceleration law is

$$g_{\rm obs}(R) = g_{b,\Pi}(R) + \Xi(R) \sqrt{a_{\rm gal} g_{b,\Pi}(R)}. \tag{10.54}$$

Using the scalar geometric transmission factor explicitly,

$$g_{\rm obs}(R) = \Pi(R) g_b(R) + \Xi(R) \sqrt{a_{\rm gal} \Pi(R) g_b(R)}. \tag{10.55}$$

The geometric factor therefore modifies the baryonic field before the nonlinear condensate response is evaluated.

10.8.2 Definition of the Terms

The quantity $g_b(R)$ is the spherical-equivalent baryonic restorative acceleration produced by visible matter. In spherical symmetry,

$$g_b(R) = \frac{GM_b(< R)}{R^2}. \tag{10.56}$$

The quantity $\Pi(R)$ is the dimensionless scalar geometric transmission factor developed in Appendix M. It represents the reduced radial transmission of a nonspherical source:

- $\Pi(R) = 1$ for spherical transmission,
- $\Pi(R) < 1$ for radial dilution or shear redistribution, and
- $\Pi(R) > 1$ for reduced-model geometric convergence or focusing.

The exact directional operation is carried by the tensor projector $\Pi_{\mu\nu}$. The scalar $\Pi(R)$ is its reduced one-dimensional representation and is not itself a strong-field solution.

When $g_b(R)$ has already been computed from the complete stellar disk, gas distribution, bulge, and other nonspherical components, the source geometry is already included. In that case, the explicit scalar factor is set to unity or absorbed into the calculated baryonic field.

The function $\Xi(R)$ is the finite-coherence screening function defined in Appendix L:

$$\Xi(R) = \left[1 + \left(\frac{g_{b,\Pi}(R)}{g_*}\right)^{n_1}\right]^{-1} \left[1 + \left(\frac{R}{R_{\rm c}}\right)^{n_2}\right]^{-1}. \tag{10.57}$$

Its first factor suppresses the extended condensate response in the high-acceleration inner region. Its second factor terminates the response beyond the source-correlated coherence radius ($R_{\rm c}$). The function acts only on the induced condensate term and does not suppress the directly transmitted baryonic field.

The fundamental lattice acceleration is

$$a_{\rm D} = \frac{c_{\rm E}^2}{R_{\rm U}}, \tag{10.58}$$

while the acceleration scale entering the galactic constitutive law is

$$a_{\rm gal} = \frac{a_{\rm D}}{2\pi}. \tag{10.59}$$

Thus, $a_{\rm D}$ characterizes the horizon-scale relaxation capacity of the active vacuum, whereas $a_{\rm gal}$ governs the reduced circular-orbit response of the Vacuum Interstitial Condensate.

10.8.3 Precision Bound-Orbit Extension

The environmental acceleration law describes the source-generated radial field of the active Soft Floor. It does not include the reduced trajectory-dependent correction responsible for weak-field perihelion precession, because that contribution depends on the tangential motion of a massive bound body.

For a massive body in a weak-field spherical orbit, the environmental acceleration is supplemented by the conservative orbital strain correction

$$g_{\rm bound}(R, v_\perp) = g_{\rm obs}(R) + g_{\rm orb}(R, v_\perp), \tag{10.60}$$

where

$$g_{\rm orb}(R, v_\perp) = 3g_b(R)\frac{v_\perp^2}{c_{\rm E}^2}. \tag{10.61}$$

This contribution is neither a condensate-impedance term nor part of the static source field. It is a reduced correction associated with the tangential motion of a massive topological defect through the radial strain field.

Introducing the conserved specific orbital angular momentum,

$$\ell_{\rm orb} = Rv_\perp, \tag{10.62}$$

the correction may be written in the spherical central-field limit as

$$g_{\rm orb}(R, \ell_{\rm orb}) = \frac{3GM\ell_{\rm orb}^2}{c_{\rm E}^2 R^4}. \tag{10.63}$$

The resulting weak-field orbital equation is

$$\frac{{\rm d}^2u}{{\rm d}\varphi^2} + u = \frac{GM}{\ell_{\rm orb}^2} + \frac{3GM}{c_{\rm E}^2}u^2, \tag{10.64}$$

which gives the perihelion advance

$$\Delta\varphi = \frac{6\pi GM}{a(1-e^2)c_{\rm E}^2}. \tag{10.65}$$

The detailed mechanical development is provided in Appendix K.

10.8.4 Mechanical Interpretation

The environmental acceleration contains two source-field channels:

$$g_{\rm obs} = \text{directly transmitted baryonic field} + \text{screened condensate response}. \tag{10.66}$$

The direct contribution is

$$g_{b,\Pi}(R) = \Pi(R)g_b(R). \tag{10.67}$$

It is the radial restorative acceleration generated by the baryonic tension field after geometric transmission has been accounted for.

The induced contribution is

$$\Xi(R)\sqrt{a_{\rm gal}g_{b,\Pi}(R)}. \tag{10.68}$$

It is the coherent reactive response of the Vacuum Interstitial Condensate. In the galactic low-acceleration regime, this term produces the excess acceleration conventionally attributed to a particulate dark-matter halo.

The orbital contribution,

$$g_{\rm orb} = 3g_b\frac{v_\perp^2}{c_{\rm E}^2}, \tag{10.69}$$

belongs to a separate dynamical category. It is a trajectory-dependent correction that appears when a massive bound topological defect moves tangentially through a radial strain field.

The resulting hierarchy is therefore

$$\text{baryonic restorative field} \quad + \quad \text{condensate impedance response} \quad + \quad \text{bound-orbit strain correction}. \tag{10.70}$$

The first two terms define the environmental acceleration field. The third provides the precision weak-field correction for massive bound orbits.

10.8.5 Regime Limits

Solar-System Regime For a nearly spherical source,

$$\Pi(R) \approx 1. \tag{10.71}$$

In the high-acceleration inner region,

$$\Xi(R) \to 0, \tag{10.72}$$

so the environmental field reduces to

$$g_{\rm obs}(R) \approx g_b(R). \tag{10.73}$$

For precision bound-orbit dynamics,

$$g_{\rm bound}(R) \approx g_b(R) + g_{\rm orb}(R). \tag{10.74}$$

The leading term recovers the inverse-square gravitational field, while the orbital strain correction produces the weak-field perihelion advance.

Galactic-Disk Regime Within the coherent galactic region,

$$\Xi(R) \approx 1. \tag{10.75}$$

The environmental acceleration becomes

$$g_{\rm obs}(R) \approx g_{b,\Pi}(R) + \sqrt{a_{\rm gal} g_{b,\Pi}(R)}. \tag{10.76}$$

Equivalently,

$$g_{\rm obs}(R) \approx \Pi(R) g_b(R) + \sqrt{a_{\rm gal} \Pi(R) g_b(R)}. \tag{10.77}$$

In the deep low-acceleration limit, the second term dominates and yields

$$v^4(R) = \Pi(R) G a_{\rm gal} M_b. \tag{10.78}$$

As the bounded geometric transmission factor approaches its far-field limit,

$$\Pi(R) \to 1, \tag{10.79}$$

the Baryonic Tully–Fisher relation becomes

$$v_\infty^4 = G a_{\rm gal} M_b. \tag{10.80}$$

Beyond the Galactic Coherence Radius For

$$R \gg R_{\rm c}, \tag{10.81}$$

the screening function approaches zero:

$$\Xi(R) \to 0. \tag{10.82}$$

The environmental field returns to

$$g_{\rm obs}(R) \to g_{b,\Pi}(R). \tag{10.83}$$

In the far-field spherical limit,

$$\Pi(R) \to 1, \tag{10.84}$$

and the acceleration resumes inverse-square decay. The outer coherence cutoff prevents the $1/R$ condensate-supported regime from generating a linearly increasing apparent dynamical mass and a logarithmically unbounded potential.

Black-Hole Regime In the strong-field regime,

$$\alpha_{\mathrm{G}} \to 1, \tag{10.85}$$

the weak-field environmental acceleration law is no longer extrapolated as the governing equation. The high local acceleration suppresses the galactic condensate contribution,

$$\Xi(R) \to 0, \tag{10.86}$$

but the remaining field cannot be represented by a Newtonian baryonic term multiplied by a scalar focusing factor.

The exterior acceleration must instead be obtained from the complete nonlinear tension and strain solution, including angular and rotational dependence where present. After the directional field has been solved, the tensor projector

$$\Pi_{\mu\nu} \tag{10.87}$$

may be used to extract its radial component. For a nonrotating spherical exterior, the scalar geometric transmission factor remains

$$\Pi(R) = 1. \tag{10.88}$$

Event-horizon formation is then associated with saturation of the active Soft Floor and the transition

$$\alpha_{\mathrm{G}} \to 1, \tag{10.89}$$

rather than with an arbitrary enhancement of the weak-field scalar projection factor.

This hierarchy preserves the distinction between the environmental source field, the coherent galaxy-scale condensate response, the trajectory-dependent bound-orbit correction, and the nonlinear strong-field solution.

Chapter 11

The Gravitational Field: Waves, Curvature, and the Optical Analogy

Standard General Relativity models gravity as geometric curvature that propagates at the speed of light. Tension Field Theory (TFT) offers a mechanical clarification, distinguishing between the static existence of the Tension Field itself and the dynamic Propagation of Change within that field.

11.1 Gravitational Waves: Static Field vs. Dynamic Propagation

11.1.1 The Static Field (Restorative Tension)

The pull of gravity, as defined in Chapter 10, is a tension gradient,

$$-\nabla\tau, \tag{11.1}$$

established in the active Spacetime Gravitational Floor (SGF). For a stationary source, this gradient is a stable, equilibrated stress configuration of the State-I Soft Floor rather than a continuously emitted gravitational disturbance.

- **Mechanism:** For a static mass distribution, the tension gradient remains established in the surrounding active vacuum. Matter within this field responds locally to the already-established restorative tension gradient of the Soft Floor.
- **Result:** A stationary gravitational field therefore does not require the source to continuously transmit a new gravitational signal to the responding body. The local acceleration is determined by the existing State-I tension configuration,

$$\mathbf{g} = -\nabla\Phi_\tau. \tag{11.2}$$

The phase-locked Hard Floor performs a different mechanical role. It supplies the flat reference structure and the underlying strain record but does not itself carry the active gravitational gradient. Within the Hard-Floor limit adopted in the vertical-topology construction, changes in this underlying record may equilibrate without the finite propagation delay of the active FCC phase. The corresponding gravitational response, however, is realized only when the State-I Soft Floor reconfigures through its own finite mechanical propagation law.

This separation is consistent with the quantum-entanglement construction of Chapter 15 and Appendix AC. There, instantaneous Hard-Floor stress transfer is associated with a pre-existing Residual Phase-Tether, whereas ordinary gravitational interaction remains a mechanical state of the active Soft Floor. Accordingly, the local complementarity

$$\alpha_{\mathrm{Q}} = 1 - \alpha_{\mathrm{G}} \tag{11.3}$$

is determined by the locally realized Soft-Floor gravitational loading.

11.1.2 The Dynamic Wave (Transverse Shear)

When a gravitating source accelerates or changes configuration, for example during a compact-object merger, the established State-I stress configuration acquires a time-dependent disturbance. This disturbance propagates through the active FCC vacuum as a coherent transverse response and is represented macroscopically by the gravitational-wave tensor field.

- **Mechanism:** The isochoric transverse deformation of the FCC scaffold produces a transient structural oscillation of the active vacuum. In the conservative coherent branch, the interstitial condensate is entrained with the scaffold without relative condensate flow,

  $$\mathbf{v}_{\mathrm{rel}} = \mathbf{v}_{\mathrm{IC}} - \dot{\mathbf{u}} = \mathbf{0}. \tag{11.4}$$

  The condensate therefore participates in the coherent motion while supplying the incremental volume constraint; the propagating wave is not generated by motion of the scaffold through a stationary condensate.

- **Speed:** At the macroscopic gravitational-wave level, the collective response is characterized by the effective tensor-response coefficient $K_{\mathrm{GW}}^{(\mathrm{eff})}$ and the corresponding equivalent continuum inertia parameter $\rho_{\mathrm{GW}}^{(\mathrm{eff})}$. Their baseline propagation normalization is

  $$\frac{K_{\mathrm{GW}}^{(\mathrm{eff})}}{\rho_{\mathrm{GW}}^{(\mathrm{eff})}} = c_{\mathrm{E}}^2. \tag{11.5}$$

  Gravitational preloading modifies the completed State-I transfer through the local structural coupling α_{G}. For an existing gravitational-wave disturbance, the local propagation speed therefore follows the Soft-Floor endpoint-transfer law,

  $$c_{\mathrm{GW}}(\mathbf{x}) = c_{\mathrm{P}}(\mathbf{x}) = c_{\mathrm{E}} \left[1 - \alpha_{\mathrm{G}}(\mathbf{x})\right]^2. \tag{11.6}$$

  In a locally gravity-neutral background, $\alpha_{\mathrm{G}} \to 0$, and the propagation speed of the disturbance approaches the baseline elastic limit, $c_{\mathrm{GW}} \to c_{\mathrm{E}}$.

- **Result:** Static gravity and gravitational radiation are different dynamical limits of the same State-I mechanical architecture. Static gravity is the equilibrated restorative tension configuration, whereas a gravitational wave is the propagating time-dependent tensor response generated when that configuration changes. The microscopic FCC scaffold and the macroscopic gravitational-wave response share the same baseline propagation capacity, while their absolute constitutive coefficients belong to different descriptive scales, as developed in Appendix N.

- **Cosmological Redshift (Visco-Elastic Phase Lag):** The coherent gravitational-wave branch described above is conservative and does not acquire damping from relative condensate flow. Cosmological attenuation belongs to the separate dissipative phase-lag sector characterized by Γ_{D}. When this long-distance dissipative response is applied to gravitational-wave propagation, its attenuation is governed by the same vacuum-damping framework developed for cosmological propagation in Appendix AQ.

11.1.3 GW150914: Continuum Strain Calibration

LIGO measures gravitational-wave strain,

$$h_{\mathrm{GW}} = \frac{\Delta L}{L}, \tag{11.7}$$

through the differential response of its interferometer arms. Within TFT, this observed strain provides a macroscopic scale against which the collective tensor response of the active vacuum can be parameterized.

- **The TFT Response:** The macroscopic gravitational-wave branch is represented by the effective response coefficient $K_{\mathrm{GW}}^{(\mathrm{eff})}$ and its equivalent inertia parameter $\rho_{\mathrm{GW}}^{(\mathrm{eff})}$.
- **The Calibration:** Using the representative strain and source-reconstructed energy-flux scale of GW150914, the continuum calibration developed in Appendix N gives

$$K_{\mathrm{GW}}^{(\mathrm{eff})} \approx 9.4 \times 10^{30}\,\mathrm{Pa}, \tag{11.8}$$

and, through

$$\rho_{\mathrm{GW}}^{(\mathrm{eff})} = \frac{K_{\mathrm{GW}}^{(\mathrm{eff})}}{c_{\mathrm{E}}^2}, \tag{11.9}$$

the corresponding equivalent continuum inertia parameter is

$$\rho_{\mathrm{GW}}^{(\mathrm{eff})} \approx 1.04 \times 10^{14}\,\mathrm{kg\,m^{-3}}. \tag{11.10}$$

These quantities are two representations of the same adopted macroscopic strain–flux normalization. They characterize the collective gravitational-wave response and are distinct from the primitive-cell microscopic FCC scaffold coefficients.

For the characteristic observed strain $h_{\mathrm{GW}} \sim 10^{-21}$, the corresponding equivalent wave-stress scale is of order

$$\sigma_{\mathrm{GW}}^{(\mathrm{eq})} \sim K_{\mathrm{GW}}^{(\mathrm{eff})} h_{\mathrm{GW}} \sim 10^{10}\,\mathrm{Pa}. \tag{11.11}$$

This is approximately 10^{86} below the microscopic FCC saturation-pressure scale. The observed gravitational-wave disturbance therefore lies deeply within the perturbative State-I regime relative to the structural saturation boundary.

Result: GW150914 supplies a representative observational calibration of the effective macroscopic tensor-response scale used in TFT. Appendix N develops the complete strain–flux normalization, tensor response, and comparison with the microscopic FCC scaffold.

11.1.4 The Collective Spin-2 Quadrupole Response

Standard General Relativity represents gravitational radiation as a transverse-traceless rank-two field possessing two tensor polarizations, conventionally denoted + and ×. Tension Field Theory represents the corresponding macroscopic deformation of the State-I active vacuum by the collective gravitational-wave response tensor

$$\mathsf{H}_{ij}^{(\mathrm{GW})}. \tag{11.12}$$

The coherent translational carrier of the dual-phase FCC vacuum satisfies the incremental volume constraint

$$\nabla \cdot \mathbf{u} = 0. \tag{11.13}$$

This condition removes the ordinary finite-frequency longitudinal volumetric polarization from the selected coherent translational sector, leaving two transverse carrier degrees of freedom. The quadrupolar spin-2 character is represented at the collective tensor level.

For propagation along the z-axis, the gravitational-wave response may be written

$$\mathsf{H}_{ij}^{(\mathrm{GW})} = \frac{1}{2}\begin{pmatrix} h_+ & h_\times & 0 \\ h_\times & -h_+ & 0 \\ 0 & 0 & 0 \end{pmatrix}. \tag{11.14}$$

The tensor is symmetric,

$$\mathsf{H}_{ij}^{(\mathrm{GW})} = \mathsf{H}_{ji}^{(\mathrm{GW})}, \tag{11.15}$$

transverse to the propagation direction,

$$s^i \mathsf{H}_{ij}^{(\mathrm{GW})} = 0, \tag{11.16}$$

and traceless,

$$\mathsf{H}_{ii}^{(\mathrm{GW})} = 0. \tag{11.17}$$

Its two independent transverse components generate the + and × quadrupolar polarization patterns.

Under a rotation of the transverse coordinate axes through an angle ψ, the components transform as

$$h'_+ = h_+ \cos(2\psi) + h_\times \sin(2\psi), \tag{11.18}$$

$$h'_\times = -h_+ \sin(2\psi) + h_\times \cos(2\psi). \tag{11.19}$$

Equivalently, this rotation can be expressed as

$$h_+ + i h_\times \longrightarrow e^{-2i\psi}\,(h_+ + i h_\times)\,. \tag{11.20}$$

The appearance of 2ψ is the characteristic spin-weight-2 transformation of a transverse rank-two field. The + and × gravitational-wave polarizations are therefore represented in TFT as the two components of the collective spin-2 tensor deformation of the active State-I vacuum.

The microscopic FCC displacement field and the collective tensor $\mathsf{H}_{ij}^{(\mathrm{GW})}$ belong to different levels of the same mechanical hierarchy. Appendix N develops the macroscopic tensor construction and its connection to the coherent transverse carrier; the explicit coarse-grained projection from the complete FCC contact, translational, rotational, and phase eigenstructure to the collective quadrupolar field defines the remaining microscopic bridge.

11.2 Gravitational Curvature and the Vacuum Catastrophe

11.2.1 The Gravitational Saturation Radius (R_{sat})

We derive the gravitational saturation radius (R_{sat}) by determining the exact geometric boundary where a local uniform density (ρ) reaches the convergence density (ρ_{QG}), triggering complete structural saturation ($\alpha_{\text{G}} = 1$). Starting from the dimensionless coupling $\alpha_{\text{G}} = \frac{GM}{Rc_{\text{E}}^2} = 1$, and substituting the spherical mass $M = \kappa R^3 \rho$:

$$\alpha_{\text{G}} = \frac{G(\kappa R^3 \rho)}{R c_{\text{E}}^2} = \frac{\kappa \rho R^2 G}{c_{\text{E}}^2} = 1 \tag{11.21}$$

$$R_{\text{sat}} = \frac{c_{\text{E}}}{\sqrt{\kappa \cdot \rho \cdot G}} \tag{11.22}$$

(Note: κ is the Topological Projection Operator that adapts to the geometric domain of the interaction. For calculating the interior saturation of this 3D localized mass, it operates strictly as the volumetric projection: $\kappa = \frac{4\pi}{3}$. See Appendix P for the full topological definition.)

Physical Implication: As demonstrated kinematically in Section 12.2, this spatial saturation boundary is strictly identical to the Black Hole Phase Transition Horizon (R_{QG}), marking the exact threshold where effective inertia diverges and causal propagation halts.

11.2.2 Resolution of the Vacuum Catastrophe

If we apply this equation to the Fundamental Substrate Density defined in Part I ($\rho_{\text{S}} \approx 10^{96}$ kg/m^3), we mathematically resolve the "Vacuum Catastrophe."

Standard Quantum Field Theory predicts a Planck-scale vacuum energy density that should manifest as an immense active cosmological curvature ($\approx 10^{70}$ m^{-2}). However, astrophysical observations show a near-zero cosmological constant ($\Lambda \approx 10^{-52}$ m^{-2}). This ~ 120 order-of-magnitude discrepancy is widely known as the worst theoretical prediction in physics [9].

TFT resolves this by identifying the immense theoretical value not as an active kinematic expansion, but as the latent Structural Limit of the Lattice Grain ($\frac{1}{\ell_{\text{S}}^2}$):

$$|G_{\mu\nu}|_{\text{limit}} = \frac{1}{\ell_{\text{S}}^2} \approx \frac{\kappa \cdot \rho_{\text{S}} \cdot G}{c_{\text{E}}^2} \approx 10^{70} \text{ m}^{-2} \tag{11.23}$$

The immense energy density ($\rho_{\text{S}} \approx 10^{96}$ kg/m^3) is real, but it is topologically locked in the Hard Floor. It represents the Static Potential of the vacuum structure, not the Active Curvature of expansion.

11.3 The Gravity Field Equation

11.3.1 Remaining Active Capacity and Induced Lattice Strain

The fundamental gravitational principle of Tension Field Theory is the Conservation of Structural Integrity. The observable vacuum is a high-tension State-I FCC continuum rather than an empty geometric manifold. A localized matter-energy load converts part of the unbroken structural capacity of the active vacuum into a strained, defect-loaded configuration.

The local convergence problem therefore contains two complementary mechanical quantities: the structural capacity remaining available for coherent State-I reconfiguration and the structural-capacity deficit converted into localized loading, condensate response, and gravitational strain.

Let ρ_{QG} denote the scale-dependent convergence density of the State-I Soft Floor, and let ρ_{L} denote the complete local converted-capacity density. Their geometric projections are defined by

$$\frac{1}{R_{\mathrm{QG}}^2} = \frac{\kappa G}{c_{\mathrm{E}}^2}\rho_{\mathrm{QG}}, \tag{11.24}$$

and

$$\frac{1}{R_{\mathrm{L}}^2} = \frac{\kappa G}{c_{\mathrm{E}}^2}\rho_{\mathrm{L}}. \tag{11.25}$$

The structural capacity remaining in the active FCC phase is therefore represented by

$$\frac{1}{R_{\mathrm{QG}}^2} - \frac{1}{R_{\mathrm{L}}^2} = \frac{\kappa G}{c_{\mathrm{E}}^2}\left(\rho_{\mathrm{QG}} - \rho_{\mathrm{L}}\right). \tag{11.26}$$

The density difference

$$\rho_{\mathrm{rem}} = \rho_{\mathrm{QG}} - \rho_{\mathrm{L}} \tag{11.27}$$

measures the local capacity still available for coherent transfer through the State-I contact network. The complementary density ρ_{L} measures the capacity converted into the loaded and strained state.

The Topological Projection Operator κ adapts to the geometric domain of the interaction:

- $\kappa = 4\pi/3$ for a three-dimensional interior mass distribution;
- $\kappa = 4\pi$ for an areal saturation boundary;
- $\kappa = 8\pi$ for the effective four-dimensional tensor projection.

The tensor normalization 8π, including its weak-field trace normalization and its TFT interpretation as the bidirectional stress projection of a closed continuum boundary, is derived in Appendix P.

As the local loading increases,

$$\rho_{\mathrm{L}} \uparrow \qquad \Longrightarrow \qquad \rho_{\mathrm{rem}} \downarrow . \tag{11.28}$$

In the unstrained limit,

$$\rho_{\mathrm{L}} = 0, \qquad \rho_{\mathrm{rem}} = \rho_{\mathrm{QG}}, \tag{11.29}$$

and the State-I Soft Floor retains its full local transfer capacity.

At gravitational saturation,

$$\rho_{\mathrm{L}} \to \rho_{\mathrm{QG}}, \qquad \rho_{\mathrm{rem}} \to 0, \tag{11.30}$$

while

$$\alpha_{\mathrm{G}} \to 1^{-}. \tag{11.31}$$

The remaining coherent transfer capacity of the FCC Soft Floor then vanishes. The State-I constitutive law terminates at this boundary, and the region undergoes the FCC-to-SC phase transition into the State-II saturated core.

The remaining active capacity and the induced lattice strain consequently evolve in complementary directions. The remaining capacity decreases as the converted-capacity deficit increases. At the saturation boundary, the remaining State-I capacity reaches zero, while the induced strain attains its active-phase limit. The State-I field equation is not continued into the phase-locked State-II interior.

11.3.2 The Tension Formulation: Remaining and Converted Capacity

Using the TFT volumetric tension relation

$$\tau = \rho c_{\mathrm{E}}^2, \tag{11.32}$$

the local convergence capacity and converted loading are

$$\tau_{\mathrm{QG}} = \rho_{\mathrm{QG}} c_{\mathrm{E}}^2, \tag{11.33}$$

and

$$\tau_{\mathrm{L}} = \rho_{\mathrm{L}} c_{\mathrm{E}}^2. \tag{11.34}$$

The structural capacity remaining in the State-I phase is

$$\tau_{\mathrm{rem}} = \tau_{\mathrm{QG}} - \tau_{\mathrm{L}}. \tag{11.35}$$

The scalar capacity equation becomes

$$\frac{1}{R_{\mathrm{QG}}^2} - \frac{1}{R_{\mathrm{L}}^2} = \frac{\kappa G}{c_{\mathrm{E}}^4} \left(\tau_{\mathrm{QG}} - \tau_{\mathrm{L}}\right) = \frac{\kappa G}{c_{\mathrm{E}}^4} \tau_{\mathrm{rem}}. \tag{11.36}$$

This equation describes the remaining-capacity branch of the local structural balance. It quantifies the fraction of the State-I capacity that remains available for coherent FCC reconfiguration after the local load has been imposed.

The complementary converted capacity is

$$\Delta\tau^{(\tau)} \equiv \tau_{\mathrm{QG}} - \tau_{\mathrm{rem}}, \tag{11.37}$$

so that

$$\Delta\tau^{(\tau)} = \tau_{\mathrm{L}}. \tag{11.38}$$

The quantity τ_{L} is the complete scalar energy-density component of the converted capacity. It includes the localized coupled defect state and any extended condensate response required by the local solution, with each contribution counted once.

The local stress balance therefore consists of three quantities:

$$\tau_{\mathrm{QG}} = \text{reference convergence capacity}, \tag{11.39}$$

$$\tau_{\mathrm{rem}} = \text{remaining State-I capacity}, \tag{11.40}$$

and

$$\tau_{\mathrm{L}} = \text{converted structural capacity}. \tag{11.41}$$

Gravity is the restorative response of the surrounding State-I continuum to this local conversion. The associated tension gradient acts toward restoration of the unbroken reference state.

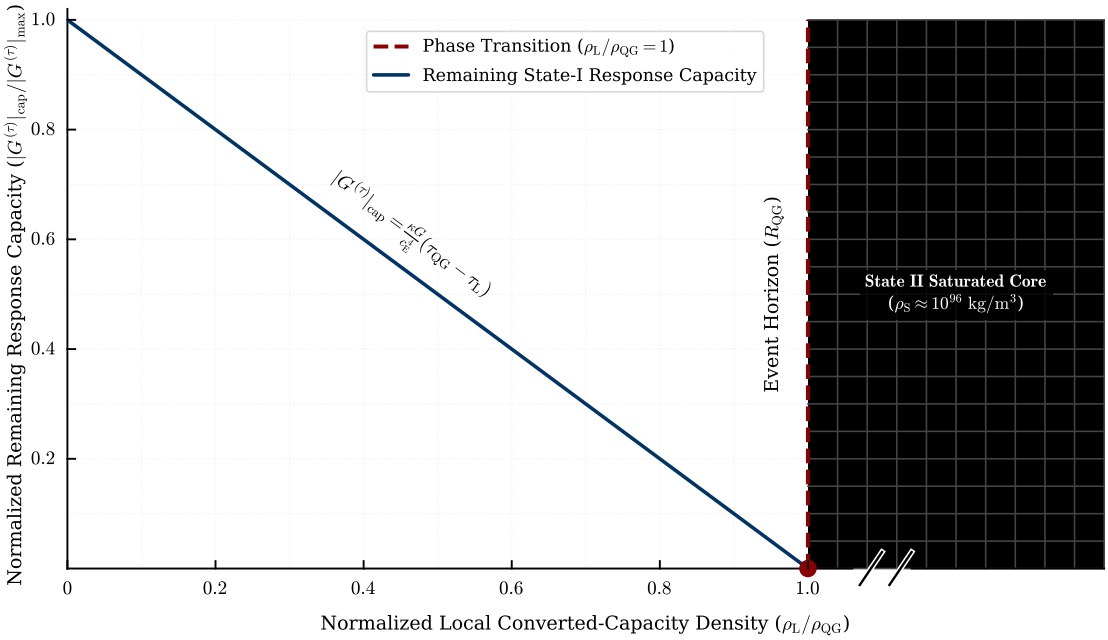

Figure 11.1: **The Exhaustion of State-I Geometric-Response Capacity.** Normalized remaining geometric-response capacity, $|G^{(\tau)}|_{\rm cap}/|G^{(\tau)}|_{\rm max}$, as a function of the normalized local converted-capacity density $\rho_{\rm L}/\rho_{\rm QG}$. In the active Soft-Floor regime ($\rho_{\rm L} < \rho_{\rm QG}$), the remaining State-I capacity is $|G^{(\tau)}|_{\rm cap} = \frac{\kappa G}{c_{\rm E}^4}(\tau_{\rm QG} - \tau_{\rm L}) = \frac{\kappa G}{c_{\rm E}^4}\tau_{\rm rem}$, with normalized form $\frac{|G^{(\tau)}|_{\rm cap}}{|G^{(\tau)}|_{\rm max}} = 1 - \frac{\rho_{\rm L}}{\rho_{\rm QG}}$. The plotted quantity measures the structural capacity still available for coherent FCC reconfiguration after local loading has converted part of the unbroken State-I capacity into a strained configuration. As $\rho_{\rm L}/\rho_{\rm QG}$ increases, the remaining geometric-response capacity decreases linearly while the complementary converted-capacity deficit and induced gravitational strain increase. At the convergence threshold ($\rho_{\rm L}/\rho_{\rm QG} = 1$), the remaining State-I capacity vanishes, defining the Event Horizon ($R_{\rm QG}$) and terminating the active FCC transfer law. The system then undergoes the FCC-to-SC phase transition into the State-II saturated core ($\rho_{\rm S} \approx 10^{96}\,{\rm kg\,m^{-3}}$), represented beyond the broken density axis. Within the phase-locked core ($\Delta\varphi = 0$), State-I geometric-response capacity is exhausted rather than divergent.

11.3.3 The Tensor Projection of the Active Tension Balance

The scalar quantity

$$|G^{(\tau)}|_{\rm cap} = \frac{\kappa G}{c_{\rm E}^4}\,(\tau_{\rm QG} - \tau_{\rm L}) \tag{11.42}$$

characterizes the structural capacity that remains available for coherent State-I reconfiguration. The gravitational response is associated with the complementary capacity converted into localized loading and induced strain. A tensorial description is therefore required to represent not only the converted energy density, but also its directional stress, momentum-transfer, and energy-flux structure.

Let $T_{\mu\nu}^{(0)}$ denote the mechanically balanced State-I reference tensor for the local convergence problem, and let $T_{\mu\nu}^{(\rm rem)}$ denote the structural-capacity tensor remaining in the active phase after local conversion.

The reference, remaining, and converted tensors satisfy

$$T^{(0)}_{\mu\nu} = T^{(\mathrm{rem})}_{\mu\nu} + \Delta T^{(\tau)}_{\mu\nu}. \tag{11.43}$$

The converted structural-capacity tensor is therefore

$$\Delta T^{(\tau)}_{\mu\nu} = T^{(0)}_{\mu\nu} - T^{(\mathrm{rem})}_{\mu\nu}. \tag{11.44}$$

In the local orthonormal State-I frame, the scalar quantities introduced in the preceding section are the temporal components of this tensor balance:

$$T^{(0)}_{\hat{0}\hat{0}} = \tau_{\mathrm{QG}}, \tag{11.45}$$

$$T^{(\mathrm{rem})}_{\hat{0}\hat{0}} = \tau_{\mathrm{rem}}, \tag{11.46}$$

and

$$\Delta T^{(\tau)}_{\hat{0}\hat{0}} = \tau_{\mathrm{L}}. \tag{11.47}$$

Accordingly,

$$\tau_{\mathrm{rem}} = \tau_{\mathrm{QG}} - \tau_{\mathrm{L}} \tag{11.48}$$

is the temporal projection of the complete structural identity.

The scalar capacity (τ_{QG}) fixes the local reference energy density. The complete tensor ($T^{(0)}_{\mu\nu}$) additionally contains the directional stress and momentum-transfer structure of the State-I FCC continuum. The corresponding continuum construction is developed in Appendix Q.

At the retained conservative order, the converted-capacity tensor is resolved into the localized baryonic-defect contribution and the extended interstitial-condensate response:

$$\Delta T^{(\tau)}_{\mu\nu} = T^{(\mathrm{b})}_{\mu\nu} + \delta T^{(\mathrm{IC})}_{\mu\nu}. \tag{11.49}$$

The tensor $T^{(\mathrm{b})}_{\mu\nu}$ represents the complete localized coupled defect state. Its inertial and gravitational normalization is determined by the single topological loading coefficient

$$M_{\mathrm{top}} = \rho^{(\mathrm{imp})}_{\mathrm{IC}} V_{\mathrm{imp}} f_{\varphi}(\Delta\varphi). \tag{11.50}$$

The localized defect topology, the reversible condensate participation that generates conservative added inertia, and the local defect–condensate boundary coupling constitute a single coupled mode. They are therefore represented within the same localized defect tensor rather than treated as independent additive mass-energy reservoirs.

The term $\delta T^{(\mathrm{IC})}_{\mu\nu}$ is reserved for the extended condensate response outside the localized defect domain. It excludes the local condensate participation already incorporated into the coupled defect state, preventing double counting of the same mechanical response.

The induced gravitational strain tensor is then

$$G^{(\tau)}_{\mu\nu} = \frac{\kappa G}{c_{\mathrm{E}}^4} \Delta T^{(\tau)}_{\mu\nu}. \tag{11.51}$$

Equivalently,

$$G^{(\tau)}_{\mu\nu} = \frac{\kappa G}{c_{\mathrm{E}}^4} \left[T^{(0)}_{\mu\nu} - T^{(\mathrm{rem})}_{\mu\nu} \right]. \tag{11.52}$$

The scalar remaining-capacity quantity and the tensor field equation therefore describe complementary aspects of the same State-I structural balance:

$$|G^{(\tau)}|_{\mathrm{cap}} \propto \tau_{\mathrm{rem}}, \tag{11.53}$$

whereas

$$G^{(\tau)}_{\mu\nu} \propto \Delta T^{(\tau)}_{\mu\nu}. \tag{11.54}$$

As loading increases, the remaining geometric-response capacity decreases while the converted-capacity tensor and induced gravitational strain increase.

The tensor $G^{(\tau)}_{\mu\nu}$ represents the induced State-I lattice strain and its associated effective measurement distortion. It is not interpreted as fundamental curvature of an empty spacetime manifold.

For an unperturbed State-I region,

$$T^{(\mathrm{rem})}_{\mu\nu} = T^{(0)}_{\mu\nu}, \tag{11.55}$$

so that

$$G^{(\tau)}_{\mu\nu} = 0. \tag{11.56}$$

A positive localized conversion produces

$$\Delta T^{(\tau)}_{\hat{0}\hat{0}} > 0. \tag{11.57}$$

Defining the converted-capacity density by

$$\Delta\rho_{\mathrm{G}} = \frac{\Delta T^{(\tau)}_{\hat{0}\hat{0}}}{c_{\mathrm{E}}^2}, \tag{11.58}$$

the weak-field temporal projection becomes

$$\nabla^2\Phi_\tau = 4\pi G\Delta\rho_{\mathrm{G}}, \tag{11.59}$$

using the tensor normalization $\kappa = 8\pi$ derived in Appendix P.

For a positive converted-capacity density, $\Phi_\tau < 0$, and the acceleration $\mathbf{g} = -\nabla\Phi_\tau$ is directed toward the source. Thus,

positive converted-capacity density $\longrightarrow$ negative tension potential $\longrightarrow$ inward restorative acceleration. (11.60)

The State-I material energy–momentum balance, phase-resolved tensor construction, and effective symmetric projection are developed in Appendix Q.

11.3.4 Cosmological Integration: The $\beta \to T_{\mu\nu}$ Mapping

The local convergence problem is governed by the scale-dependent capacity τ_{QG}. The unbroken cosmological State-I background is governed instead by the global structural scale

$$\tau_{\mathrm{G}} = \rho_{\mathrm{G}} c_{\mathrm{E}}^2. \tag{11.61}$$

These quantities have distinct mechanical roles:

$$\tau_{\mathrm{QG}} = \text{local convergence capacity}, \tag{11.62}$$

whereas

$$\tau_{\mathrm{G}} = \text{global State-I structural reference capacity.} \tag{11.63}$$

The structural density ρ_{G} is distinct from the operational nodal density ρ_{D} and the mode-resolved condensate impedance density $\rho_{\mathrm{IC}}^{(\mathrm{imp})}$. The operational quantities govern microscopic contact mechanics, coherent inertia, and defect response. They do not independently define the cosmological structural budget.

The exact FCC packing fractions satisfy

$$\beta_{\mathrm{geo}} + \beta_{\mathrm{IC}} = 1. \tag{11.64}$$

The phase-resolved reference tensor of the unperturbed State-I background is

$$\left\langle T_{\mu\nu}^{(0)} \right\rangle = \beta_{\mathrm{geo}} T_{\mu\nu}^{(\mathrm{D},0)} + \beta_{\mathrm{IC}} T_{\mu\nu}^{(\mathrm{IC},0)}. \tag{11.65}$$

The nodal and interstitial tensors represent mechanically distinct sectors:

$$T_{\mu\nu}^{(\mathrm{D},0)} \neq T_{\mu\nu}^{(\mathrm{IC},0)}. \tag{11.66}$$

The nodal tensor includes the homogenized FCC scaffold together with the contact-interface energy and stress assigned to the bonded network. The interstitial tensor contains the condensate energy, momentum transport, and stress not already incorporated into a localized coupled defect state.

TFT adopts the uniform structural-capacity closure for the reference energy component per occupied phase volume:

$$T_{\hat{0}\hat{0}}^{(\mathrm{D},0)} = T_{\hat{0}\hat{0}}^{(\mathrm{IC},0)} = \tau_{\mathrm{G}}. \tag{11.67}$$

This closure assigns a common structural-capacity scale to the two occupied phase volumes. It does not require equal operational densities or equal spatial stresses.

The total reference energy density is therefore

$$\begin{aligned} \left\langle T_{\hat{0}\hat{0}}^{(0)} \right\rangle &= \beta_{\mathrm{geo}} \tau_{\mathrm{G}} + \beta_{\mathrm{IC}} \tau_{\mathrm{G}} \\ &= \tau_{\mathrm{G}}. \end{aligned} \tag{11.68}$$

The normalized TFT structural fractions are

$$\Omega_{\mathrm{D}}^{(\mathrm{TFT},0)} = \beta_{\mathrm{geo}} = \frac{\pi}{3\sqrt{2}} \approx 0.74048, \tag{11.69}$$

and

$$\Omega_{\mathrm{IC}}^{(\mathrm{TFT},0)} = \beta_{\mathrm{IC}} = 1 - \frac{\pi}{3\sqrt{2}} \approx 0.25952. \tag{11.70}$$

The FCC fractions are exact geometric quantities. Their interpretation as normalized TFT structural-energy fractions follows from the uniform structural-capacity closure. Their comparison with conventional critical-density parameters additionally requires the cosmological normalization developed in Part III.

Baryonic matter is represented by localized topological defects of the State-I active vacuum. Its normalized structural fraction is

$$\beta_{\mathrm{b}} = \frac{\left\langle T_{\hat{0}\hat{0}}^{(\mathrm{b})} \right\rangle}{\tau_{\mathrm{G}}}. \tag{11.71}$$

Under the TFT defect-conversion closure, the structural energy required to form the baryonic sector is drawn from the nodal structural allocation. The remaining smooth nodal fraction is therefore

$$\beta_{\Lambda,\mathrm{eff}} = \beta_{\mathrm{geo}} - \beta_{\mathrm{b}}. \tag{11.72}$$

For

$$\beta_{\mathrm{b}} \approx 0.05, \tag{11.73}$$

this gives

$$\beta_{\Lambda,\mathrm{eff}} \approx 0.74048 - 0.05 \approx 0.69048. \tag{11.74}$$

The complete homogeneous structural-energy ledger is

$$(\beta_{\mathrm{geo}} - \beta_{\mathrm{b}}) + \beta_{\mathrm{IC}} + \beta_{\mathrm{b}} = 1. \tag{11.75}$$

Baryonic defect formation therefore redistributes the State-I structural energy rather than adding an independent fourth sector. The nodal contribution is reduced by the amount converted into localized coupled defect states, while the total reference energy remains conserved.

For a statistically homogeneous and isotropic background, the phase-resolved TFT tensor is

$$\begin{aligned}\left\langle T^{(\mathrm{TFT})}_{\hat{\mu}\hat{\nu}} \right\rangle = {} & (\beta_{\mathrm{geo}} - \beta_{\mathrm{b}})\, \tau_{\mathrm{G}}\, \mathrm{diag}\,(1, w_{\mathrm{D}}, w_{\mathrm{D}}, w_{\mathrm{D}}) \\ & + \beta_{\mathrm{IC}} \tau_{\mathrm{G}}\, \mathrm{diag}\,(1, w_{\mathrm{IC}}, w_{\mathrm{IC}}, w_{\mathrm{IC}}) \\ & + \beta_{\mathrm{b}} \tau_{\mathrm{G}}\, \mathrm{diag}\,(1, w_{\mathrm{b}}, w_{\mathrm{b}}, w_{\mathrm{b}})\,.\end{aligned} \tag{11.76}$$

The three sectors possess distinct constitutive responses.

The remaining nodal sector carries the smooth structural tension of the bonded FCC scaffold. Under the isotropic nodal structural-tension closure,

$$w_{\mathrm{D}} = -1. \tag{11.77}$$

The effective negative-pressure form represents positive isotropic tensile stress in the State-I solid. It does not require a fundamental thermodynamic negative-pressure fluid.

The interstitial sector carries the structural fraction

$$\beta_{\mathrm{IC}} \approx 0.25952. \tag{11.78}$$

Under the late-time cold interstitial reference-state closure,

$$w_{\mathrm{IC}} \simeq 0. \tag{11.79}$$

The geometric fraction specifies the homogeneous structural allocation. Dark-matter-like clustering and galactic loading arise from the perturbative condensate response $\delta T^{(\mathrm{IC})}_{\mu\nu}$, including coherent reactive loading and cosmic impedance, rather than from the volume fraction alone.

The baryonic tensor represents the complete localized coupled defect state normalized by M_{top}. For a nonrelativistic cosmological defect population,

$$w_{\mathrm{b}} \simeq 0. \tag{11.80}$$

The total effective equation-of-state diagnostic is

$$w_{\mathrm{tot}} = (\beta_{\mathrm{geo}} - \beta_{\mathrm{b}})\, w_{\mathrm{D}} + \beta_{\mathrm{IC}} w_{\mathrm{IC}} + \beta_{\mathrm{b}} w_{\mathrm{b}}. \tag{11.81}$$

Under the late-time closures

$$w_{\mathrm{D}} = -1, \qquad w_{\mathrm{IC}} \simeq 0, \qquad w_{\mathrm{b}} \simeq 0, \tag{11.82}$$

the effective total value becomes

$$w_{\mathrm{tot}} \simeq -\left(\beta_{\mathrm{geo}} - \beta_{\mathrm{b}}\right) \simeq -0.69048. \tag{11.83}$$

This quantity is the effective source-side stress diagnostic associated with the same mechanical background. It does not make FLRW expansion fundamental to TFT. The redshift, distance, and apparent-acceleration mechanisms remain governed by the visco-elastic and optical kinematics developed in Part III.

The resulting TFT correspondence is

$$\beta_{\mathrm{geo}} - \beta_{\mathrm{b}} \longrightarrow \Omega_{\Lambda,\mathrm{eff}}^{(\mathrm{TFT})}, \tag{11.84}$$

$$\beta_{\mathrm{IC}} \longrightarrow \Omega_{\mathrm{DM}}^{(\mathrm{TFT},0)}, \tag{11.85}$$

and

$$\beta_{\mathrm{b}} \longrightarrow \Omega_{\mathrm{b}}^{(\mathrm{TFT})}. \tag{11.86}$$

This mapping follows from phase-volume averaging of mechanically distinct nodal, interstitial, and defect tensors under the stated TFT structural closures. The complete continuum and phase-resolved tensor derivation is provided in Appendix Q, the 8π tensor normalization is developed in Appendix P, and the macroscopic transverse-shear, spin-2 strain, and stress-energy formulation are developed independently in Appendix N.

11.4 The Optical Analogy: Gravity as a Refractive Medium

In Part I (Postulate IV), we differentiated the invariant energy constant c_{E} from the dynamic propagation speed c_{P}, where c_{P} is a variable governed by the local effective inertia μ_{eff}. In this section, we demonstrate that the metric tensor of General Relativity is functionally identical to the variable refractive index n created by this inertial density.

Furthermore, to address the relationship between the mechanical vacuum and relativistic observations, we distinguish between two distinct regimes of measurement, both fundamentally modulated by the unitary lattice strain α_{G}:

- **Intrinsic physics:** The objective state of the source.
- **Observed physics:** The integration of the wave path.

11.4.1 The Vacuum as a Variable Dielectric

In previous sections, we established that gravity is not a geometric curvature of empty space, but a physical variation in the strain state of the active vacuum lattice. Light, in this framework, is a minimum transverse tension ripple propagating through that strained medium. We now show that the weak-field metric behavior normally attributed to spacetime curvature can be represented mechanically as the refractive index of the active vacuum.

We define the general strain-induced vacuum refractive index $n_\tau(\mathbf{x})$ as the ratio of the invariant lattice kinematic budget c_{E} to the local propagation speed c_{P} of a causal signal:

$$n_\tau(\mathbf{x}) = \frac{c_{\mathrm{E}}}{c_{\mathrm{P}}}. \tag{11.87}$$

Here the spatial argument $\mathbf{x}$ is attached to n_τ, because the refractive index is the field quantity that varies across the strained Soft Floor. The propagation speed c_{P} is understood as the corresponding local signal speed at the point being considered.

Using the effective optical inertia derived in Section 10.4, where

$$\mu_{\mathrm{eff}} \propto (1-\alpha_{\mathrm{G}})^{-4}, \tag{11.88}$$

the local propagation speed of a transverse signal through the strained Soft Floor is

$$c_{\mathrm{P}} = c_{\mathrm{E}}(1-\alpha_{\mathrm{G}})^2. \tag{11.89}$$

Therefore, the general strain-induced refractive index is

$$n_\tau(\mathbf{x}) = \frac{1}{(1-\alpha_{\mathrm{G}})^2}. \tag{11.90}$$

In this expression, α_{G} denotes the local value of the gravitational strain variable at the point $\mathbf{x}$. When no ambiguity arises, its spatial argument is suppressed for compactness.

For a static, spherically symmetric source of mass M, the local strain variable reduces to

$$\alpha_{\mathrm{G}} = \frac{GM}{rc_{\mathrm{E}}^2}. \tag{11.91}$$

In that special spherical case, the refractive index becomes

$$n_\tau(r) = \frac{c_{\mathrm{E}}}{c_{\mathrm{P}}} = \frac{1}{(1-\alpha_{\mathrm{G}})^2}. \tag{11.92}$$

In the weak-field limit, where

$$\alpha_{\mathrm{G}} \ll 1, \tag{11.93}$$

we apply the binomial approximation

$$(1-x)^{-2} \approx 1 + 2x. \tag{11.94}$$

Thus,

$$n_\tau(r) \approx 1 + 2\alpha_{\mathrm{G}} = 1 + \frac{2GM}{rc_{\mathrm{E}}^2}. \tag{11.95}$$

This result shows that the weak-field optical correction normally encoded by the spatial part of the General Relativistic metric can be reinterpreted mechanically as the refractive response of the active vacuum lattice. In TFT, the apparent curvature experienced by light is therefore not fundamental curvature of empty spacetime, but the optical consequence of strain-induced propagation through the Soft Floor.

The Mechanics of Time Dilation ($1\alpha_{\mathrm{G}}$)

We must distinguish between the intrinsic state of a system and the observed measurement of that system. This distinction resolves the confusion between local time dilation and remote signal delay.

The Intrinsic State:
In Postulate II, we established that for localized mass, Proper Time (t_{p}) is the emergent internal clock defined strictly by the accumulation of stationary, integer 360° volumetric phase cycles (n).

The duration of a single phase cycle (one fundamental "tick") is governed by the structural energy coupling: $t_{\text{tick}} = h/E$.

Phase Damping (The Strain Deficit):
In Tension Field Theory, an atomic clock functions as a harmonic oscillator coupled to the lattice. In a region of high macroscopic lattice strain (α_{G}), a fraction of the vacuum's baseline elastic capacity is pre-emptively consumed by the gravitational tension. Consequently, the local rest energy (E_α) available to drive the node's rotation is proportionally reduced relative to the unstrained vacuum baseline (E_0):

$$E_\alpha = E_0(1 - \alpha_{\text{G}}) \tag{11.96}$$

Because the physical energy driving the rotation is damped, the node struggles against the viscoelastic damping of the medium and physically takes longer to complete a single 2π phase cycle. The expanded duration of Proper Time on the strained surface ($t_{\text{p},\alpha}$) relative to the unstrained vacuum baseline ($t_{\text{p},0}$) becomes:

$$t_{\text{p},\alpha} = n\left(\frac{h}{E_0(1 - \alpha_{\text{G}})}\right) = \frac{t_{\text{p},0}}{1 - \alpha_{\text{G}}} \tag{11.97}$$

Conclusion:
The apparent slowing of time is not a geometric curvature of a background temporal dimension, but a strict mechanical consequence of Phase Damping. The (α_{G}) local energy deficit physically forces the fundamental structural clock to rotate more slowly. When this damped node emits a wave, the sequential phase transfer is inherited by the emission, matching gravitational redshift observations exactly without invoking geometric curvature.

Corollary: Gravitational Length Contraction (Structural Sag)
Just as Phase Damping slows the internal clock of a localized mass, it also physically deforms its spatial footprint. A macroscopic object is held together by internal structural bonds (transverse shear waves). Because the local elastic capacity is pre-emptively consumed by gravitational tension (α_{G}), the available energy to maintain these bonds drops to $E_\alpha = E_0(1 - \alpha_{\text{G}})$. Lacking the full baseline energy to hold the constituent atoms apart, the object's structural bonds physically compress to reach mechanical equilibrium with the surrounding vacuum. Therefore, while the underlying geometric lattice (r_{D}) remains invariant, the macroscopic object itself physically shrinks in the direction of the tension gradient by the exact ratio of the strain deficit: $L_\alpha = L_0(1 - \alpha_{\text{G}})$.

11.4.2 From Strain-Weighted Paths to the Effective Optical Metric

The strain-weighted path functional introduced in Part I defines the accumulated spatial penalty experienced by a propagating excitation moving through a nonuniform tension field. At the postulate level, this object is written compactly as

$$D_\tau = \int \left(1 + \frac{r_{\text{D}}}{\tau_{\text{S}}}|\nabla\tau(\mathbf{x})|\right) \mathrm{d}\ell. \tag{11.98}$$

This expression is not a spacetime metric tensor. It is a scalar path functional: it measures the accumulated spatial cost of propagation through the active vacuum. When the path dependence must be made explicit, we write

$$D_\tau[\mathcal{P}] = \int_{\mathcal{P}} n_\tau(\mathbf{x})\, \mathrm{d}\ell, \tag{11.99}$$

where $\mathcal{P}$ denotes the chosen propagation path and $n_\tau(\mathbf{x})$ is the local strain-induced optical index of the active vacuum.

In the gravitational optical limit developed above, this strain index is governed by the local gravitational coupling

$$\alpha_{\mathrm{G}} = \frac{GM}{rc_{\mathrm{E}}^2}. \tag{11.100}$$

Since the dynamic propagation speed of a transverse signal through the strained Soft Floor is

$$c_{\mathrm{P}} = c_{\mathrm{E}}(1-\alpha_{\mathrm{G}})^2, \tag{11.101}$$

the corresponding effective refractive index is

$$n_\tau(r) = \frac{c_{\mathrm{E}}}{c_{\mathrm{P}}(r)} = \frac{1}{(1-\alpha_{\mathrm{G}})^2}. \tag{11.102}$$

Thus, in the gravitational propagation regime, the path functional becomes

$$D_\tau[\mathcal{P}] = \int_{\mathcal{P}} \frac{1}{(1-\alpha_{\mathrm{G}})^2}\,\mathrm{d}\ell. \tag{11.103}$$

The corresponding optical travel time is

$$\Delta t = \frac{1}{c_{\mathrm{E}}}\int_{\mathcal{P}} n_\tau(\mathbf{x})\,\mathrm{d}\ell = \frac{1}{c_{\mathrm{E}}}\int_{\mathcal{P}} \frac{1}{(1-\alpha_{\mathrm{G}})^2}\,\mathrm{d}\ell. \tag{11.104}$$

The physical path followed by a freely propagating light signal is therefore obtained by the least-time condition

$$\delta\int_{\mathcal{P}} n_\tau(\mathbf{x})\,\mathrm{d}\ell = 0. \tag{11.105}$$

This is the TFT refractive form of the null-path condition. It does not require fundamental curvature of an empty manifold. Instead, the apparent bending of light arises because the wave follows the path of stationary optical time through the strain-index field of the active vacuum.

To compare this refractive mechanics with the standard language of General Relativity, we may package the same propagation law into an effective Soft Floor measurement tensor. For a static, isotropic gravitational strain field, the minimal operational line element is

$$\mathrm{d}s_\tau^2 = -(1-\alpha_{\mathrm{G}})^2 c_{\mathrm{E}}^2 \mathrm{d}t^2 + (1-\alpha_{\mathrm{G}})^{-2}\delta_{ij}\mathrm{d}x^i\mathrm{d}x^j. \tag{11.106}$$

This defines the effective metric tensor

$$g_{\mu\nu}^{(\tau)} = \mathrm{diag}\left[-(1-\alpha_{\mathrm{G}})^2 c_{\mathrm{E}}^2, (1-\alpha_{\mathrm{G}})^{-2}, (1-\alpha_{\mathrm{G}})^{-2}, (1-\alpha_{\mathrm{G}})^{-2}\right] \tag{11.107}$$

in locally isotropic spatial coordinates.

For a null path,

$$\mathrm{d}s_\tau^2 = 0. \tag{11.108}$$

Therefore,

$$(1-\alpha_{\mathrm{G}})^2 c_{\mathrm{E}}^2 \mathrm{d}t^2 = (1-\alpha_{\mathrm{G}})^{-2}\mathrm{d}\ell^2, \tag{11.109}$$

which gives

$$\frac{\mathrm{d}\ell}{\mathrm{d}t} = c_{\mathrm{E}}(1-\alpha_{\mathrm{G}})^2 = c_{\mathrm{P}}. \tag{11.110}$$

Thus the effective metric reproduces exactly the TFT propagation law for light through the strained Soft Floor.

In the weak-field limit, where

$$\alpha_{\mathrm{G}} \ll 1, \tag{11.111}$$

we have

$$(1-\alpha_{\mathrm{G}})^2 \approx 1 - 2\alpha_{\mathrm{G}}, \tag{11.112}$$

and

$$(1-\alpha_{\mathrm{G}})^{-2} \approx 1 + 2\alpha_{\mathrm{G}}. \tag{11.113}$$

The effective line element therefore becomes

$$\mathrm{d}s_\tau^2 \approx -(1-2\alpha_{\mathrm{G}})c_{\mathrm{E}}^2\mathrm{d}t^2 + (1+2\alpha_{\mathrm{G}})\mathrm{d}\ell^2. \tag{11.114}$$

Using the Newtonian strain potential

$$\Phi_\tau = -\frac{GM}{r}, \tag{11.115}$$

so that

$$\alpha_{\mathrm{G}} = -\frac{\Phi_\tau}{c_{\mathrm{E}}^2}, \tag{11.116}$$

the weak-field expression becomes

$$\mathrm{d}s_\tau^2 \approx -\left(1+\frac{2\Phi_\tau}{c_{\mathrm{E}}^2}\right)c_{\mathrm{E}}^2\mathrm{d}t^2 + \left(1-\frac{2\Phi_\tau}{c_{\mathrm{E}}^2}\right)\mathrm{d}\ell^2. \tag{11.117}$$

This is the standard weak-field relativistic form, recovered here as an effective optical geometry of the active vacuum. In this limit, TFT reproduces the operational metric behavior associated with gravitational redshift, Shapiro delay, and weak-field light deflection (Note: Massive bound orbits probe a different channel of the same strained Soft Floor: the conservative coupling between radial strain potential and tangential topological transport. The corresponding perihelion precession mechanism is introduced in Section 10.6 and derived fully in Appendix K).

The tensor $g_{\mu\nu}^{(\tau)}$ should therefore be read as an effective Soft Floor measurement tensor. Under coordinate relabeling, it transforms as a tensor,

$$g_{\alpha\beta}^{(\tau)\prime} = \frac{\partial x^\mu}{\partial x'^\alpha}\frac{\partial x^\nu}{\partial x'^\beta}g_{\mu\nu}^{(\tau)}. \tag{11.118}$$

If desired, one may construct the corresponding connection and curvature objects from $g_{\mu\nu}^{(\tau)}$ using the standard differential-geometric machinery. However, in TFT these objects are not fundamental causes of gravity. They are the observational bookkeeping of a deeper mechanical process: localized matter-energy changes the strain state of the active vacuum, the strain field changes the local refractive index, and the refractive index determines the effective paths of waves, rods, and clocks.

Therefore, TFT does not treat spacetime curvature as the fundamental origin of gravity. Rather, curvature appears as the effective geometric representation of strain-induced refractive propagation through the Soft Floor. The same strain variable α_{G} that generates the weak-field optical metric also defines the nonlinear failure boundary of the active vacuum. In the weak-field regime ($\alpha_{\mathrm{G}} \ll 1$), TFT reproduces the operational metric behavior of General Relativity. In the saturation regime ($\alpha_{\mathrm{G}} \to 1$), however, TFT does not extend the effective metric to a geometric singularity. Instead, the active FCC Soft Floor reaches its finite mechanical yield limit and undergoes a phase transition into the phase-locked SC Substrate. Thus, the GR singularity is replaced by a physical lattice-saturation boundary.

11.4.3 The Mechanics of Light Propagation ($2\alpha_{\mathrm{G}}$)

While a stationary clock only suffers from the localized energy deficit ($1\alpha_{\mathrm{G}}$), a propagating signal such as a radar ping interacts dynamically with the strained vacuum medium across space.

The Variable Speed of Light (c_{P}): Due to the transverse nature of electromagnetic waves, the optical inertia scales quadratically with the lattice strain, $\mu_{\mathrm{eff}} \propto (1-\alpha_{\mathrm{G}})^{-4}$. This imposes a double penalty on the traversing wave derived from the medium itself:

- **Temporal Impedance ($1\alpha_{\mathrm{G}}$):** Caused by the reduced vibrational rate of the local vacuum nodes. Because the strained medium oscillates more slowly under the local energy deficit, the sequential transmission of the wave is mechanically delayed.
- **Spatial Impedance ($1\alpha_{\mathrm{G}}$):** Caused by the physical deformation of the lattice, requiring the wave to traverse spatially stretched node geometries.

As derived earlier, the effective strain-induced refractive index is

$$n_\tau(r) \approx 1 + 2\alpha_{\mathrm{G}}. \tag{11.119}$$

Consequently, the local propagation speed of light is not a fixed coordinate speed, but a variable determined by the local strain state of the active vacuum:

$$c_{\mathrm{P}}(r) = \frac{c_{\mathrm{E}}}{n_\tau(r)} \approx c_{\mathrm{E}}(1 - 2\alpha_{\mathrm{G}}). \tag{11.120}$$

Because the signal travels more slowly than the unstrained vacuum baseline ($c_{\mathrm{P}} < c_{\mathrm{E}}$), it accumulates a time delay when traversing a gravitational potential. The total flight time Δt is obtained by integrating the inverse propagation speed along the geometric path:

$$\Delta t = \int \frac{1}{c_{\mathrm{P}}}\,\mathrm{d}\ell = \int \frac{n_\tau(r)}{c_{\mathrm{E}}}\,\mathrm{d}\ell \approx \frac{1}{c_{\mathrm{E}}}\int (1 + 2\alpha_{\mathrm{G}})\,\mathrm{d}\ell. \tag{11.121}$$

Conclusion: The factor of $2\alpha_{\mathrm{G}}$ accounts for the Shapiro delay [10]. *(The full step-by-step macroscopic integration recovering the logarithmic delay is provided in Appendix R).* This confirms that the mechanics of light propagation rely on a variable local propagation speed, and that the observed time delay is the integral of this reduced velocity through a strain-induced refractive medium.

The Artifact of Local Invariance: While c_{P} objectively decelerates relative to the absolute vacuum baseline (c_{E}) by a factor of $2\alpha_{\mathrm{G}}$, a local observer situated within the gravitational potential cannot detect this deceleration. This is governed by strict kinematic coupling:

- Both the propagating signal (light) and the physical tools measuring it (matter) are mechanical excitations of the exact same FCC lattice nodes.
- Consequently, the observer's measurement tools suffer the exact same refractive strain (α_{G}) as the light wave itself.
- **The Covariant Cancellation:** The local atomic clock is damped by the $1\alpha_{\mathrm{G}}$ energy deficit, causing it to tick slower (Time Dilation). Simultaneously, the structural bonds of the observer's ruler are weakened by the same $1\alpha_{\mathrm{G}}$ deficit, causing the physical object to compress (Length Contraction).

When an observer uses a proportionally shrunken ruler to measure distance ($D_{\text{obs}} = D_{\text{true}}/(1 - \alpha_{\text{G}})$) and a proportionally slowed clock to measure time ($T_{\text{obs}} = T_{\text{true}} \cdot (1 - \alpha_{\text{G}})$), dividing distance by time (D/T) yields a combined measurement handicap of

$$\frac{1}{(1 - \alpha_{\text{G}})^2} \approx 1 + 2\alpha_{\text{G}}. \tag{11.122}$$

This handicap mathematically cancels the signal's $2\alpha_{\text{G}}$ deceleration. Therefore, the locally measured invariance of c in General Relativity is reinterpreted in TFT as a localized measurement artifact—the inevitable mathematical consequence of conducting kinematics inside a covariant refractive medium using tools made of that same medium.

11.4.4 Gravitational Lensing ($4\alpha_{\text{G}}$)

The most famous prediction of relativity—the bending of starlight—is a direct consequence of the refractive gradient. Light follows the stationary optical-time path through a spherical strain-index field. The explicit evaluation of the transverse refractive gradient, yielding the total deflection angle of $4\alpha_{\text{G}}(b)$, is detailed in Appendix R.

Consider a wavefront passing a massive object at an impact parameter b. The inner part of the wavefront, closer to the mass, travels through a region of higher refractive index ($n_{\tau,\text{high}}$) and thus moves more slowly than the outer part ($n_{\tau,\text{low}}$). This velocity differential causes the wavefront to steer toward the mass.

The total deflection angle θ is the magnitude of the accumulated transverse refractive-gradient steering along the full line-of-sight path z. Let b be the impact parameter—the perpendicular distance from the center of mass to the unperturbed photon path—such that the radial distance is

$$r = \sqrt{b^2 + z^2}. \tag{11.123}$$

The deflection magnitude is therefore

$$\theta = \left| \int_{-\infty}^{+\infty} \nabla_{\perp} n_{\tau} \, \mathrm{d}z \right| = \left| \int_{-\infty}^{+\infty} \frac{\partial}{\partial b} \left(1 + \frac{2GM}{c_{\text{E}}^2 \sqrt{b^2 + z^2}} \right) \mathrm{d}z \right|. \tag{11.124}$$

The integration accumulates the transverse refractive steering along the geometric path, yielding

$$\theta_{\text{total}} = \frac{4GM}{bc_{\text{E}}^2} = 4\alpha_{\text{G}}(b). \tag{11.125}$$

Conclusion: Tension Field Theory recovers the precise Einstein deflection angle, approximately 1.75 arcseconds for the Sun, purely through wave optics.

The factor of 4 arises from integrating the transverse gradient of the weak-field refractive index

$$n_{\tau}(r) \approx 1 + 2\alpha_{\text{G}}(r) \tag{11.126}$$

along the full line-of-sight path. Furthermore, this macroscopic factor of 4 is interpreted in TFT as the geometric signature of the photon wave packet being compressed across the four degrees of freedom of the FCC lattice: longitudinal, temporal, and two transverse. As demonstrated in Part III (Section 23.4), this exact four-dimensional optical impedance acts as the mechanical mirror to the Tolman surface brightness drop [11], where the wave packet isotropically relaxes across those same four dimensions to yield a $(1 + z)^{-4}$ reduction in apparent optical power.

Table 11.1: **Summary of Relativistic Coefficients**

Phenomenon	**TFT Mechanism**	**Coefficient**
Gravitational redshift	Mechanical damping (source energy deficit)	$1\alpha_{\mathrm{G}}$
Shapiro delay	Optical refraction (path impedance)	$2\alpha_{\mathrm{G}}$
Light deflection	Gradient steering (integrated refraction)	$4\alpha_{\mathrm{G}}(b)$

Chapter 12

Microphysics of Black Holes: The Vacuum Phase Transition

Standard General Relativity predicts that unbounded gravitational contraction ends in a singularity—a mathematical point of infinite density. Tension Field Theory (TFT) resolves this mathematical divergence. Instead of yielding to empty geometry, we treat the vacuum as a physical mechanical medium with a finite structural yield limit and a discrete lattice architecture.

12.1 Postulate: The Substrate Core

We postulate that the core of a Black Hole is not a spatial singularity, but a macroscopic region of the fundamental Substrate (Hard Floor). It is a localized volume where the total gravitational potential (GM/r) has structurally saturated the active vacuum's energy budget (c_{E}^2).

12.2 Black Hole Formation

Specifically, Black Hole formation represents a crystallographic Phase Transition of the vacuum. The active spacetime medium—which we have defined as a Face–Centered Cubic (FCC) lattice allowing vibrational motion—structurally locks under extreme tension into a Simple Cubic (SC) configuration. This SC phase is the "Hard Floor" of the universe: an internally phase-locked, fully packed crystal with zero interstitial voids, which was explained in Part I.

In this model, the "Event Horizon" is not merely a light trap; it is the physical phase boundary between the Dynamic Vacuum (FCC / Time-Enabled) and the Phase-Locked Substrate (SC / Internally Time-Arrested).

(a) State I Active Vacuum (b) State II Saturated Core

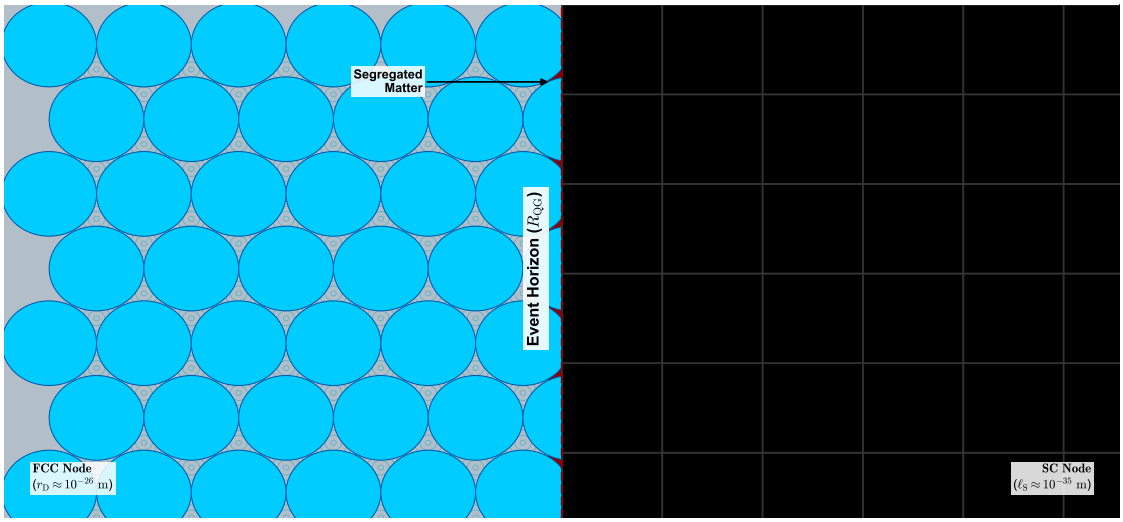

Figure 12.1: **The Vacuum Phase Transition (FCC → SC).** The Event Horizon (R_{QG}) is visualized not as a spatial hole, but as a macroscopic crystallization front driven by gravitational saturation ($\alpha_G = 1$). **(a) State I Active Vacuum:** The dynamic Face–Centered Cubic (FCC) lattice provides the geometric tolerance (interstitial voids) required for mass-energy. This structural flexibility permits ordered pilot-wave vibration (concentric ripples) and the active flow of time ($t > 0$). **(b) State II Saturated Core:** As the boundary advances, critical gravitational strain forces the nodes into a strict Simple Cubic (SC) lock. This structural phase transition back to the substrate floor completely eliminates the interstitial voids, mechanically arresting all field oscillation and locking the core into an internally phase-arrested, fully packed, zero-void substrate domain ($t = 0$). **Phase Segregation:** Because baryonic matter requires interstitial void space to exist, it cannot penetrate the SC core. As the crystallization front advances, topological mass defects are mechanically swept outward, accumulating at the boundary as a layer of segregated matter.

12.2.1 Phase-Locked Core and Live Boundary

The SC saturated domain should be understood as internally phase-locked, not as a globally inert object. Phase-locking means that the saturated interior no longer supports the active FCC degrees of freedom required for local vibration, interstitial transport, or ordinary material circulation. It does not imply that the black-hole system cannot translate, orbit, accrete, merge, or carry angular momentum through its boundary.

Thus, the TFT black hole has three mechanical layers:

$$\text{Black Hole} = \text{SC Saturated Domain} + \text{FCC/SC Phase Boundary} + \text{External Strained Soft Floor}. \tag{12.1}$$

The interior SC domain defines the saturated phase state. The FCC/SC boundary carries the phase-segregated inertial mass and mediates growth, spin, merger, and relaxation. The external Soft Floor carries the surrounding strain field. Detailed boundary dynamics are developed in Appendix U.

12.3 The Microphysics of Convergence: Vacuum Crystallization and Topological Phase Segregation

The formation of this Substrate Core follows a precise mechanical sequence, governed by the density hierarchy derived in Appendix S. It is a process of stripping away the geometric conditions required for vibration.

- **Deconfinement (The Neutron Breakdown):** As gravitational pressure exceeds Strong Force tension, neutrons are mechanically crushed. They dissolve into a quark-gluon plasma of fundamental knots (r_{D}).
- **Vibrational Saturation (ρ_{Q}):** As the plasma densifies, the vibrational velocity of these fundamental knots approaches the speed of light. The system reaches the Quantum Saturation Density ($\rho_{\mathrm{Q}} \approx 1.1416 \times 10^{62}$ kg/m^3). The lattice voids are energetically saturated, but the FCC geometry remains intact.
- **Geometric Locking (ρ_{QG}):** Gravity forces the topological knots to pack 'shoulder-to-shoulder,' acting as the localized pressure catalyst. When the density reaches the Convergence Density ($\rho_{\mathrm{QG}} \approx 5.2625 \times 10^{70}$ kg/m^3), the Interstitial Voids (the empty space in the FCC lattice required for oscillation) are exhausted.
- **The Phase Transition (FCC $\rightarrow$ SC):** To resolve the topological stress of "zero void" packing, the lattice undergoes a martensitic transformation. The FCC geometry snaps into the Simple Cubic (SC) configuration.
  - *Mechanism:* The packing factor (β_{geo}) jumps discontinuously from 0.74 to 1.0.
  - *Result:* The voids vanish. Without voids, vibration is mechanically impossible. The active vacuum nodes snap into substrate-locked structural stress, while the trapped 'Matter' (topological defects) is mechanically segregated outward to the phase boundary.

12.4 The Micro-Black Hole Limit and the Vacuum Safety Margin

While the convergence density (ρ_{QG}) defines the volumetric threshold for a localized phase transition, Tension Field Theory dictates that the formation of a micro-black hole is governed by two distinct mechanical mass limits: the phase transition trigger and the permanent stability threshold.

12.4.1 The Phase Transition Trigger (m_{sat})

To initiate a geometric collapse, localized mass must exhaust the structural voids of a fundamental cell. Multiplying the convergence density (ρ_{QG}) by the uncompressed volume of a Soft Floor node (r_{D}^3) yields the absolute maximum mass a resting node can contain:

$$m_{\mathrm{sat}} = \rho_{\mathrm{QG}} \cdot r_{\mathrm{D}}^3 = \left(\sqrt{\frac{\hbar c_{\mathrm{E}}}{G r_{\mathrm{D}}^6}} \right) r_{\mathrm{D}}^3 = \sqrt{\frac{\hbar c_{\mathrm{E}}}{G}} = m_{\mathrm{S}} \approx 2.1764 \times 10^{-8} \text{ kg} \tag{12.2}$$

This derivation perfectly recovers the Substrate Mass (m_{S}), mathematically proving that injecting one unit of m_{S} into a fundamental cell (r_{D}) is sufficient to mechanically fracture that specific node via volumetric void exhaustion. However, this microscopic rupture cannot survive the immense restorative tension of the surrounding active vacuum. Because the localized gravitational strain at this threshold is near zero ($\alpha_{\mathrm{G}} \approx 10^{-7}$), the lattice instantly decompresses the collapsed node. The phase transition fires, but it cannot structurally hold.

12.4.2 The Stable Micro-Black Hole ($M_{\mathrm{D,G}}$)

To permanently lock open a physical phase boundary (an Event Horizon) at the fundamental scale of the vacuum lattice ($R_{\mathrm{QG}} \geq r_{\mathrm{D}}$), the nucleated core must possess an absolute minimum localized inertial mass. We define this permanent stability threshold as the Micro Black Hole Mass ($M_{\mathrm{D,G}}$).

As rigorously derived in Appendix S, projecting the 2D surface load capacity of the active vacuum ($\mu_{\mathrm{D}} = c_{\mathrm{E}}^2/Gr_{\mathrm{D}}$) onto the geometric cross-section of a single fundamental node (r_{D}^2) yields:

$$M_{\mathrm{D,G}} = \frac{c_{\mathrm{E}}^2 r_{\mathrm{D}}}{G} \approx 10.033 \text{ kg} \tag{12.3}$$

This value represents the exact localized mass required to push the vacuum structure boundary to 100% mechanical strain ($\alpha_{\mathrm{G}} = 1$). In physical terms, it requires an extreme mass (roughly 10.0 kg) localized strictly within the fundamental radial boundary ($r_{\mathrm{D}} \approx 10^{-27}$ m) to structurally balance the restorative pressure and hold the vacuum bonds permanently open. Crucially, this defines the absolute minimum limit for the existence of a stable black hole. Any mass lower than $M_{\mathrm{D,G}}$ lacks the gravitational tension necessary to sustain a permanent phase boundary.

12.4.3 The 10^{17} Safety Margin of the Vacuum

This absolute structural limit reveals a profound dimensional symmetry regarding the stability of the active spacetime lattice. By comparing the maximum structural holding capacity of a single node boundary to its maximum quantum vibrational capacity, we uncover the exact mechanical tolerance of the universe.

The Energetic Ratio: The structural kinetic energy required to hold a Soft Floor boundary open and stabilize a micro-black hole is $E_{\mathrm{struc}} = M_{\mathrm{D,G}} c_{\mathrm{E}}^2 \approx 9.017 \times 10^{17}$ J. Conversely, the maximum kinematic vibrational energy a node can carry before reaching light-speed saturation (the standard quantum boundary) is $E_{\mathrm{vib}} = \frac{hc_{\mathrm{E}}}{r_{\mathrm{D}}} \approx 2.666 \times 10^{1}$ J.

The Density Ratio: As derived in Appendix S, the ultimate gravitational yield density (ρ_{G}) required to physically fracture the lattice bonds across the fundamental volume is $\approx 2.4259 \times 10^{79}$ kg/m^3. The standard operational saturation limit of the active node (ρ_{D}) is $\approx 1.7124 \times 10^{62}$ kg/m^3.

Both parameters yield an identical, scale-invariant stability ratio:

$$\frac{E_{\mathrm{struc}}}{E_{\mathrm{vib}}} \approx \frac{\rho_{\mathrm{G}}}{\rho_{\mathrm{D}}} \approx 1.4166 \times 10^{17} \tag{12.4}$$

Physical Implication: The Face-Centered Cubic (FCC) vacuum is a hyper-rigid medium. During standard quantum mechanical operations, a fundamental node is loaded to only $\sim 10^{-17}$ of its breaking pressure. This immense geometric safety margin is precisely what permits stable, continuous harmonic oscillation (the foundation of quantum mechanics) without the vacuum structurally failing and triggering microscopic phase transitions.

12.5 Merging with the Substrate: The Scale Transition

Once the geometric voids are saturated at ρ_{QG}, the lattice loses the vibrational pressure that maintains the FCC Node Radius (r_{D}). The "Inactive Soft Floor" is unstable. The system undergoes a structural Scale Transition, causing the macroscopic r_{D} scaffolding ($\sim 10^{-26}$ m) to dissolve directly into the underlying Substrate ($\ell_{\mathrm{S}} \sim 10^{-35}$ m).

Consequently, the core density does not stop at the trigger point ($\rho_{\mathrm{QG}} \approx 5.2625 \times 10^{70}$ kg/m^3). Instead, it undergoes a discontinuous Density Jump to the Substrate Limit ($\rho_{\mathrm{S}} \approx 5.1550 \times 10^{96}$ kg/m^3), as detailed in Appendix S.

The Isoenergetic Continuity: Despite this catastrophic discontinuity in physical density (a jump of 26 orders of magnitude), this structural scale transition is perfectly conservative. As proven in Appendix S (Section L.8), the total energy of the system at the Convergence Trigger (E_{QG}) and the final Substrate State (E_{S}) are mathematically identical, both yielding exactly the Planck Energy:

$$E_{\mathrm{QG}} = E_{\mathrm{S}} = E_{\mathrm{P}} = \sqrt{\frac{\hbar c_{\mathrm{E}}^5}{G}} \tag{12.5}$$

Because the total energy is strictly conserved across the structural phase transition, the event is dictated entirely by spatial failure (the absolute geometric contraction of volume) rather than thermodynamic energy dissipation.

The Black Hole core is therefore the end of gravity. Because the core is a 100% packed solid, it is strictly incompressible. An incompressible medium cannot support a density gradient ($\nabla\tau = 0$), so gravity ceases to exist within the interior. Crucially, because the SC Substrate possesses zero interstitial voids, it cannot sustain topological defects. Therefore, the baryonic matter that fell in does not merge into the core; the advancing crystallization front acts as a geometric sieve. It purifies the vacuum into the SC lattice and physically extrudes all topological knots, twists, and energetic debris onto the 2D Event Horizon.

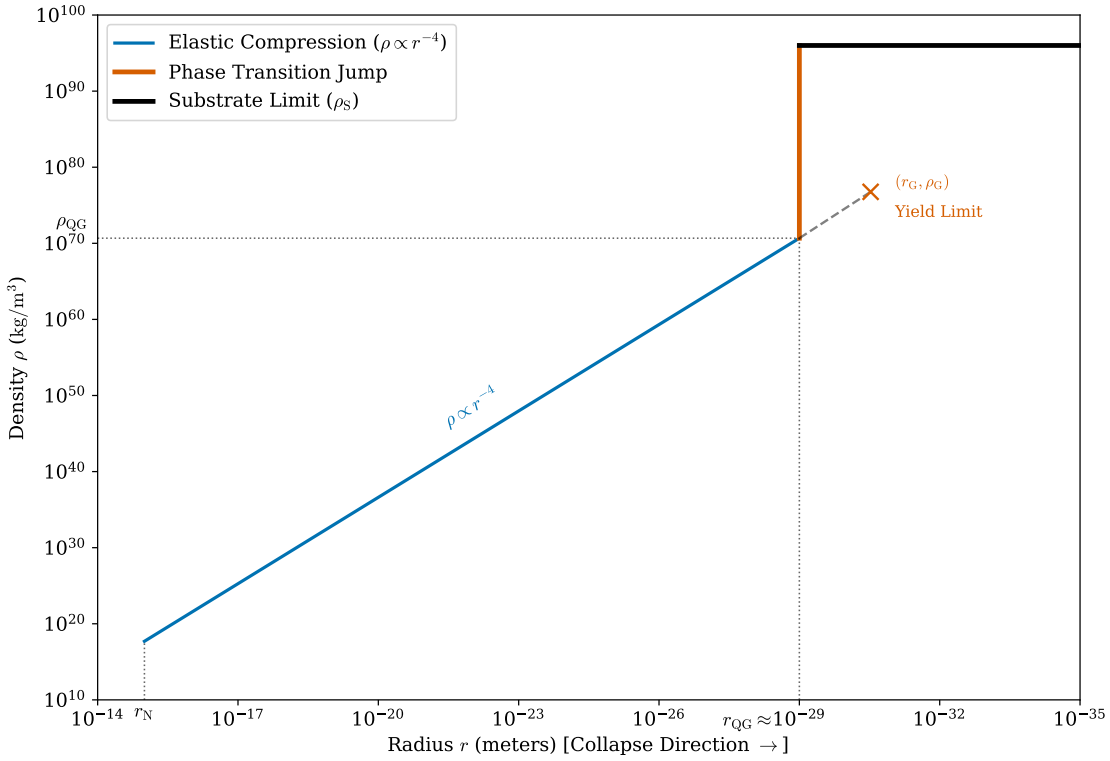

Figure 12.2: **Gravitational Saturation and the Vacuum Phase Transition.** This log–log plot illustrates the mechanical response of the vacuum lattice during continuous gravitational contraction. **Elastic Compression (Blue Line):** Starting from the nucleon scale (r_N), as the local radius decreases, the field density rises according to the vacuum geometric scaling law ($\rho \propto r^{-4}$). **Void Exhaustion ($r_{QG} \approx 5.6248 \times 10^{-29}$ m):** At the convergence density ($\rho_{QG} \approx 5.2625 \times 10^{70}$ kg/m^3), the active interstitial voids are mechanically exhausted. The lattice reaches absolute gravitational saturation ($\alpha_G = 1$). **Phase Transition Jump (Red Line):** Instead of compressing further toward the structural yield limit where the space manifold would physically fracture (red "×" at ρ_G), the system undergoes a discontinuous scale transition. The core phase-shifts directly to the fundamental substrate density ($\rho_S \approx 5.1550 \times 10^{96}$ kg/m^3), effectively resetting the localized volume to the phase-locked stability limit of the Hard Floor.

Mechanical Resolution of the Singularity Theorems

Standard General Relativity relies on the Raychaudhuri equation [12] and the Penrose singularity theorems [13] to demonstrate that unbounded gravitational collapse inevitably terminates at a geometric singularity ($r = 0$). However, these mathematical proofs implicitly presuppose a continuous spacetime manifold capable of infinite geometric compressibility. Tension Field Theory strictly precludes these terminal boundary conditions by introducing a mechanical yield limit to the vacuum medium.

When the localized mass-energy density reaches the convergence threshold (ρ_{QG}), the vacuum undergoes a structural phase transition into the Simple Cubic (SC) Substrate, which possesses a strict crystallographic packing factor of $\beta_{geo} = 1.0$. Because all interstitial voids are mechanically exhausted within this state, the volumetric contraction of the lattice physically terminates ($dV/d\tau =$

0). Consequently, the Raychaudhuri expansion scalar ($\theta = \frac{1}{V}\frac{dV}{d\tau}$) is structurally forced to halt at zero, mathematically arresting the geometric collapse.

Furthermore, because baryonic matter (topological defects) requires interstitial void space to propagate, it is mechanically segregated to the macroscopic phase boundary during this transition. As a result, no massive geodesics can penetrate or exist within the SC core. By substituting an infinitely compressible geometric manifold with a rigid, zero-void crystallographic continuum, TFT mechanically aborts the Raychaudhuri collapse and physically invalidates the geometric prerequisites for a Penrose singularity.

12.6 The Resolution of the Information Paradox (Phase Segregation)

The Phase Transition model provides a direct, mechanical resolution to the Information Paradox (the conflict between quantum Unitarity and Hawking Radiation) and gives a strict physical cause for the Holographic Principle [14].

Standard physics struggles to explain why the entropy of a Black Hole scales with its 2D surface area (A) rather than its 3D volume (V), leading to the assumption that the 3D interior is somehow "projected" holographically onto the boundary. Tension Field Theory (TFT) proves that this is not a mathematical projection; it is a strict crystallographic reality governed by the mechanical decoupling of physical capacity, actual occupancy, and topological information.

- **The Zero-Entropy Core:** As established in Section 2.3, Definition V and Appendix AB, information is the discrete longitudinal strain footprint cast by dynamic Soft Floor carriers onto the phase-locked Simple Cubic (SC) Substrate. Because the interior of the Black Hole has phase-converted entirely into a fully packed SC Substrate ($\beta_{\text{geo}} = 1.0$), it contains no interstitial voids. Without voids, kinematic circulation is forbidden. As formally defined in Appendix X, this forces the core into the absolute ground state of the universal order parameter ($\Psi_{\text{S}} = \sqrt{\rho_{\text{S}}} \cdot e^{i0}$), where the global phase gradient is absolutely locked ($\nabla\varphi = 0$). Without localized phase-twists to act as physical defects, no strain shadows can be cast. Because thermodynamic entropy (S) is the physical measure of possible internal geometric arrangements (W) of these defects, this void-less, phase-locked core ($\Delta\varphi = 0$) constitutes a single, monolithic structural state ($W = 1$). Following Boltzmann's entropy relation ($S = k_{\text{B}} \ln W$), this absolute kinematic lock mathematically and physically dictates that the volumetric entropy of the core is exactly zero ($S_{\text{core}} = 0$).
- **Phase Segregation (The Boundary Layer):** As the Black Hole grows, the crystallization front phase-converts the surrounding vacuum. The dynamic carriers (baryonic matter and energetic waves) cannot fit into the void-less SC geometry. They are mechanically displaced and phase-segregated strictly into a 2D physical boundary shell residing within the adjacent Face–Centered Cubic (FCC) active vacuum.

12.6.1 The Decoupling of Capacity and Occupancy

Standard black hole thermodynamics historically conflated physical capacity (Entropy) with the actual localized mass footprint (Occupancy), and further conflated both with the underlying topological record (Information). TFT structurally separates them based on the scale of the lattice:

- **Geometric Capacity ($S_{\text{geo}}/k_{\text{B}}$):** This measures the maximum physical capacity of the boundary layer to hold segregated baryonic defects. Because these defects require the interstitial voids of the active vacuum, the physical shell has an absolute minimum thickness of one FCC node (r_{D}). Dividing the macroscopic boundary volume by the volume of a single FCC node yields the absolute dimensionless geometric capacity limit:

$$\frac{S_{\text{geo}}}{k_{\text{B}}} = \frac{4\pi R_{\text{QG}}^2}{r_{\text{D}}^2} \tag{12.6}$$

  For comparison with entropy-valued quantities, TFT denotes the corresponding Boltzmann-scaled capacity by $S_{\text{geo}} \equiv k_{\text{B}}(4\pi R_{\text{QG}}^2/r_{\text{D}}^2)$. This is a geometric slot-capacity measure, not by itself a thermodynamic entropy.

- **Information Capacity Limit (N_{QG}):** Information is the dimensionless topological strain footprint that the segregated mass imposes upon the underlying phase-locked SC core. Because every fundamental SC tile on the saturated boundary can sustain a maximum of 2π radians of longitudinal strain, the absolute informational capacity of the core scales strictly with the SC substrate length (ℓ_{S}):

$$N_{\text{QG}} = \frac{8\pi^2 R_{\text{QG}}^2}{\ell_{\text{S}}^2} \tag{12.7}$$

12.6.2 The Solution: The Blank Ledger Reality

Information is never destroyed, nor is it swallowed into an inaccessible singular volume. 100% of the mass, energy, and structural debris of everything that has ever fallen into the Black Hole is mechanically trapped on the phase boundary as a topological condensate.

However, by rigorously deriving these limits in Appendix T, TFT interprets the R^2 area scaling as a boundary-capacity scale rather than the actual occupancy of the structural information ledger (R^1). As a Black Hole expands, it generates structural capacity (R^2) exponentially faster than it accumulates inertial mass (R^1).

Consequently, the physical matter dilutes across the Event Horizon ($\Phi_{\text{kin}} \propto R^{-1}$), while its true coherent information footprint condenses to a singularity of phase ($\Phi_{\text{info}} \propto R^{-4}$). TFT interprets the standard Bekenstein–Hawking area law (S_{holo}) [15, 16] as a maximal boundary-state measure rather than as the actual occupancy of the TFT strain ledger.

12.6.3 Numerical Proof and the Vacuum Safety Margin

We can quantify the magnitude of this dimensional distinction by comparing the absolute Geometric Capacity of the FCC Soft Floor against the maximum Information Capacity on the SC Hard Floor for a standard stellar-mass Black Hole ($R_{\text{QG}} \approx 10^4$ m):

- **The Information Capacity ($S_{\text{holo}}/k_{\text{B}}$):** Utilizing the SC substrate scale ($\ell_{\text{S}} \approx 1.6163 \times 10^{-35}$ m), the standard equation yields $\approx 1.20 \times 10^{78}$ nodes of topological strain capacity.
- **The Geometric Capacity ($S_{\text{geo}}/k_{\text{B}}$):** Utilizing the active FCC node scale ($r_{\text{D}} \approx 7.4504 \times 10^{-27}$ m), the physical boundary shell possesses a maximum capacity of $\approx 2.26 \times 10^{61}$ nodes.

The ratio between the maximal Information Capacity and the maximal Geometric Capacity is perfectly geometric:

$$\text{Ratio} = \frac{1}{4}\left(\frac{r_{\text{D}}}{\ell_{\text{S}}}\right)^2 \approx 10^{17} \tag{12.8}$$

Therefore, standard models isolate the correct topological ledger metric, but attribute the 10^{78} node capacity of the SC underlying continuum to the physical FCC boundary shell, which is fundamentally limited to 10^{61} physical capacity states. This 17-order-of-magnitude distinction precisely matches the Vacuum Safety Margin ($\rho_{\mathrm{G}}/\rho_{\mathrm{D}}$) required for lattice stability. A singular physical defect state on the active Soft Floor necessitates a highly stable structural strain capacity footprint spanning $\approx 10^{17}$ fundamental tiles on the phase-locked SC Substrate.

12.6.4 The Topological Invariant and Absolute Unitarity

The explicit decoupling of these scales reveals an absolute geometric conservation law governing mass (M). As formally derived in Appendix T, evaluating the true coherent information footprint of mass as an active, localized state (N_{M}) against the maximal informational capacity of that same mass dispersed as a phase boundary (N_{QG}) yields a strictly conserved topological invariant:

$$N_{\mathrm{QG}} \cdot N_{\mathrm{M}} = 16\pi^3 \quad (\approx 496.06) \tag{12.9}$$

This dimensionless invariant proves mathematically that Information is indestructible. The product of a system's true coherent information (N_{M}) and its maximal geometric capacity (N_{QG}) is structurally locked by the lattice geometry. Quantum Unitarity is thereby definitively preserved; whether mass exists as a dynamic standing wave or is completely crushed into a frozen phase boundary, its total topological ledger remains an invariant geometric property of the underlying continuum, permanently isolated from the thermal dynamics of the active vacuum.

12.7 The Absolute Ground State and the Impossibility of Evaporation

Standard quantum field theory in curved spacetime posits that a Black Hole possesses a non-zero thermodynamic temperature and will consequently evaporate over time via the emission of Hawking radiation [16]. The crystallographic framework of Tension Field Theory renders this thermodynamic process physically impossible. Under the mechanical framework of the Spacetime Gravitational Floor, evaporation is structurally precluded at both the core and the boundary.

- **The Thermodynamic Definition:** In TFT, thermodynamic temperature ($T > 0$) is defined strictly as the kinematic vibration of nodes within the dynamic Face–Centered Cubic (FCC) lattice. This vibration requires both the geometric tolerance of interstitial voids and the kinematic freedom to physically displace.
- **The Internally Time-Arrested Core:** As established in Section 12.3, the interior of the Event Horizon represents a strict phase transition into the Simple Cubic (SC) configuration. Because the SC core has a geometric packing factor of 1.0, it possesses zero voids. Mechanical vibration is completely arrested. The interior exists in an absolute configurational ground state ($T = 0$).
- **The Pinned Boundary Shell:** While the phase-segregated topological mass resides in the singular FCC boundary layer (r_{D}), it cannot thermally radiate. At the convergence limit, the immense inward Boundary Tension (τ_{QG}) of the surrounding vacuum forces the localized nodes to convert 100% of their dynamic kinetic energy into phase-boundary holding tension to maintain the phase boundary. The topological condensate is mechanically pinned against the $T = 0$ core, structurally arresting its kinematic vibration.

Because the interior is an internally phase-locked crystal ground state and the mass on the boundary layer is locked in maximum structural tension, the system cannot harbor or emit thermal energy. Furthermore, the Event Horizon operates strictly as a one-way crystallization front, actively converting the dynamic kinetic energy of the surrounding vacuum into the phase-locked structural state of the expanding core.

Therefore, a Black Hole does not thermally evaporate; it can only mechanically grow until it reaches the local causal saturation limit (M_{Sat}), where the pressure gradient vanishes and the boundary dissolves into the global continuum.

12.8 Conclusion: The Black Hole Horizon and the Failure of Causality

In Part I, we established that inertial mass arises from the hydrodynamic impedance of the lattice condensate. We further defined the lattice kinematic budget as c_{E}^2, representing the invariant energy cost of the vacuum structure. Therefore, the propagation speed of any causal signal (c_{P}) is governed by the ratio of this invariant potential to the effective inertia (μ_{eff}) of the local medium:

$$c_{\text{P}} = c_{\text{E}}\sqrt{\frac{\mu_{\text{D}}}{\mu_{\text{eff}}}} \tag{12.10}$$

We define the effective inertia as a function of the dimensionless gravitational coupling ($\alpha_{\text{G}} = \frac{GM}{rc_{\text{E}}^2}$). As derived in Section 11.4.3, a transverse wave suffers a kinematic double-penalty from the strained lattice (temporal and spatial impedance), reducing its local speed to $c_{\text{P}} = c_{\text{E}}(1-\alpha_{\text{G}})^2$. By equating these kinematic boundaries and squaring both sides, the effective inertia of the strained vacuum mechanically resolves to:

$$\mu_{\text{eff}} = \frac{\mu_{\text{D}}}{(1-\alpha_{\text{G}})^4} \tag{12.11}$$

This strict fourth-power scaling law is not an arbitrary parameter - it is derived in Section 10.4. As established in Appendix B (Conservation of Action and the Master Geometric Law), the effective density of the vacuum must scale by the inverse-fourth power (r^{-4}) to strictly conserve the universal quantum of action ($\hbar$) across geometric phase states. The optical double-penalty is simply the macroscopic manifestation of this fundamental geometric invariant.

As the gravitational potential approaches the vacuum budget ($\alpha_{\text{G}} \to 1$), the effective inertia diverges ($\mu_{\text{eff}} \to \infty$), and causal speed halts ($c_{\text{P}} \to 0$). Therefore, we define the Black Hole Horizon radius as $R_{\text{QG}} = \frac{GM}{c_{\text{E}}^2}$. This radius marks the exact geometric threshold of the FCC $\to$ SC phase transition, where the local density reaches the convergence limit (ρ_{QG}), as derived in Appendix S.

> *(Note: TFT predicts that at the standard Schwarzschild radius R_{s}, where $\alpha_{\text{G}} = 0.5$, the causal speed slows to $c_{\text{P}} \approx 0.25c_{\text{E}}$, meaning propagation remains physically possible).*

The Failure of Causality: The Black Hole is not a mathematical singularity tearing the fabric of spacetime. It is a strict mechanical boundary representing localized gravitational causal failure. As the local inertial density reaches the absolute convergence limit ($\alpha_{\text{G}} = 1$), the active FCC lattice undergoes a phase transition to the fully packed SC Substrate. This eliminates the interstitial voids necessary for vibration. Without the transverse shear capacity of the FCC nodes, wave propagation is mechanically impossible ($c_{\text{P}} = 0$). The light cones squeeze completely shut, irrevocably halting all causal trajectories against the internally time-arrested, phase-locked core.

Chapter 13

Black Hole Mass and Growth Saturation

This chapter establishes the complete mechanical lifecycle of the macroscopic black hole within Tension Field Theory. It details how mass is strictly confined to the FCC/SC phase boundary, how this boundary dynamically grows through vacuum crystallization, and how it manages spin and binary mergers without relying on spacetime curvature. Finally, it derives the absolute macroscopic limits of this growth, demonstrating that as a black hole expands, its surface gravity inevitably decays, ultimately setting the mechanical stage for universal catastrophic decompression.

13.1 Phase Segregation and the Holographic Mass Location

Since the interior core of a Black Hole exists in the Simple Cubic (SC) phase, it possesses maximum structural stiffness but zero intrinsic inertia ($\mu_S \to 0$) because it lacks the interstitial voids required for kinematic vibration. Therefore, the inertial mass (M) of the Black Hole is not distributed throughout its internal volume. Instead, 100% of the effective mass is located strictly at the Phase Boundary (R_{QG}).

Mechanically, the mass is the physical aggregate of phase-segregated topological defects. Because these defects cannot penetrate the void-less core, they are mechanically displaced by the advancing crystallization front and pinned against the boundary. Thus, a Black Hole is mechanically a solid, inertially passive, phase-locked crystal of maximum tension, enveloped by a hyper-compressed Face–Centered Cubic (FCC) boundary shell containing the entire dynamic mass of the system. *(Note: This aligns exactly with Part I, where mass was established as a topological defect strictly on the boundary layer).*

The Singular Boundary Layer (r_D) The topological mass does not stack into multiple volumetric layers under pressure; it is mathematically confined to the absolute first layer of active FCC nodes (r_D) touching the core. This is guaranteed by the linear scaling law of the Event Horizon.

At the fundamental limit to form a micro black hole, the system consists of a single saturated cell with radius $R_{QG} = r_D$. Its volumetric density is the convergence limit (ρ_{QG}):

$$M \approx \rho_{QG} \cdot r_D^3 \tag{13.1}$$

Because the macroscopic Event Horizon radius scales strictly linearly with mass ($M \propto R_{QG}$), the macroscopic mass is the fundamental seed mass multiplied by the radial scaling factor (R_{QG}/r_D):

$$M \approx (\rho_{QG} \cdot r_D^3) \left(\frac{R_{QG}}{r_D} \right) \tag{13.2}$$

$$M \approx \rho_{\mathrm{QG}} \cdot r_{\mathrm{D}}^2 \cdot R_{\mathrm{QG}} \tag{13.3}$$

This exact geometric formula dictates that as the Black Hole grows, its surface area ($A \propto R_{\mathrm{QG}}^2$) expands exponentially faster than its mass accumulation ($M \propto R_{\mathrm{QG}}^1$). Consequently, the boundary layer actually becomes less crowded as the core expands, permanently eliminating the mechanical necessity for mass to compress into multiple radial layers. The inertia of the system remains a strictly two-dimensional topological boundary phenomenon.

13.2 Black Hole Growth Mechanism (Vacuum Phase Conversion)

The Density Gap Problem: In Section 12.5, we established that the core density must be the Substrate Density ($\rho_{\mathrm{S}} \approx 10^{96}$ kg/m^3). Standard accretion of inertial matter is insufficient to generate this hyper-density at cosmic scales. Therefore, a Black Hole cannot expand solely through the accretion of localized matter; it must structurally phase-convert the surrounding Active Vacuum.

The Solution: The Crystallization Front

The Black Hole grows by propagating a phase transition into the surrounding medium. It converts the voluminous FCC Lattice into the hyper-dense SC Substrate, effectively "mining" the vacuum for structural density.

1. **Nucleation (The Ignition):** The initial gravitational contraction of baryonic matter (a star) acts strictly as a Catalytic Event. It provides the localized pressure required to bridge the gap from atomic density to the Convergence Density (ρ_{QG}). Once crossed, the vacuum phase transition becomes self-sustaining. The star does not create the black hole; the star breaks the vacuum, allowing the black hole to form.

2. **Geometric Locking:** As active vacuum nodes contact the phase-locked SC core, they are destabilized by geometric proximity. The immense tension of the core overrides the vibrational freedom of the adjacent nodes, forcing them to snap into the Latent SC configuration.

3. **Topological Percolation (The Extrusion):** Because the newly forged SC nodes possess a geometric packing factor of 1.0, they contain zero interstitial voids. Consequently, any pre-existing physical defects (baryonic matter or energetic waves) residing within the consumed FCC vacuum cannot be absorbed into the core. These topological defects are mechanically rejected, forcing them to percolate outward. They continuously ride the advancing crystallization front, accumulating directly on the Event Horizon to maintain the hyper-compressed boundary shell.

4. **The Chain Reaction:** Each captured node becomes part of the phase-locked wall, extending the boundary of the core and contacting new active nodes. The crystal grows outward, continuously sweeping and percolating all active mass-energy to its surface.

5. **Energy Conservation:**

   - *Input:* The Kinetic Energy of the active vacuum node (Time/Vibration).
   - *Output:* The phase-locked structural potential energy of the substrate (Compression/Tension).
   - *Result:* The node ceases to tick ($t \to 0$) and becomes a unit of stored stress. The Black Hole is a Cosmic Battery, storing the kinetic energy of the universe as phase-locked lattice tension.

13.3 The Kinematics of Vacuum Consumption

To formalize this phase conversion, we define the growth of the Black Hole not as standard mass-accretion, but as the strict rate of topological node creation (N) and mechanical horizon displacement (R_{QG}).

13.3.1 The Interior Growth Law (Node Multiplication)

The rate at which the active Face–Centered Cubic (FCC) vacuum is structurally crystallized into phase-locked Simple Cubic (SC) Substrate nodes is governed by the net kinetic power injected into the system:

$$\frac{\mathrm{d}N}{\mathrm{d}t} = \frac{\eta_{\mathrm{N}} P_{\mathrm{in}} - L_{\mathrm{out}}}{E_{\mathrm{S}}} \tag{13.4}$$

Where:

- P_{in}: The injected kinematic power (from consumed matter and active vacuum).
- L_{out}: The mechanical leakage (e.g., gravitational radiation or stress shedding during topological mismatch).
- η_{N}: The nucleation efficiency (the geometric probability of an active FCC node snapping into the phase-locked SC configuration upon contact with the core).
- E_{S}: The absolute structural energy capacity of a single SC Substrate node ($\approx 1.956 \times 10^9$ J).

This establishes that interior growth is strictly node-driven; the core expands only when the incoming kinetic energy exceeds the threshold required to forge new substrate geometry.

13.3.2 The Kinematics of Event Horizon Phase Expansion

Because the Event Horizon is a physical phase boundary, its macroscopic expansion requires mechanical work. The internal mechanical work exerted by the outward crystallization pressure of these newly formed SC nodes must equal the gravitational work required to expand the mass-energy of the exterior surface.

As fully derived in Appendix S (Section 9), equating the differential expansion power of the horizon's mass-energy ($E = Mc_{\mathrm{E}}^2$) to the internal mechanical work rate (Force $\times$ Velocity) yields a strict phase-locked identity for the Horizon Surface Tension (τ_{QG}):

$$\tau_{\mathrm{QG}} = \left(\frac{c_{\mathrm{E}}^2}{4\pi G R_{\mathrm{QG}}} \right) g_{\mathrm{QG}} \tag{13.5}$$

This derivation proves from first principles that macroscopic horizon expansion is not a kinematic stretch of empty mathematical space, but a strict mechanical displacement. It is driven purely by the crystallization pressure of the growing SC core pressing outward against the elastic FCC vacuum.

13.4 Live Boundary Dynamics Beyond Spherical Growth

The radial growth law describes the spherically averaged motion of the saturation boundary,

$$\dot{R}_{\mathrm{QG}} = \frac{G}{c_{\mathrm{E}}^2} \dot{M}. \tag{13.6}$$

For a nonspherical or dynamically loaded black hole, the boundary may be written schematically as

$$R(\theta, \varphi, t) = R_{\mathrm{QG}}(t) + \delta R(\theta, \varphi, t), \tag{13.7}$$

where R_{QG} is the averaged saturation radius and δR is the local boundary deformation.

The live FCC/SC boundary contains several coupled mechanical channels: center-of-mass motion, normal phase-front growth, tangential redistribution of boundary stress, and torsional boundary motion. Axial spin is assigned to torsional loading of the FCC/SC boundary and shear strain in the surrounding Soft Floor. In the first-order surface-shell model developed in Appendix U,

$$\mathcal{J}_{\mathrm{BH}} = I_{\mathrm{surf}} \frac{v_{\mathrm{tor}}}{R_{\mathrm{QG}}}, \tag{13.8}$$

and

$$a_* = \frac{c_{\mathrm{E}} \mathcal{J}_{\mathrm{BH}}}{GM^2} = \left(\frac{I_{\mathrm{surf}}}{M R_{\mathrm{QG}}^2} \right) \frac{v_{\mathrm{tor}}}{c_{\mathrm{E}}}. \tag{13.9}$$

Thus, in this approximation, $a_* \leq 1$ follows from the finite kinematic capacity of the Soft Floor and the confinement of the angular-momentum carrier to the boundary scale.

For a circular binary with component saturation radii

$$R_i = \frac{GM_i}{c_{\mathrm{E}}^2}, \tag{13.10}$$

and center-to-center separation d, the relative orbital velocity scale becomes

$$v_{\mathrm{rel}} = c_{\mathrm{E}} \sqrt{\frac{R_1 + R_2}{d}}. \tag{13.11}$$

The contact-scale limit $v_{\mathrm{rel}} \to c_{\mathrm{E}}$ occurs only when $d \to R_1 + R_2$. It is not a universal binary velocity law.

In TFT, binary merger is the formation of a common saturated phase boundary, not the geometric limit $d = 0$. A schematic bridge condition is

$$\alpha_{\mathrm{bridge}} = \alpha_{\mathrm{G},1} + \alpha_{\mathrm{G},2} + \alpha_{\mathrm{dyn}} \geq 1, \tag{13.12}$$

where α_{dyn} denotes dynamic loading from orbital compression, shear, torsion, and nonlinear boundary deformation.

After merger, the common boundary sheds excess stress and relaxes. The ringdown stage is therefore interpreted as damped relaxation of the live FCC/SC phase boundary. A minimal linearized form is

$$\frac{\partial^2 \delta R}{\partial t^2} + \Gamma_{\mathrm{QG}} \frac{\partial \delta R}{\partial t} + \omega_{\mathrm{QG}}^2 \delta R = 0. \tag{13.13}$$

The detailed surface-dynamical treatment of spin, bridge formation, stress shedding, and ringdown is given in Appendix U. The separate Kerr-limit matching problem is formulated in Appendix V.

13.5 Kerr Correspondence and the Observational Surface Map

A viable alternative to the Kerr exterior must reproduce established spin-dependent astrophysical observables without importing the geometric singularity or the empty-spacetime metric. In TFT,

this is achieved through a strict continuum-mechanical closure of the rotating Soft Floor, detailed in Appendix W.

Torsional loading of the FCC/SC boundary generates an exterior azimuthal shear field. Weak-field angular momentum matching enforces the standard Lense–Thirring frame-dragging rate:

$$\omega_{\mathrm{drag}}(r) = \frac{2G\mathcal{J}_{\mathrm{BH}}}{c_{\mathrm{E}}^2 r^3}. \tag{13.14}$$

Furthermore, boundary relaxation requires that transient surface deformations shed excess strain energy via gravitational wave emission until the exterior multipoles depend only on mass and spin. This dissipative no-hair selection rule yields a relaxed quadrupole moment matching the Kerr limit:

$$Q_{\mathrm{TFT}} = -a_*^2 M R_{\mathrm{QG}}^2. \tag{13.15}$$

Because TFT replaces the GR interior and horizon ontology, the "surface" of a rotating black hole is not a single coordinate radius. It is a layered mechanical and optical map:

$$R_{\mathrm{obs}}(a_*) = \{R_{\mathrm{QG}},\, r_{\mathrm{sat}},\, r_{\mathrm{cap}},\, r_{\gamma,s_{\mathrm{br}}},\, B_{\gamma,s_{\mathrm{br}}},\, r_{\mathrm{ISCO},s_{\mathrm{br}}}\}\,. \tag{13.16}$$

Here, R_{QG} is the mass-defined saturation scale. The actual spin-deformed physical boundary is $r_{\mathrm{sat}}(\theta, a_*)$. The ergosphere is mechanically replaced by the torsional capacity surface, $r_{\mathrm{cap}}(\theta, a_*)$, where the Soft-Floor drift speed equals the local propagation capacity. Finally, the observable photon rings (r_γ), shadow-impact scales (B_γ), and massive-particle Innermost Stable Circular Orbits (r_{ISCO}) are derived directly from the dragged, strain-refractive Soft Floor Hamiltonian.

This establishes a fully computable TFT replacement framework for rotating black-hole exteriors, where exact Kerr-correspondence is maintained in the weak field, leaving strong-field deviations to be governed by the nonlinear mechanics of the saturated FCC/SC phase transition.

13.6 The Black Hole Saturation Mass

A Black Hole is not a static object; it is a dynamic phase boundary stable only due to the existence of a Pressure Gradient:

- **Crystallization Pressure (Outward):** The mechanical force of the advancing SC phase domain converting the vacuum, driven by the geometric locking of new nodes.
- **Boundary Tension (Inward):** The elastic holding tension (τ_{QG}) of the hyper-compressed FCC boundary shell resisting the expansion, generated by the areal mass density (Σ_{surf}) of the segregated defects, and supported by the ambient pressure of the surrounding vacuum.

As a Black Hole grows, it obeys a strict inverse scaling law. While its microscopic volumetric boundary density remains locally maxed at the convergence limit (ρ_{QG}), its macroscopic Areal Mass Density (Σ_{surf}) diffuses. By dividing the macroscopic mass equation derived above by the spherical surface area ($A = 4\pi R_{\mathrm{QG}}^2$), we find:

$$\Sigma_{\mathrm{surf}} = \frac{\rho_{\mathrm{QG}} \cdot r_{\mathrm{D}}^2 \cdot R_{\mathrm{QG}}}{4\pi R_{\mathrm{QG}}^2} = \left(\frac{\rho_{\mathrm{QG}} \cdot r_{\mathrm{D}}^2}{4\pi}\right) \frac{1}{R_{\mathrm{QG}}} \tag{13.17}$$

Because mass scales linearly while area scales quadratically, the segregated mass spreads thinner across the growing boundary. Consequently, the inward Boundary Tension ($\tau_{\mathrm{QG}} = \Sigma_{\mathrm{surf}} \cdot c_{\mathrm{E}}^2$) generated by this mass strictly decreases inversely with the radius ($\tau_{\mathrm{QG}} \propto R_{\mathrm{QG}}^{-1}$).

The Saturation Limit: The growth of a Black Hole is bounded by the causal limits of the lattice. The limit is reached when the areal mass density of the Black Hole dilutes to match the ambient density of the Viscous Cosmic Horizon (R_{U}). At this point, the pressure gradient vanishes ($\Delta P = 0$), the Event Horizon dissolves, and the Black Hole ceases to function as a bounded object.

Derivation of the Saturation Mass (M_{Sat}): We derive the theoretical universal mass limit by equating the Black Hole's causal radius with the Universe's causal radius.

- *Black Hole Radius (Lattice Convergence Limit):* $R_{\mathrm{QG}} = \frac{GM}{c_{\mathrm{E}}^2}$
- *Cosmic Causal Radius (Lattice Damping Limit):* $R_{\mathrm{U}} = \frac{c_{\mathrm{E}}}{\Gamma_{\mathrm{D}}}$

The Saturation Condition ($R_{\mathrm{QG}} = R_{\mathrm{U}}$):

$$\frac{GM_{\mathrm{Sat}}}{c_{\mathrm{E}}^2} = \frac{c_{\mathrm{E}}}{\Gamma_{\mathrm{D}}} \tag{13.18}$$

The Universal Closure Mass:

$$M_{\mathrm{Sat}} = \frac{c_{\mathrm{E}}^3}{G\Gamma_{\mathrm{D}}} \tag{13.19}$$

Physical Interpretation:

- **If $M < M_{\mathrm{Sat}}$:** The object is a local Black Hole (Type I) with a distinct horizon and a strong stabilizing pressure gradient.
- **If $M = M_{\mathrm{Sat}}$:** The object's boundary expands to encompass the entire causal volume ($\propto R_{\mathrm{U}}^3$). The localized topological defect dissolves into the contiguous global continuum, mechanically eliminating the "Inside/Outside" boundary.

13.7 Derivation of the Reservoir Radius (R_{Res})

To build a solid SC core the size of the Cosmic Horizon ($R_{\mathrm{U}} \approx 1.2665 \times 10^{26}$ m), the Black Hole must harvest a specific volume of vacuum nodes. Applying the strict conservation of mass ($V_{\mathrm{FCC}} \cdot \rho_{\mathrm{QG}} = V_{\mathrm{SC}} \cdot \rho_{\mathrm{S}}$), we utilize the exact phase densities derived in Appendix S:

$$\frac{\rho_{\mathrm{S}}}{\rho_{\mathrm{QG}}} = \frac{5.1550 \times 10^{96}\ \mathrm{kg/m^3}}{5.2625 \times 10^{70}\ \mathrm{kg/m^3}} \approx 9.7957 \times 10^{25} \tag{13.20}$$

The total required volume of active vacuum (V_{FCC}) is exactly 9.7957×10^{25} times larger than the resulting core. Since radius scales with the cube root of volume ($R \propto V^{1/3}$), the radial multiplier is $(9.7957 \times 10^{25})^{1/3} \approx 4.6098 \times 10^8$.

$$R_{\mathrm{FCC}} = R_{\mathrm{U}} \cdot (4.6098 \times 10^8) \approx (1.2665 \times 10^{26}\ \mathrm{m}) \cdot (4.6098 \times 10^8) \approx 5.8383 \times 10^{34}\ \mathrm{m} \tag{13.21}$$

The Structural Phase Limits: Based strictly on the mass-energy conservation of this phase transition, the active lattice must extend to a macroscopic boundary of $R_{\mathrm{Res}} \approx 5.8383 \times 10^{34}$ m to structurally support the total mass-energy of the local cosmic domain. We define this ultimate boundary as the Geometric Cosmic Horizon, which physically bounds the total Cosmic Reservoir. This mathematically confirms that the Cosmological Cycle operates perfectly between the two absolute mechanical limits of the continuum: the microscopic limit of the latent Substrate ($\ell_{\mathrm{S}} \sim$

10^{-35} m) defines the fundamental geometric grain, while the total volumetric capacity of the active phase ($R_{\text{Res}} \approx 10^{35}$ m) defines the macroscopic reservoir.

(Note: As established in Part I for the microscopic node scale, because the coefficient 5.8383 falls above the logarithmic midpoint of a base-10 scale ($\sqrt{10} \approx 3.16$), the ultimate volumetric capacity of the active vacuum is strictly classified as an order-of-magnitude scale of $R_{\text{Res}} \sim 10^{35}$ m in all subsequent macroscopic expressions).

13.8 The End of Gravity (Surface Acceleration)

Standard physics assumes larger mass means stronger surface gravity. TFT reveals the opposite at the Event Horizon due to the linear scaling of the radius ($R_{\text{QG}} \propto M$).

Standard Formula: Surface Gravity at the horizon is $g_{\text{QG}} = \frac{GM}{R_{\text{QG}}^2}$.

TFT Substitution: Substituting the gravitational saturation-radius relation $R_{\text{QG}} = \frac{GM}{c_{\text{E}}^2}$:

$$g_{\text{QG}} = \frac{GM}{\left(\frac{GM}{c_{\text{E}}^2}\right)^2} = \frac{GM \cdot c_{\text{E}}^4}{G^2M^2} = \frac{c_{\text{E}}^4}{GM} \tag{13.22}$$

The Result:

$$g_{\text{QG}} \propto \frac{1}{M} \tag{13.23}$$

Implication: As a Black Hole grows, the gravitational acceleration at its surface inversely decreases. The system is bounded by two strict mechanical limits:

- **The Minimum Limit (The Micro-Black Hole):** At the fundamental node saturation limit ($M_{\text{D,G}} \approx 10.033$ kg), the surface gravity reaches its absolute theoretical maximum ($g_{\text{QG,max}}$). The tension is perfectly concentrated on a single fundamental cell.
- **The Macroscopic State:** A Supermassive Black Hole has vastly weaker surface gravity because the holding tension is distributed over an immense, macroscopic surface area.
- **The Maximum Limit (Saturation):** When the Black Hole expands to the universal closure boundary ($R_{\text{QG}} = R_{\text{U}}$), the mass reaches M_{Sat}. At this extreme, the surface gravity g_{QG} approaches zero.

The Consequence: At the cosmic scale, the Black Hole possesses no holding gradient left to maintain its boundary. The hyper-compressed boundary shell of extruded topological mass becomes too diffuse to contain the outward crystallization pressure of the phase-locked Substrate Core.

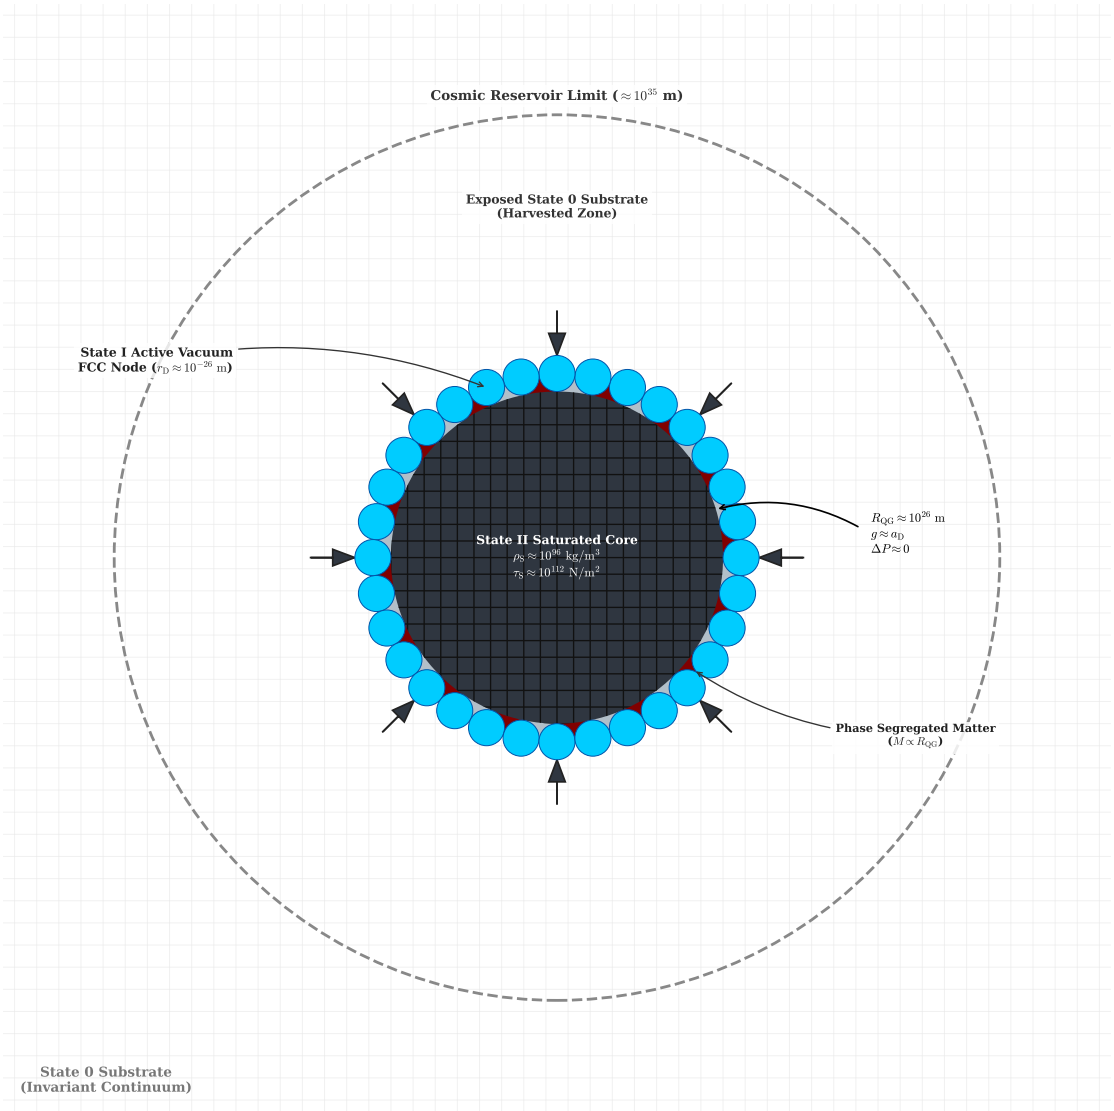

Figure 13.1: **The Structural Mechanics of Black Hole Saturation.** The Event Horizon is a dynamic solid-state phase boundary. Following the Topological Extrusion Rule, the zero-void Simple Cubic core (State II) possesses no internal inertial mass. As the active vacuum crystallizes into this hyper-dense core, all topological defects (matter) are mechanically extruded outward and strictly confined to the interstitial voids (red) of the innermost Face–Centered Cubic (FCC) contact layer (r_{D}). The Black Hole grows by continuously converting the voluminous active vacuum into rigid core geometry. If the object were to reach the causal mass limit (M_{Sat} at R_{U}), the surface holding tension (g) would drop to the ambient cosmic impedance (a_{D}), causing the containment pressure (ΔP) to vanish and triggering catastrophic decompression.

13.9 Mechanism of Failure

If a single Black Hole could hypothetically reach the universal closure boundary (M_{Sat}), it would suffer an inevitable local rupture. At this scale, the restorative holding force at the surface (g) drops to the fundamental Cosmic Impedance Acceleration ($a_{\mathrm{D}} \approx 10^{-10}$ m/s^2). Because the internal

gravitational binding energy is fully counteracted by the vacuum's inertial energy, the pressure gradient vanishes ($\Delta P \to 0$). The boundary would dissolve, and the super-compressed Simple Cubic (SC) core would violently decompress back into the active Face–Centered Cubic (FCC) state.

However, it is mechanically impossible for a single Black Hole to actually reach this macroscopic saturation limit. A Black Hole does not exist in isolation; it is part of a distributed, universe-wide network of growing State II defect cores.

Because multiple Black Holes are simultaneously consuming the active vacuum, the global geometric capacity of the FCC lattice will structurally fail long before any single core can expand to R_{U}. Therefore, the ultimate fate of the Black Hole is not determined by its own local growth limit (M_{Sat}), but is prematurely triggered by the global percolation fault line—resulting in the catastrophic decompression detailed in Part III.

Chapter 14

The Quantum Structure of the Vacuum

14.1 The Hydrodynamics of the Pilot Wave

Standard Quantum Mechanics treats particles as dimensionless points governed by abstract probability waves, leaving wave-particle duality, uncertainty, and wavefunction collapse without physical mechanisms. Tension Field Theory (TFT) replaces this stochastic abstraction with a deterministic foundation.

To translate these abstract probabilities into physical lattice hydrodynamics, we rely on the mechanical properties of the contiguous active Face–Centered Cubic (FCC) vacuum. We derive the motion of a particle—mechanically defined as a localized topological knot—as the result of a physical pilot wave propagating through the interstitial condensate of the active vacuum ($r_{\mathrm{D}} \approx 10^{-26}$ m). Building on the resolution of wave-particle duality established in Part I (Section **??**), we do not treat the wave and particle as separate entities. Rather, the extended topological phase-twist (the pilot wave) physically steers its own localized hydrodynamic impedance footprint (the particle mass).

14.1.1 The Physical Fluid (The Madelung Transformation)

To translate abstract quantum mechanics into physical condensate dynamics, TFT utilizes the Madelung transformation [17]. By establishing the SGF Soft Floor, TFT provides the physical medium required to map the abstract wavefunction (Ψ) directly to the mechanical properties of the lattice. Rather than a probability amplitude, Ψ functions as the macroscopic physical order parameter of the SGF, analogous to a Ginzburg–Landau superfluid *(The strict boundary conditions for Ψ across both the Hard and Soft Floors are defined in Appendix X).*

$$\Psi = \sqrt{\rho} \cdot \exp\left(\frac{iS}{\hbar}\right) \tag{14.1}$$

This maps the mathematics to three physical variables:

- **Local Wave Density (ρ):** The dynamic variation in the vibrational energy of the propagating wave on the Soft Floor. *(Note: This varies locally and is distinct from the static baseline node density, ρ_{D}).*
- **Action (S):** The continuous mechanical phase of the wave. Geometrically, it is tied to the fundamental lattice phase angle (φ) established in Part I by the direct relation $S = \hbar \cdot \varphi$.

- **Velocity (v):** The physical flow rate of the tension field. Because the spatial gradient of action (∇S) is physically the momentum of the field, the local wave velocity is $v = \frac{\nabla S}{m}$. Here, m is the kinematic mass generated by the hydrodynamic impedance of the interstitial condensate ($m \propto r_{\text{amp}}$), as derived in Part I. *(Note: Because $S = \hbar \cdot \varphi$, the momentum term ∇S hydrodynamically fulfills the physical translation of the De Broglie relation, $\mathbf{p} = \hbar \nabla \varphi$, established in Part I).*

14.1.2 The TFT Governing Wave Equation

By modeling the active vacuum as a physical condensate, the dynamics of the FCC soft floor are governed by the Viscous Non-Linear Wave Equation (VNLW)—a deterministic, mechanical formulation of the Schrödinger equation. We introduce the scaling factor $\hbar$ to ensure the viscous term accurately represents physical energy dissipation:

$$i\hbar \frac{\partial \Psi}{\partial t} = \left[-\frac{\hbar^2}{2m} \nabla^2 + V \right] \Psi - \left[i(\hbar \Gamma) \ln(|\Psi|^2) \right] \Psi \tag{14.2}$$

This single deterministic equation governs both the smooth propagation and the sharp localization of the wave:

- **The Linear Pilot Wave (Flight):** The first bracketed term describes the frictionless propagation of the wave on the Soft Floor. This dominates when the boundary friction is negligible ($\Gamma \to \Gamma_{\text{D}}$), such as during vacuum transit. In this regime, the wave generates interference patterns, and standard Heisenberg uncertainty applies because the lattice is vibrating without localized damping.

- **The Viscous Focusing (Wave Arrest):** The second bracketed term describes the viscous energy dissipation when the wave interacts with dense matter. Here, Γ is the mechanical damping rate (s^{-1}), and $\hbar\Gamma$ is the exact kinetic energy lost as thermal exhaust (J). This forces the extended wave Ψ to rapidly shrink into a single localized packet.

The Cosmological Limit ($\Gamma \to \Gamma_{\text{D}}$):
The Quantum Damping Rate (Γ) and the cosmological Vacuum Damping Rate (Γ_{D}) are the exact same physical mechanism operating at two different extremes of Topological Knot Density (n_{K}). Both parameters govern the visco-elastic boundary friction of the FCC Soft Floor:

- **The Microscopic Extreme (Wave Arrest):** Inside a dense macroscopic detector ($n_{\text{K}} \gg 0$), the extreme knot density creates a massive damping rate ($\Gamma \approx 10^{15}\ \text{s}^{-1}$). The pilot wave is drained of its kinetic energy in femtoseconds, trapping the particle and resulting in absolute kinematic localization. *(This is the physical, mechanical reality of what standard quantum mechanics abstracts as "wavefunction collapse").*

- **The Macroscopic Extreme (Cosmic Redshift):** In the deep intergalactic vacuum, n_{K} approaches zero. Here, the damping rate reduces strictly to the baseline geometric impedance of the lattice itself, establishing the absolute minimum: $\Gamma_{\text{D}} \approx 2.3 \times 10^{-18}\ \text{s}^{-1}$. The pilot wave bleeds energy over billions of years, causing the thermal exhaust that standard cosmology misinterprets as metric expansion.

14.1.3 The Hydrodynamic Force Law

By separating the real and imaginary parts of the master equation, we recover the condensate-dynamic Euler force law for the topological knot:

$$F = -\nabla V - \nabla Q - F_{\text{fr}} \tag{14.3}$$

Here, Q is the localized lattice strain energy, conventionally known in Bohmian mechanics as the quantum potential [18]:

$$Q = -\frac{\hbar^2}{2m}\left(\frac{\nabla^2\sqrt{\rho}}{\sqrt{\rho}}\right) \tag{14.4}$$

This formulation provides a purely mechanical explanation for particle motion. The particle is pushed by three specific lattice forces:

- **Classical Force ($-\nabla V$):** The macroscopic tension gradients of the lattice, manifesting as gravity or electric fields.
- **Quantum Force ($-\nabla Q$):** The hydrodynamic pressure gradient generated by the lattice vibration (interference). Mechanically, the lattice pushes the particle away from "quiet" zones (destructive interference) and pulls it into "loud" zones (constructive interference).
- **Viscous Force ($-F_{\text{fr}}$):** The macroscopic damping generated by visco-elastic boundary friction (Γ) upon interaction with dense matter, which forces absolute kinematic localization (wave arrest). *(The kinetic derivation of the constitutive law for Γ is detailed in Appendix Y).*

This physical mechanism precisely maps the resolution of wave-particle duality to condensate dynamics: the extended internal phase-twist creates a macroscopic interference pattern in the SGF (the Wave), which deterministically steers the node's localized hydrodynamic impedance artifact (the Particle) into regions of constructive interference. The particle does not pass through both slits; its extended hydrodynamic wake does, steering the localized mass along a deterministic streamline.

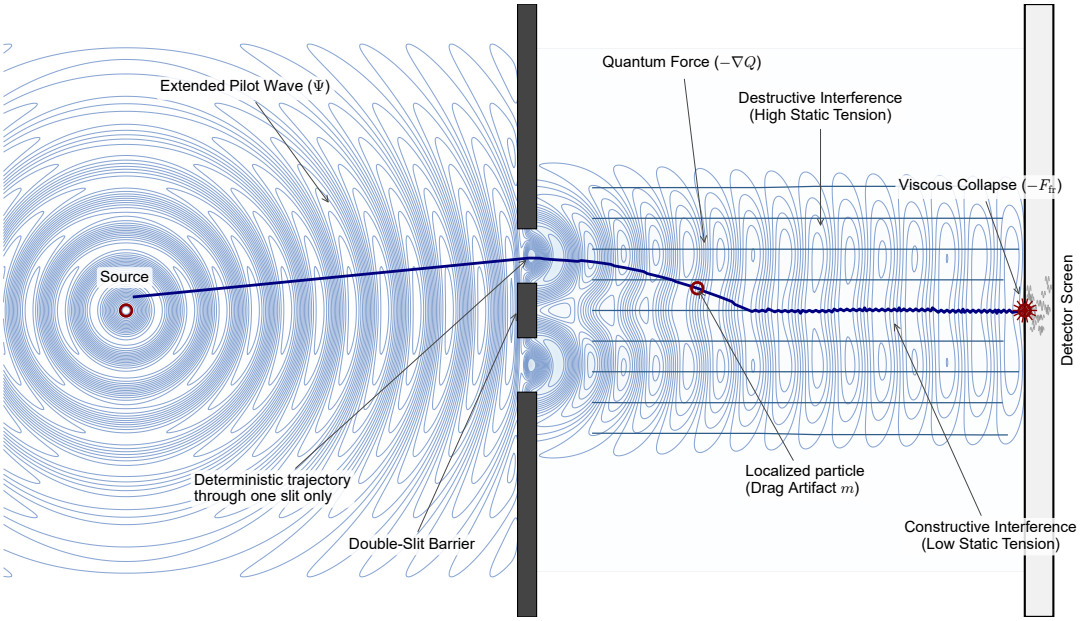

Figure 14.1: **Hydrodynamic Steering in the Double-Slit Experiment.** A deterministic lattice-dynamic model of wave-particle duality governed by the FCC active vacuum. The extended topological phase-twist (the Pilot Wave, Ψ) passes through both slits, generating a macroscopic interference pattern within the vacuum condensate. This interference creates localized surface tension gradients across the lattice. The particle—acting as a localized hydrodynamic impedance artifact (m)—does not exist in superposition; its initial coordinate dictates that it travels deterministically through a single slit. It is actively steered by the quantum force ($-\nabla Q$) along a continuous streamline, physically squeezed out of high-tension nodes (Destructive Interference) and funneled into low-tension channels (Constructive Interference), until its extended wake undergoes absolute kinematic localization (wave arrest) via visco-elastic friction ($-F_{\text{fr}}$) upon impact with the macroscopic detector screen.

14.1.4 The TFT Governing Equation for Massless Shear Waves

Unlike Fermions, which are governed by the VNLW, the photon is an untethered transverse shear wave. Because it lacks a localized topological knot, it possesses zero hydrodynamic impedance mass ($m = 0$) and is not steered by the quantum potential (Q). Instead, by applying the physical parameters of the FCC active vacuum to the classical **D'Alembert wave equation**, we derive the damped Bosonic Shear equation:

$$\nabla^2 \mathbf{A} - \frac{1}{c_{\text{E}}^2} \frac{\partial^2 \mathbf{A}}{\partial t^2} - \left(\frac{\Gamma_{\text{D}}}{c_{\text{E}}^2} \right) \frac{\partial \mathbf{A}}{\partial t} = 0 \tag{14.5}$$

Where:

- $\mathbf{A}$: The continuous transverse phase displacement (the phase twist) of the Soft Floor lattice.
- c_{E}: The fundamental propagation velocity of the contiguous medium, dictated strictly by the ratio of the vacuum's baseline shear stiffness (τ_{D}) to its effective 2D interface inertia (μ_{D}):

$$c_{\text{E}} = \sqrt{\frac{\tau_{\text{D}}}{\mu_{\text{D}}}} \tag{14.6}$$

- Γ_{D}: The Vacuum Damping Rate, representing the minute visco-elastic friction of the active medium.

This equation proves that the photon propagates across the vacuum surface lever without non-linear wave arrest. Absolute kinematic localization (the measurement "click") cannot occur in free flight; it is strictly triggered when this continuous stress field impacts a quantized boundary (The Threshold Gate Mechanism). Furthermore, the inclusion of the linear dissipation term governed by the Vacuum Damping Rate (Γ_{D}) ensures the wave's kinetic energy is perfectly conserved on quantum timescales, while accurately predicting the exponential energy decay over cosmological distances, deriving the Visco-Elastic Damping Equation ($1 + z = e^{\frac{\Gamma_{\mathrm{D}} x}{c_{\mathrm{E}}}}$) established in Part III.

14.2 The Topology of Quantum Spin: Shear Waves vs. Tethered Knots

In standard quantum mechanics, "spin" is treated as an abstract, intrinsic angular momentum with no physical analog. In Tension Field Theory (TFT), spin is the literal, mechanical rotation of the localized 3D inertia of a discrete lattice node.

To understand how spin operates, we must separate the continuous 2D boundary of the vacuum from the discrete 3D volume of the physical nodes.

14.2.1 The Two Action Levers: μ_{D} vs. M_{D}

The contiguous FCC lattice possesses two distinct geometric levers through which quantum action (h) is mechanically generated.

- **The Surface Lever ($\mu_{\mathrm{D}} \cdot r_{\mathrm{D}}^3$):** μ_{D} is the node interface inertia (the 2D skin where contiguous nodes touch). It governs the propagation of transverse waves (light). The vacuum uses this lever to shear the surface without permanently displacing the core.
- **The Volumetric Lever ($M_{\mathrm{D}} \cdot r_{\mathrm{D}}$):** M_{D} is the quantum mass (the total 3D localized inertia) of a single Soft Floor node. It governs the mechanical rotation of Fermions (matter). The vacuum uses this geometric lever ($\rho_{\mathrm{D}} \cdot r_{\mathrm{D}}^4$) to physically rotate the entire 3D volume of the node.

14.2.2 Spin 1: The Photon's Rolling Shear (360°)

A photon is not a solid object; it is an untethered, propagating transverse shear wave.

- **The Mechanism:** As the electromagnetic wave hits FCC lattice node A, the wave's vertical transverse displacement drags against the node's 2D skin (μ_{D}).
- **The Rotation:** This shear force physically rolls the 3D volume of FCC lattice node A exactly 360° (2π radians) forward.
- **The Hand-off:** Because the wave is untethered and moving at c_{E}, this single 360° roll perfectly transfers one fundamental quantum of action ($1h$) to adjacent FCC lattice node B.
- **The Wake:** FCC lattice node A immediately comes to a dead rest, returning to its flat, zero-stress baseline. The node remains completely untwisted in the photon's wake.

14.2.3 Spin 1/2: The Electron's Tethered Knot (720°)

An electron is not a propagating wave; it is a localized, standing wave phase-locked onto a specific coordinate. Because it is phase-locked, the central node is permanently tethered to the contiguous lattice bonds of its neighbors.

- **The First Turn (0° to 360°):** When a localized energy gradient induces a full 360° spatial rotation upon FCC lattice node A, the node returns to its original orientation, but the connecting lattice bonds are physically braided into a tight coil. Half of the input energy ($h/2$) manifests as the kinetic spin of the node, while the other half ($h/2$) is stored as potential elastic strain in the twisted vacuum.
- **The Second Turn (360° to 720°):** Because space is 3-dimensional, a continuous directional rotation forces the braided tethers to slip over the topological poles of the central node. As the node completes a 720° (4π) cycle, the vacuum completely untangles itself back to a zero-stress state. This mechanism is known in standard topology as the Dirac Belt Trick (or Feynman's Plate Trick).

14.2.4 The Geometric Origin of "Half" Spin

The designation "Spin 1/2" is not a measure of total absolute rotation; it is a fraction of our macroscopic laboratory reference frame.

In a standard 3D spatial rotation, the maximum observable angle before coordinates repeat is 360° (2π). The untethered photon requires exactly 360° (a linear kinematic path of exactly $2r_{\mathrm{D}}$) to deliver $1h$ of work. In one spatial frame, it completes 1 full geometric cycle ($f_\gamma = c_{\mathrm{E}}/2r_{\mathrm{D}}$).

The tethered electron requires exactly 720° (4π) to deliver $1h$ of work and untie the vacuum. As it completes the mandatory inward and outward topological transit ($4r_{\mathrm{D}}$), it requires twice the geometric displacement to complete its cycle. In one 360° spatial frame, it has only completed exactly 1/2 of its mechanical requirement.

Therefore, standard observable angular momentum is halved ($\hbar/2$). The 1/2 is not a statistical probability; it is a strict topological winding number required to sustain a localized knot in a contiguous elastic medium. This dual-crossing constraint provides the formal geometric proof for the constant internal topological resonance ($f_{\mathrm{m}} = \frac{c_{\mathrm{E}}}{4r_{\mathrm{D}}} \equiv \frac{1}{2}f_\gamma$) established in Appendix F. This tethered topology defines the deterministic geometric origin of the foundational "slow clock" mechanism, from which the macroscopic Proper Time (t_{p}) of all matter emerges.

14.2.5 Mechanical Resolution of the Electron Speed Limit Paradox

Standard physics famously abandoned the mechanical model of spin because of a kinematic paradox: to generate an angular momentum of $\hbar/2$, an object with the mass and radius of an electron would have to spin vastly faster than the speed of light ($v \gg c$).

TFT mathematically and mechanically resolves this paradox by enforcing the strict separation between Hydrodynamic Impedance Mass (m_{e}) and the intrinsic mass-energy of the Quantum Node. By setting the equatorial velocity of the physical gear to exactly the speed of light ($v = c_{\mathrm{E}}$), we can solve for the required mass (M_{spin}) necessary to carry Spin 1/2:

$$v = \frac{L}{M_{\mathrm{spin}} \cdot r} \tag{14.7}$$

$$c_{\mathrm{E}} = \frac{\hbar/2}{M_{\mathrm{spin}} \cdot r_{\mathrm{D}}} \tag{14.8}$$

Solving for the required node mass:

$$M_{\text{spin}} = \frac{\hbar}{2 \cdot c_{\text{E}} \cdot r_{\text{D}}} \tag{14.9}$$

Using the standard constants and the updated TFT FCC Node Radius ($r_{\text{D}} \approx 7.4504 \times 10^{-27}$ m):

$$M_{\text{spin}} = \frac{1.05457 \times 10^{-34}}{2 \cdot (299792458) \cdot (7.4504 \times 10^{-27})} \approx 2.3609 \times 10^{-17} \text{ kg} \tag{14.10}$$

This required rotational mass (2.3609×10^{-17} kg) is exactly half the equatorial kinematic mass limit of the FCC lattice node ($m_{\text{eq}} = \hbar/(c_{\text{E}} r_{\text{D}}) \approx 4.7218 \times 10^{-17}$ kg), perfectly mirroring the 1/2 geometric factor of the tethered topology.

Conclusion: The paradox is an illusion caused by conflating two different mechanical properties. As established in Section **??**, all fundamental particles reside on lattice nodes of the exact same physical radius (r_{D}). The observable electron mass ($\approx 10^{-31}$ kg) is merely the macroscopic hydrodynamic impedance generated by its tiny vibrational amplitude (the "whisper"). The physical object spinning to generate the angular momentum is the discrete lattice node itself, operating at the equatorial kinematic mass limit ($m_{\text{eq}} \approx 10^{-17}$ kg). Because this microscopic "gear" is a physical structure of the vacuum, its equatorial rotation is governed by the elastic shear limit of the contiguous lattice ($\sqrt{\tau_{\text{D}}/\mu_{\text{D}}}$). Therefore, it operates perfectly at, and physically cannot exceed, the speed of light (c_{E}).

14.3 The Mechanics of Measurement and Wave Arrest

Rather than an abstract or observer-driven event, Tension Field Theory (TFT) provides a deterministic, mechanical explanation for absolute kinematic localization: measurement is a physical, topological interaction driven by visco-elastic boundary friction.

14.3.1 The "Sticky Pad" Detector

To understand measurement, we must analyze the physical difference between the vacuum and a detector.

In free space, the FCC Soft Floor acts as an ideal, nearly frictionless condensate. The localized topological knot (the particle) is steered frictionlessly by the pilot wave, creating the macroscopic "blur" of uncertainty because its exact geometric location is continually translated by the broad wavefront.

Inside a detector, composed of dense solid matter (heavy atoms), the lattice is physically loaded and its internal visco-elasticity becomes dominant. The detector functions mechanically as a viscous sink. The localized boundary friction of this dense medium instantly drains the kinetic energy from the pilot wave, analogous to a water wave hitting a pool of thick honey.

14.3.2 The Quantum Damping Rate (Γ)

This wave arrest is driven by a single environmental parameter: the quantum damping rate (Γ). This represents the mechanical rate of energy dissipation from the coherent pilot wave into incoherent lattice heat (thermal exhaust).

As the transverse wave propagates, it must work against the boundary friction generated between the solid nodes and the interstitial condensate. We define the constitutive law governing this localized friction—and its resulting macroscopic damping rate—as:

$$\Gamma(x) = \sigma \cdot c_{\mathrm{P}} \cdot n_{\mathrm{K}}(x) \tag{14.11}$$

Where:

- σ (Scattering Cross-Section): The effective interaction area of a single structural lattice defect (atom) that disrupts the wave.
- c_{P} (Dynamic Wave Speed): The propagation speed at which the pilot wave feeds into the friction.
- n_{K} (Topological Knot Density): The number of localized topological defects (atoms) per unit volume.

This law explains the binary nature of measurement by mapping it directly to lattice density. In the deep vacuum, the local defect density approaches zero. Consequently, the localized friction drops to its absolute baseline minimum ($\Gamma \to \Gamma_{\mathrm{D}}$). As detailed in Appendix AQ, this baseline limit is the Vacuum Damping Rate. While this minute visco-elastic damping ($\Gamma_{\mathrm{D}} \approx 10^{-18}$ s^{-1}) manifests macroscopically as cosmological redshift over billions of years, on quantum timescales it is effectively zero. This allows the wave to maintain a linear superposition without noticeable energy loss.

Inside a detector wall, however, the topological defect density is massive ($n_{\mathrm{K}} \approx 10^{23}$ m^{-3}), causing the boundary friction (Γ) to spike. This massive localized friction drains the pilot wave energy in femtoseconds.

14.3.3 Viscous Focusing and the Topological Sink

This energy dissipation is governed by the second term of the Viscous Non-Linear Wave Equation (VNLW):

$$-\left[i(\hbar\Gamma)\ln(|\Psi|^2)\right]\Psi \tag{14.12}$$

Here, the scaling factor $\hbar\Gamma$ quantifies the precise energy cost of the damping, representing the kinetic energy permanently lost as thermal exhaust into the lattice. (See derivation of quantum damping rate (Γ) in Appendix Y).

In a non-linear visco-elastic medium like the FCC Soft Floor under stress, damping creates a self-focusing effect. As the wave's energy is dissipated, it does not simply fade away evenly; it acts as a chiral stress vortex over a topological sink. The internal viscosity draws the interstitial condensate (ρ_{IC}) inward toward the density peak (the topological knot). The extended wavefront instantly shrinks into a soliton—a single localized wave packet.

The Stasis of Certainty: As derived in Part I, the topological knot generates mass via hydrodynamic impedance but possesses no intrinsic propulsion; it requires the pilot wave to move. Once the detector's boundary friction fully dissipates the wave's kinetic energy, the driving force is eliminated. The particle becomes stranded on the specific lattice cell where the wave died. This results in a perfectly defined position ($\Delta x \to 0$) and zero momentum fluctuation ($\Delta p \to 0$). Certainty, therefore, is mechanically defined as the absence of a driving wave.

14.4 The Unified Law of Certainty

The Heisenberg Uncertainty Principle is interpreted by standard quantum mechanics as a fundamental, unbreakable limit of reality. Tension Field Theory (TFT) reinterprets this not as a universal law, but as a structural bandwidth limit of the vibrating Soft Floor ($r_{\mathrm{D}} \approx 10^{-26}$ m). Uncertainty is not a constant; it is a strict function of lattice mobility.

14.4.1 The Mechanical Origin of Baseline Uncertainty

Before modifying the uncertainty principle, we must define its physical origin. In TFT, Heisenberg's baseline uncertainty is not probabilistic magic; it is the Mechanical Resolution Limit (the Nyquist limit) of an elastic spacetime lattice.

- **The Spatial Limit ($\Delta x_{\mathrm{min}} \approx r_{\mathrm{D}}$):** You cannot define the position (x) of a topological knot more precisely than the discrete spacing of the lattice cells (r_{D}) that hold it. Position is fundamentally quantized by the geometry of the Soft Floor.
- **The Measurement Intrusion (Δp):** To measure the position of a node with extreme precision, one must probe it with a wavelength equivalent to the absolute structural cutoff ($\lambda = 2r_{\mathrm{D}}$). Hitting a Soft Floor node with this maximum-energy frequency excites the surrounding elastic lattice, introducing massive vibrational noise.
- **The Trade-off:** The harder you try to pin down the physical node (minimizing Δx), the more violently you vibrate the interstitial condensate (maximizing momentum uncertainty, Δp). Baseline uncertainty is simply the inevitable thermodynamic noise floor of probing a discrete, elastic system.

14.4.2 The Damping of Uncertainty via Gravitational Strain (α_{G})

Because baseline uncertainty is a strict function of lattice elasticity, it is directly governed by the local Structural Gravitational Coupling (α_{G}). As defined in Section 10.3, α_{G} quantifies the macroscopic strain applied to the Soft Floor. The mechanical origin of this strain is established by the Vertical Topology architecture (Chapter 15), where localized mass anchors the dynamic Soft Floor to the static Hard Floor via a physical Tension Column. As local mass increases, the Tension Column pulls the elastic Soft Floor taut against the immovable substrate. This mechanism physically consumes the structural "slack" of the active vacuum, actively eliminating its capacity to sustain quantum vibration.

- **On the Soft Floor (The Active Vacuum):** Far from massive bodies, lattice mobility is high and the pilot wave vibrates freely, maximizing uncertainty. The local gravitational strain is negligible ($\alpha_{\mathrm{G}} \approx 0$).
- **At the Phase Boundary (The Black Hole Core):** The local mass consumes 100% of the available Soft Floor tension ($\alpha_{\mathrm{G}} = 1$). The lattice saturates into the rigid Simple Cubic substrate. Zero mobility is permitted, and vibration is physically forbidden.

14.4.3 The Generalized TFT Uncertainty Laws

Standard quantum mechanics defines uncertainty using the statistical inequality $\Delta x \cdot \Delta p \geq \hbar/2$ for all states, where the $1/2$ is an artifact of continuous probability distributions. TFT enforces a strict mechanical separation between linear spatial translation and internal angular rotation.

A. The Linear Uncertainty Law (Wave Translation)

Because TFT operates on a discrete grid, statistical half-steps do not exist in spatial translation. A wave translating across a single contiguous lattice node completes one full geometric cycle; therefore, the absolute minimum linear physical action of the lattice is h.

TFT replaces the standard probability limit with a dynamic mechanical law that accounts for the physical scale of the lattice (via α_{G}) and the boundary friction of the interaction (via Γ). We introduce the Generalized TFT Linear Uncertainty Law:

$$\Delta x \cdot \Delta p \geq h \cdot (1 - \alpha_{\mathrm{G}}) \cdot e^{-\Gamma t} \tag{14.13}$$

This equation seamlessly governs the three regimes of linear quantum mechanics:

- **Free Flight (The Standard Model Limit):** In the vacuum ($\alpha_{\mathrm{G}} \approx 0$), the macroscopic extreme of topological density applies ($n_{\mathrm{K}} \to 0$). With localized interaction dropping to the Vacuum Damping Rate ($\Gamma \to \Gamma_{\mathrm{D}}$), the exponential term remains 1 over quantum timescales. The equation simplifies to $\Delta x \cdot \Delta p \geq h$. The particle knot surfs the pilot wave, and uncertainty applies because the lattice vibrates without localized damping.
- **The Measurement Event (The Arrest):** When the particle hits a detector, it encounters the microscopic extreme of topological density ($n_{\mathrm{K}} \gg 0$). The boundary friction (Γ) becomes massive. Over time t, the pilot wave's kinetic energy is converted to thermal exhaust, and the uncertainty decays exponentially to zero. The wave localizes into a single geometric dot.
- **The Saturated Core (Fundamental Certainty):** At the substrate or inside a black hole core, gravitational saturation is absolute ($\alpha_{\mathrm{G}} = 1$). The $(1 - \alpha_{\mathrm{G}})$ term drops exactly to zero. Therefore, $\Delta x \cdot \Delta p = 0$. Absolute determinism emerges.

B. The Angular Uncertainty Law (Node Rotation)

While linear translation requires full h wave cycles, the localized angular rotation of a phase-locked particle (a Fermion knot) is governed by its internal topology. We introduce the TFT Angular Uncertainty Law:

$$\Delta\theta \cdot \Delta L \geq \frac{\hbar}{2} \tag{14.14}$$

In TFT, the 1/2 is not a statistical artifact; it is a strict Topological Winding Number. Because an electron is a tethered 3D phase-knot, it must physically rotate 720° (4π radians) to untangle its surrounding lattice bonds and deliver one full quantum of action ($1h$). However, our macroscopic laboratory frame can only measure a standard 360° (2π radians) spatial sweep. Therefore, in one standard observable rotation, the tethered node physically completes exactly half of its required mechanical cycle.

14.4.4 The Generalized Commutator and the Mechanical Origin of i

In standard quantum mechanics, the uncertainty principle is mathematically derived from the commutator of position and momentum ($[x, p] = i\hbar$). Because standard physics assumes this commutator is an eternal constant, it concludes that uncertainty can never reach zero.

In TFT, the commutator is directly dependent on the physical elasticity of the lattice. We introduce the Generalized TFT Commutator:

$$[x, p] = i\hbar \cdot (1 - \alpha_{\mathrm{G}}) \cdot e^{-\Gamma t} \tag{14.15}$$

The imaginary unit i acts as the physical operator of harmonic lattice oscillation, representing the mathematical capacity of the medium to continuously exchange static potential energy (strain) for dynamic kinetic energy (motion).

- **On the Soft Floor (Vibrating):** In the active vacuum ($\alpha_G \approx 0, \Gamma \to \Gamma_D$), the scaling terms equal 1. The commutator simplifies to standard $i\hbar$. The state vector constantly oscillates between real spatial strain and imaginary dynamic motion.
- **On the Hard Floor (Frozen):** The lattice is saturated and possesses effectively infinite bulk stiffness. As $\alpha_G \to 1$, the term $(1 - \alpha_G)$ drops exactly to zero, neutralizing the equation. Without the geometric capacity to deform or oscillate, the imaginary operator is mathematically nullified ($i\hbar \cdot 0 = 0$). The commutator drops strictly to zero, leaving only a static, non-rotating geometric address.

14.4.5 Information Storage and the Deterministic Substrate

This zero-commutator limit explains how physical information is permanently stored in the universe. A permanent geometric property cannot be stored on a vibrating surface (high uncertainty) because it would fluctuate randomly due to thermodynamic lattice noise.

To "write" a permanent fundamental property—such as a particle's discrete spin or entanglement coordinate—the system must project its state down the Tension Column to the absolute ground state of the Hard Floor. As formally derived in Appendix AB, this zero-uncertainty anchor is the Graviton. It acts as the static topological cursor that permanently encodes the dynamic state as physical Information ($N = 1/\alpha_G$). Because the generalized commutator drops to zero at the substrate, the structural ledger of the universe is written in a font of absolute determinism, formally guaranteeing Quantum Unitarity.

Conclusion: Einstein's intuition was right: "God does not play dice." The "dice" are simply the mechanical vibrations of the Soft Floor ($\alpha_G \approx 0$), while the "board" is the static geometry of the Hard Floor ($\alpha_G = 1$). TFT reconciles the two by proving mathematically that quantum probability is simply the dynamic interface of a deterministic substrate. The Uncertainty Principle is merely the mechanical noise floor of the active vacuum, not the governing law of the underlying substrate.

14.5 Mechanical Resolutions of Quantum Paradoxes

By treating the vacuum as a physical, mechanical structure, Tension Field Theory (TFT) inherently resolves several localized quantum paradoxes—specifically, the "missing energy" of destructive interference and the "borrowed energy" of quantum tunneling. We now demonstrate how the Spacetime Gravitational Floor (SGF) resolves these mysteries.

14.5.1 The Energy Paradox of Interference (Conservation via Lattice Potential)

In standard wave mechanics, destructive interference presents an apparent violation of energy conservation. If two identical photons meet exactly 180° out of phase, their net amplitude is zero ($A_{net} = 0$). Since energy is proportional to the square of the amplitude ($E \propto A_{net}^2$), standard calculations imply the energy at that physical location is zero. Where did the energy of the two incoming photons go?

TFT resolves this by discarding the reliance on a single macroscopic amplitude vector, which fails to capture internal structural forces. Instead, TFT treats the photon not as an abstract scalar

probability, but as a mechanical vibration of the physical active SGF lattice. The total energy of a single lattice cell is governed by the standard mechanical Hamiltonian, which is the sum of potential energy (strain) and kinetic energy (motion):

$$E_{\text{total}} = \frac{1}{2}\tau_{\text{D}}(\Delta x)^2 + \frac{1}{2}\mu_{\text{eff}}v^2 \tag{14.16}$$

Here τ_{D} is the baseline shear stiffness of the Soft Floor, acting locally as the discrete linear spring constant, and μ_{eff} is its effective kinematic mass within the lattice cell:

$$\mu_{\text{eff}} = \frac{\mu_{\text{D}} r_{\text{D}}^2}{1 - \alpha_{\text{G}}} \tag{14.17}$$

The term Δx represents the transverse physical displacement of the node, and v represents its transverse oscillation velocity. (The strict dimensional consistency of mapping fundamental SGF parameters to a microscopic harmonic oscillator is proven in Appendix Z).

- **Mechanical Cancellation (The Dark Spot):** When two waves meet out of phase, their kinetic motions perfectly cancel. Wave A pulls the lattice link in one direction, while Wave B pulls it in the exact opposite direction. This results in zero net velocity ($v = 0$). Because standard electromagnetic detectors only measure kinetic momentum (power), the detector registers a "dark spot."
- **Strain Accumulation:** However, while the kinetic motion cancels, the structural strain accumulates. The lattice link is not moving, but it is under double the stress. The potential energy is maximized. The energy did not vanish; it converted perfectly from dynamic vibration (detectable light) into latent static tension (undetectable strain). Because the SGF lattice is elastic, it redistributes this static tension sideways, mechanically pushing the energy into the adjacent bright spots of constructive interference.

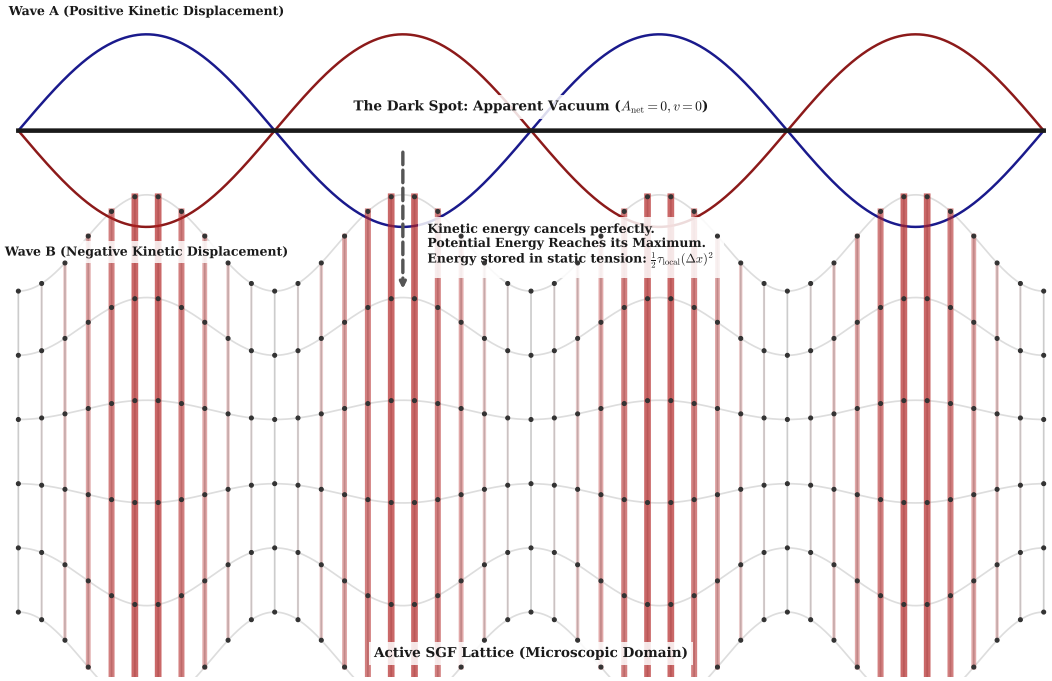

Figure 14.2: **The Mechanics of Destructive Interference.** When two transverse waves meet 180° out of phase, their opposing kinetic vectors perfectly cancel ($v = 0$, $A_{\text{net}} = 0$), producing a macroscopic kinetic "dark spot." However, the total energy is strictly conserved. It converts entirely from dynamic motion into latent static strain within the microscopic TFT lattice. The active structural nodes remain kinetically frozen, but the local potential energy ($\frac{1}{2}\tau_{\text{local}}(\Delta x)^2$) reaches its absolute maximum.

14.5.2 Quantum Tunneling: Evanescent Coupling, Coherent Boundary Control, and Active Knot Transport

Standard Quantum Mechanics describes tunneling as finite wave transmission through a classically forbidden region ($E < V_{\text{B}}$), where the barrier solution is evanescent while total energy remains conserved. Tension Field Theory (TFT) retains this boundary-value structure but assigns it a mechanical interpretation: tunneling is finite coupling of the physical matter order parameter through an evanescent region of the active vacuum.

- **Passive Evanescent Coupling:** A material barrier represents an effective mechanical work threshold V_{B}. When $E < V_{\text{B}}$, the extended matter-wave field cannot sustain a freely propagating branch inside the barrier and instead becomes an evanescent active-vacuum deformation. For finite barrier thickness L, this field remains nonzero at the exit boundary and therefore supports finite transmitted current.

- **Coherent Boundary Control:** A downstream coherent input can modify the complete barrier boundary state. Treating the barrier as a two-port scatterer, incident-side reflection is canceled when the downstream input is matched in both amplitude and phase to the barrier's complex scattering coefficients.

- **Active Knot Transport:** For the uniform rectangular barrier, the reflection-cancelled field

possesses a finite forward phase-action current throughout the barrier. Under the TFT phase-action guidance closure, this controlled matter-order-parameter state determines the corresponding continuous trajectory of the localized topological knot.

Structured barriers may additionally support resonantly enhanced passive transmission when an internal phase-matching condition is satisfied. The full passive, resonant, coherently driven, and active knot-transport constructions are developed in Appendix AA.

The barrier therefore need not disappear mechanically. The extended matter order parameter couples the entrance and exit boundaries through the evanescent active-vacuum region. Passive wave transmission alone does not determine a localized defect trajectory; however, under coherent reflection cancellation, the TFT phase-action guidance closure yields an explicit forward topological-knot transport law.

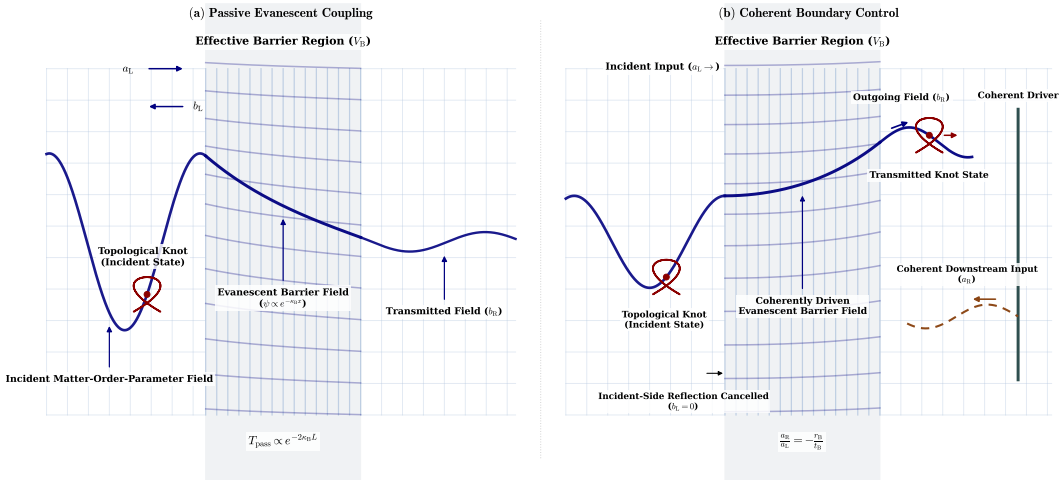

Figure 14.3: **Quantum tunneling as evanescent coupling and coherent boundary control.** The same effective barrier is shown under passive and coherently driven boundary conditions. **Passive:** For $E < V_B$, the matter order parameter becomes evanescent within the finite barrier, producing exponentially suppressed but nonzero transmitted current. **Active:** A coherent downstream input a_R is adjusted so that its contribution cancels the incident-side reflected amplitude b_L. The resulting boundary-matched, coherently driven evanescent field provides the controlled state to which the TFT phase-action guidance closure is applied, yielding the transmitted topological-knot state shown. The barrier remains present in both regimes; coherent control modifies the boundary state rather than removing the barrier.

Transmission Regimes

The tunneling problem is therefore expressed in TFT as a mechanical boundary-value problem with distinct passive and coherently controlled limits.

1. Passive Transmission Scale

For an undriven opaque barrier, the leading transmission suppression is controlled by the dimensionless evanescence depth $\kappa_B L$:

$$T_{\text{pass}} \propto \exp\left(-2\kappa_B L\right), \qquad \kappa_B \equiv \frac{\sqrt{2m(V_B - E)}}{\hbar}. \tag{14.18}$$

Thus, passive transmission decreases exponentially as the barrier becomes thicker or as the excess barrier energy $V_{\mathrm{B}} - E$ increases. This reproduces the standard opaque-barrier exponential dependence while assigning the evanescent branch a physical active-vacuum interpretation.

2. Active Reflection-Cancellation Condition

For a reciprocal symmetric barrier driven coherently from both sides, incident-side reflection vanishes when

$$\frac{a_{\mathrm{R}}}{a_{\mathrm{L}}} = -\frac{r_{\mathrm{B}}}{t_{\mathrm{B}}}. \tag{14.19}$$

Here a_{L} and a_{R} are the incoming complex amplitudes from the source and downstream driver, while r_{B} and t_{B} are the complex reflection and transmission coefficients of the barrier. Because this condition is complex, it fixes both the required drive magnitude and relative phase.

When the condition is satisfied, the downstream input destructively cancels the incident-side reflected field and establishes a coherently controlled scattering state. The right-side output contains contributions from both incident inputs and therefore represents externally assisted boundary control rather than intrinsic removal of the barrier.

3. Active Topological-Knot Transport

For the uniform rectangular barrier, the reflection-cancellation condition gives the explicit downstream drive

$$\frac{a_{\mathrm{R}}}{a_{\mathrm{L}}} = i\frac{V_{\mathrm{B}}}{2\sqrt{E(V_{\mathrm{B}} - E)}} \sinh\left(\kappa_{\mathrm{B}} L\right). \tag{14.20}$$

The resulting boundary-matched field carries a finite forward phase-action current throughout the barrier. Under the TFT guidance closure, the localized topological-knot coordinate $x_K(t)$ obeys

$$\frac{\mathrm{d}x_K}{\mathrm{d}t} = \frac{\hbar k/m}{\cosh^2(\kappa_{\mathrm{B}} x_K) + \dfrac{k^2}{\kappa_{\mathrm{B}}^2}\sinh^2(\kappa_{\mathrm{B}} x_K)}, \qquad 0 \le x_K \le L, \tag{14.21}$$

where

$$k = \frac{\sqrt{2mE}}{\hbar}. \tag{14.22}$$

Every term in the denominator is nonnegative, so the controlled state satisfies

$$\frac{\mathrm{d}x_K}{\mathrm{d}t} > 0 \tag{14.23}$$

throughout the barrier. Within the stationary conservative rectangular-barrier model and the TFT phase-action guidance closure, coherent reflection cancellation therefore determines both the controlled matter-wave state and a continuous forward topological-knot trajectory.

The complete downstream-drive requirement, matter-order-parameter current, traversal time, energy-current balance, weak-relaxation limit, and constitutive regime map are derived in Appendix AA.

14.5.3 The Illusion of the Photonic Particle (The Threshold Gate Mechanism)

Standard quantum mechanics treats the photon as a point-particle carrying a discrete lump of energy, an assumption largely derived from the discrete interactions observed in the photoelectric effect and single-photon detectors. Tension Field Theory (TFT) eliminates the necessity for this

wave-particle duality. In the TFT framework, the "particle" behavior of light is demonstrated to be an artifact of the discrete, quantized nature of the receiver (matter) and the structural medium (the Soft Floor), rather than a geometric property of the photon itself.

The Continuous Wave and the Quantized Target

The interaction between light and matter is mechanically defined as a continuous stress field acting upon a quantized structural defect. This interaction is governed by three specific mechanical states:

- **The Incident Wave (Continuous):** The photon is strictly a continuous 2D transverse phase twist ($\nabla\varphi$) propagating at c_{P}. It possesses no topological knot, no internal radial velocity (v_{int}), and no rest mass. It carries energy hydrodynamically across the contiguous lattice.
- **The Target Knot (Quantized):** The target (e.g., an electron) is a 3D Topological Knot tethered to the FCC Soft Floor. The lattice functions as a stiff resonator that physically rejects non-resonant vibrational modes. As established, a node can only rotate in discrete, whole-cycle packets dictated by the quantum of action ($h = 2\pi \cdot J_{\mathrm{D}} \cdot c_{\mathrm{E}}$).
- **The Threshold Gate (The Interaction):** When the continuous transverse wave impacts the electron knot, the knot cannot absorb the incident elastic energy gradually. Constrained by the strict harmonic limits of the FCC lattice, the electron acts as a mechanical threshold gate. It accumulates the hydrodynamic pressure of the wave until it reaches the exact rotational threshold of h. At this saturation point, the lattice yields, and the knot abruptly snaps to a higher energy state or breaks its tether completely.

Reinterpreting Empirical Particle Observations

By assigning quantization to the local lattice threshold rather than the propagating field, TFT mechanically resolves the foundational empirical proofs of the photonic particle without resorting to stochastic abstractions:

- **The Photoelectric Mechanism:** The discrete ejection of an electron does not prove that light is a localized bullet. It proves that the binding energy of the Topological Knot is locked by the geometric limits of the contiguous medium. The continuous transverse wave provides the tension, but the lattice only yields in quantized structural snaps ($E = h\nu$).
- **Single-Photon Detectors:** When a photomultiplier tube registers a discrete "click," standard physics assumes a single independent particle impacted the screen. TFT demonstrates that the continuous wavefront has reached a localized point of structural instability on the detector's atomic lattice, triggering a localized, quantized release of lattice tension. The measurement event is the mechanical acoustic signature of the receiver snapping under threshold pressure, not a localized particle striking a barrier.
- **Beam Splitter Anti-Correlation (The Non-Linear Sink):** In standard quantum optics, anti-correlation experiments—where a beam splitter directs a highly attenuated signal to two detectors that never fire simultaneously [19]—are heralded as definitive proof of an indivisible photon particle. TFT resolves this via the mechanics of non-linear wave arrest. When the continuous transverse wave reaches the beam splitter, it divides classically, propagating spatial tension toward both detectors. However, measurement is not the arrival of a particle; it is the physical yielding of the detector's lattice structure. Whichever detector's local lattice reaches the structural yield threshold first—even by a fractional margin—becomes a non-linear topological sink. Governed by the Viscous Non-Linear Wave Equation (VNLW), this

localized lattice rupture instantly drains the remaining tension from the contiguous stress field. The wave does not "choose" a path; rather, the first structural collapse entirely dissipates the shared wave energy, mechanically preventing the second detector from reaching its required yield threshold.

Conclusion: The Eradication of Duality

This threshold-gate mechanism eliminates wave-particle duality for light entirely. Matter (Fermion knots) possesses rest mass, internal kinematics (v_{int}), and behaves as a discrete topological defect steered by an extended pilot wave. Light (Boson shear waves) possesses no localized knot and is purely a continuous phase twist. The historical "Duality Paradox" arises solely from mistakenly attributing the quantized, discrete snap of the mechanical detector to the geometry of the incident continuous wave.

Chapter 15

The Vertical Topology: The Graviton, Information, and Quantum Entanglement

Standard physics treats Gravity (a continuous boson field) and Entanglement (a non-local quantum state) as fundamentally unrelated phenomena. Tension Field Theory (TFT) unifies them by identifying the Vertical Topology of the Spacetime Gravitational Floor (SGF). They are, in fact, the mechanical and topological aspects of the exact same underlying lattice structure.

15.1 The Dual-Floor Topology and the Tension Column

To understand this unification, we must cease defining a particle as a zero-dimensional point on a 2D sheet. Instead, a particle is a 3D topological structure spanning a strict dimensional gap called the Thickness of Reality.

- **The Soft Floor (Surface):** The active vibrating lattice where the particle manifests as a localized, radially pulsating node (Breathing Mode at radius $r_{\mathrm{D}} \approx 10^{-26}$ m). This surface vibration generates inertial mass via hydrodynamic impedance (as validated in Appendix F).
- **The Hard Floor (Substrate):** The ultra-dense, phase-locked core (pixel spacing $\ell_{\mathrm{S}} \approx 10^{-35}$ m) where the latent physics of the universe is permanently recorded.
- **The Tension Column:** The physical longitudinal connection extending from the dynamic pulsating surface node down to its static substrate anchor.

Every particle on the observable Soft Floor is merely the surface termination of a Tension Column anchored deeply to the Hard Floor.

15.2 The Graviton: Mechanical Stress and the Dynamic Cursor

As a localized wave propagates across the Soft Floor, it drags its Tension Column through the discrete Hard Floor addresses. Because the wave possesses finite energy, this displacement creates a localized longitudinal strain field in the deeper substrate.

In TFT, the graviton is not an independent exchange particle (a spin-2 boson); it is the dynamic strain shadow—a longitudinal phonon of strain—dragged across the Hard Floor. The substrate

pixels themselves do not translate; rather, the graviton acts as an active structural state (a cursor) tracking the primary transverse wave. Gravity is strictly the elastic response of the substrate to the downward mechanical stress of this column.

The Geometric Coupling and the Hierarchy Problem

Standard physics struggles to explain why gravity is phenomenologically vastly weaker than electromagnetism (The Hierarchy Problem), often resorting to non-physical extra dimensions or arbitrary constants. TFT resolves this entirely through discrete lattice mechanics.

As proven in Appendix AB, the gravitational strain ($\alpha_{\mathrm{G},\gamma}$) induced by a propagating photon is strictly defined by the geometric ratio between the fundamental Substrate lattice spacing (ℓ_{S}) and the macroscopic wavelength (λ) of the wave:

$$\alpha_{\mathrm{G},\gamma} = 2\pi \left(\frac{\ell_{\mathrm{S}}}{\lambda} \right)^2 \tag{15.1}$$

This fractional strain scales the total transverse energy of the photon to yield the absolute longitudinal energy of its accompanying graviton wake:

$$E_{\mathrm{g}} = \frac{h^2 G}{c_{\mathrm{E}}^2 \lambda^3} \tag{15.2}$$

The Numerical Resolution: To demonstrate the natural emergence of this weakness, consider a standard visible photon ($\lambda \approx 500$ nm).

- The primary transverse vibrational energy (the photon) is $E_\gamma \approx 10^{-19}$ J.
- The resulting longitudinal strain energy (the graviton) is $E_{\mathrm{g}} \approx 10^{-75}$ J.

This yields a strict, deterministically derived scaling ratio of $\approx 10^{-56}$.

Gravity is not an inherently weak fundamental force; it is mathematically proven here to be the secondary, localized elastic cost of a primary transverse vibration. By defining the graviton as the geometric shadow of the photon, TFT naturally eliminates the Hierarchy Problem entirely from first principles.

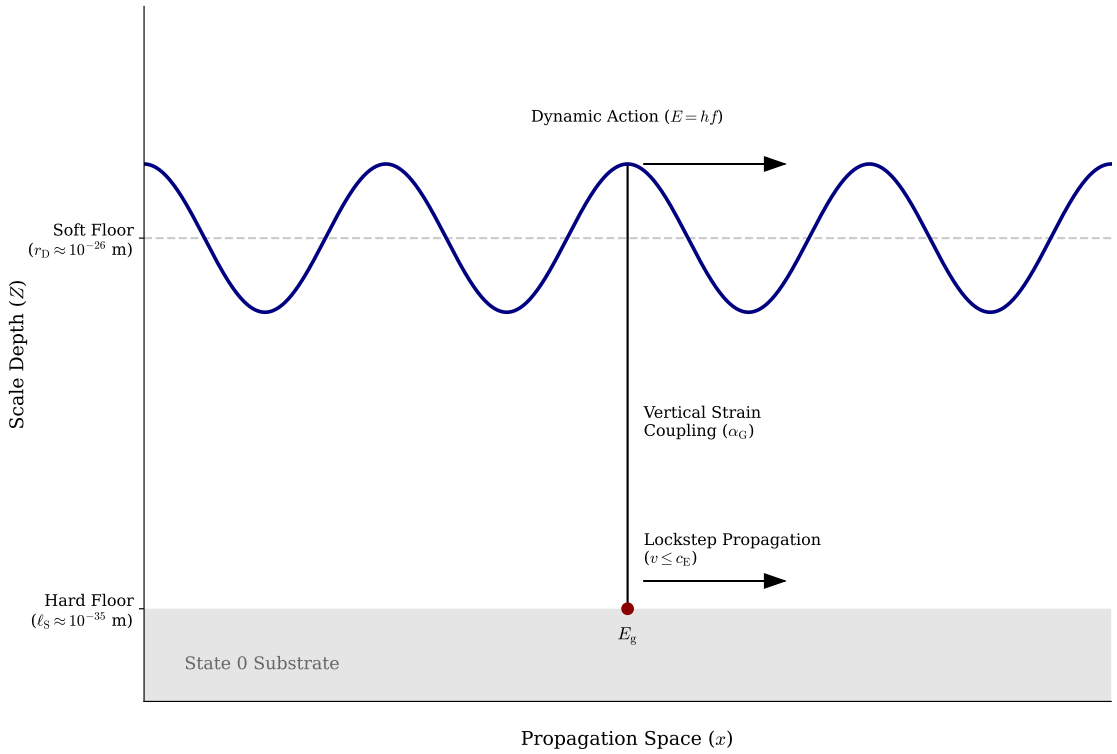

Figure 15.1: **Graviton — The Strain Shadow to the Hard Floor.** This schematic illustrates the vertical topology of a propagating wave. A primary transverse wave on the Soft Floor ($r_{\mathrm{D}} \sim 10^{-26}$ m) is mechanically tethered to the flat, unyielding Hard Floor ($\ell_{\mathrm{S}} \sim 10^{-35}$ m) via a rigid Tension Column. The geometric magnitude of this tether is the vertical strain coupling ($\alpha_{\mathrm{G},\gamma}$, see Eq. 15.1). As the primary wave propagates ($v \leq c_{\mathrm{E}}$), this column drags a highly localized, high-stress contact point—the Graviton—across the rigid substrate in perfect lockstep, carrying a longitudinal strain energy (E_{g}, see Eq. 15.2). The graviton is therefore not an independent exchange particle, but the requisite elastic response of the active vacuum pressing against the immovable substrate due to the wave's dynamic action.

15.3 The Holographic Record: Information as Lattice Strain

Because the Graviton acts as a physical cursor dragging across the perfectly rigid SC Substrate, its interaction is not transient. As established in Definition V, the localized downward stress exerted by the dynamic Soft Floor is continuously encoded within the Hard Floor as a discrete longitudinal strain configuration—a physical topological footprint.

Therefore, the Graviton is not merely a mechanical anchor; it constitutes the fundamental unit of physical Information (N).

Standard physics often conflates information with thermodynamic entropy (dynamic chaos). In Tension Field Theory, information is strictly geometric. It is the permanent, static mechanical ledger of the universe, safely preserved within the latent potential of the rigid substrate.

As formally derived in Appendix AB, the information footprint of any dynamic state scales inversely with its macroscopic gravitational strain, with the normalization fixed by the topology of the carrier. For the propagating-wave branch ($N_\gamma = 1/\alpha_{\mathrm{G},\gamma}$), whereas localized matter carries the additional 2π winding normalization ($N_{\mathrm{m}} = 2\pi/\alpha_{\mathrm{G,m}}$). This Information-Energy Inverse Law

dictates that a state's information footprint is governed by its spatial localization:

- **Waves (Kinematic Identity):** An untethered propagating wave (e.g., a photon) possesses a macroscopic wavelength, gently distributing its topological footprint across a massive, delocalized array of discrete substrate nodes ($N_\gamma \approx 10^{56}$).
- **Matter (Inertial Identity):** Conversely, when energy condenses into localized invariant inertial mass (m_i), it withdraws its extended footprint. As formally derived in Appendix AB, this geometry is governed by the absolute universal Substrate Mass Potential (m_S), scaling as $N_\mathrm{m} = 2\pi(m_\mathrm{S}/m_\mathrm{i})^2$. It focuses intense mechanical strain onto a highly concentrated cluster of substrate bits, culminating at the absolute mass limit ($m_\mathrm{i} \to m_\mathrm{S}$) where the footprint reduces to exactly one fundamental geometric phase rotation ($N \to 2\pi$).

Ultimately, the Vertical Topology provides the absolute mechanical guarantee for Quantum Unitarity. As derived in Appendix AB, the structural yield strength of a single Hard Floor node ($\approx 10^9$ J) exceeds the energy of a single written data bit ($E_\mathrm{g} \approx 10^{-75}$ J) by an astounding 84 orders of magnitude. The dynamic, chaotic actions of the active Soft Floor can never mechanically fracture or thermally erase the underlying substrate.

Therefore, information is continuously and permanently written into the immutable structural memory of the Hard Floor. (The macroscopic consequence of this indestructible volumetric storage—and its definitive resolution of the Black Hole Information Paradox [20]—is fully explored in Section 12.6 and Appendix T).

15.4 Quantum Entanglement: The Topological Tether (The Goalpost Topology)

Standard physics claims entangled particles share a non-local wavefunction that mysteriously ignores space. Tension Field Theory (TFT) demonstrates that they share a physical topological connection across the substrate. Entanglement is a Goalpost Topology.

When entangled particles A and B are born together, they initially share a single anchor on the Hard Floor. As they separate, they maintain their strictly independent, perpendicular Tension Columns and local gravitational dimples (g_A and g_B). However, they leave behind a Residual Phase-Tether—a continuous line of microscopic longitudinal strain connecting them directly along the rigid substrate.

(The geometric limits of this permanent correlation, including the modified CHSH inequality [21], are detailed in Appendix AC, while the mechanics of temporary phase crosstalk via transient strain overlap are formalized in Appendix AD).

The Goalpost Architecture:

- **Separation:** On the Soft Floor, Particles A and B may be separated by vast cosmic distances.
- **Connection:** On the Hard Floor, they remain mechanically linked by the residual phase-tether. While their spatial distance is non-zero, their operational transit time is strictly zero ($\Delta t \to 0$).

15.4.1 Resolution of Bell's Theorem (Dimensional Non-Locality)

Standard quantum mechanics relies on Bell's Theorem [22] to rule out "local hidden variables," proving that entanglement must be fundamentally non-local. TFT perfectly satisfies Bell's inequality by providing a deterministic mechanism for this non-locality. The Goalpost Topology does

not violate Bell's Theorem because the connection is dimensionally non-local relative to the active vacuum. The particles do not communicate across the 3D Soft Floor; their physical connection bypasses the observable manifold entirely, routing through the absolute depth of the Hard Floor. This replaces the probabilistic "spooky action at a distance" of the wavefunction with a deterministic, dimensionally displaced mechanical bridge.

15.4.2 The Mechanism of Instantaneous Action

If a detector applies torque to Particle A (by measuring its spin), that mechanical twist is transmitted straight down its Tension Column to its local graviton anchor (g_{A}). The signal does not travel transversely across the universe through the Soft Floor bulk; it travels longitudinally across the Hard Floor phase-tether to g_{B}, and instantly up to Particle B.

Because the Hard Floor is a fully saturated, perfectly rigid potential, it cannot support transverse waves. However, its longitudinal tension transmission is effectively infinite. The propagation speed (c_{S}) through any mechanical medium is governed by the ratio of its structural stiffness (τ_{S}) to its dynamic inertia (μ_{S}):

$$c_{\mathrm{S}} = \sqrt{\frac{\tau_{\mathrm{S}}}{\mu_{\mathrm{S}}}} \tag{15.3}$$

Because the fully saturated substrate is perfectly rigid ($\tau_{\mathrm{S}} \to \infty$) and possesses virtually zero free dynamic inertia to resist longitudinal stress ($\mu_{\mathrm{S}} \to 0$), the resulting stress transmission speed is effectively infinite ($c_{\mathrm{S}} \to \infty$).

15.4.3 Preservation of Special Relativity and Causality (Result of Measurement)

While the transmission of stress across the Hard Floor is instantaneous, it does not violate the causal speed limit (c_{E}) of Special Relativity. We must strictly differentiate between kinematic signals and stress equilibration:

- **Kinematic Signals (Usable Information):** Require the transfer of transverse energy across the Soft Floor, which is strictly speed-limited by the surface inertia of the lattice.
- **Stress Equilibration (Entanglement):** The Hard Floor cannot support transverse waves or localized energy packets. It only supports the instantaneous equilibration of longitudinal static stress.

Therefore, the mechanical result of a measurement unfolds as follows:

- Stress transfer across the tether is instantaneous.
- This forces immediate phase-locking (the strict conservation of angular momentum) across the universe.
- Because this is strictly longitudinal stress equilibration, no macroscopic causal information is transmitted faster than c_{E}, perfectly preserving Special Relativity.
- Upon measurement, the extreme energy of the applied macroscopic torque overloads the localized microscopic tension budget, snapping this fragile phase-tether.
- The entanglement is permanently destroyed, while the primary vertical gravitational columns remain perfectly intact.

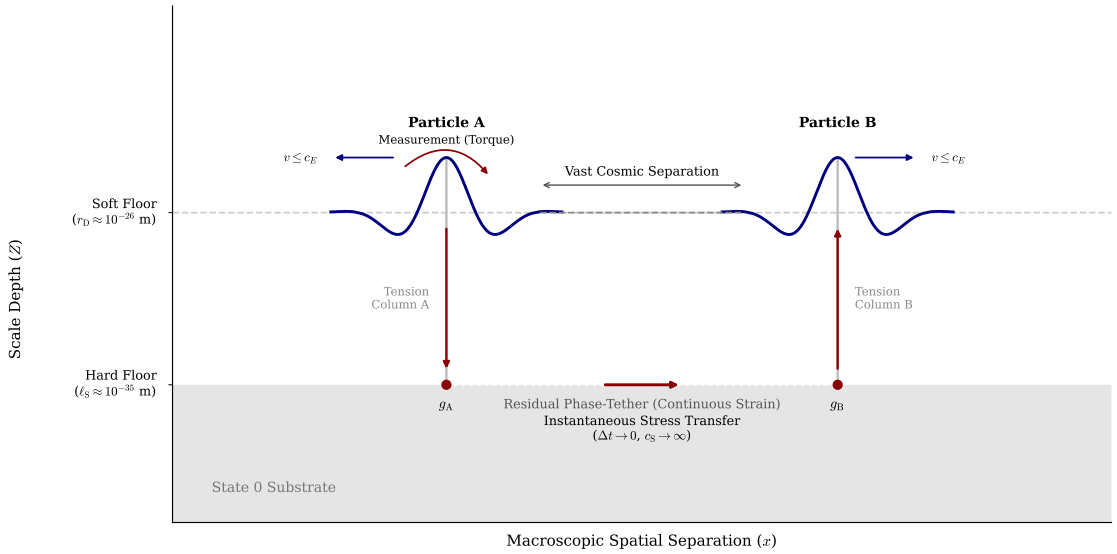

Figure 15.2: **Quantum Entanglement: The Goalpost Topology.** This schematic illustrates the mechanical resolution to quantum non-locality. As entangled Particles A and B separate across macroscopic distances on the Soft Floor ($r_{\mathrm{D}} \approx 10^{-26}$ m, $v \leq c_{\mathrm{E}}$), they maintain their independent, perpendicular Tension Columns extending down the Scale Depth (Z) to local gravitational contact points (their respective gravitons, g_{A} and g_{B}). However, due to their shared topological origin, they remain linked by a delicate Residual Phase-Tether—a continuous line of microscopic longitudinal stress directly along the flat, perfectly rigid Hard Floor ($\ell_{\mathrm{S}} \approx 10^{-35}$ m). When measurement torque is applied to Particle A, the mechanical stress drops to its anchor and transfers instantaneously across this incompressible substrate ($\Delta t \to 0$, $c_{\mathrm{S}} \to \infty$) to Particle B. This geometric framework permits immediate phase-locking—forcing Particle B to instantly assume its correlated quantum state to conserve angular momentum—without violating the causal speed limit of the active vacuum above.

15.5 The Grand Unification of the Kinematic Budget

We can now state the fundamental TFT identity: Gravity and entanglement are orthogonal manifestations of the Tension Column's topology.

- **Gravity (Mechanical / Vertical):** The restorative radial tension gradient within the elastic Soft Floor, induced by the localized structural deficit ($\tau_{\mathrm{S}} - \tau_{\mathrm{L}}$) at the anchor ($E_{\mathrm{S}}$). The dynamic lattice actively contracts to restore the rigid equilibrium of the underlying Hard Floor, physically pulling inertial mass from regions of high static potential toward the topological defect.
- **Entanglement (Topological / Horizontal):** The physical connectivity of the local anchors (g_{A} and g_{B}) across the Hard Floor via the Residual Phase-Tether, resulting in instantaneous stress transmission and phase-locking.

Because both phenomena rely on the finite structural capacity of the structured vacuum (the invariant kinematic budget, c_{E}^2), they are mechanically inextricably linked. As proven in Appendix AC, the macroscopic gravitational saturation (α_{G}) and the microscopic topological coupling (α_{Q})

must compete for the exact same local tension budget. This yields the strict zero-sum identity:

$$\alpha_{\mathrm{Q}} = 1 - \alpha_{\mathrm{G}} \tag{15.4}$$

Implications of the Identity:

- This equation dictates that strong gravitational fields physically consume the structural slack required to maintain phase correlations.
- As macroscopic strain approaches saturation ($\alpha_{\mathrm{G}} \to 1$), microscopic connectivity is mechanically severed.
- The heavier the environmental gravitational load becomes, the less slack remains in the structural budget to sustain the horizontal topological connection.

Chapter 16

Grand Unification of the Fundamental Forces

In Tension Field Theory (TFT), there are no distinct "fundamental forces," nor are there arbitrary exchanges of force-carrying gauge bosons. There is only one source of physical action: Lattice Stress (τ).

As established in the foundational definitions of TFT in Part I:

- **Energy** is the fundamental measure of scalar tension integrated over a volume:

$$E = \tau \cdot V \equiv \hbar \cdot \left(\frac{\partial \varphi}{\partial t} \right) \tag{16.1}$$

- **Force** is the restorative vector field generated by the vacuum's tendency to minimize a phase defect and return local topology to equilibrium:

$$F = -\nabla \tau \cdot V \equiv -\nabla \varphi \cdot E \tag{16.2}$$

Mechanically, a physical force is simply the relaxation of geometric stress. The four observed fundamental interactions are strictly the four geometric modes by which the Spacetime Gravitational Floor (SGF) resolves this stress.

16.1 The Geometric Modes of Stress Relaxation

The hierarchy of forces arises from how the universal tension gradient ($-\nabla\tau$) is projected through the active lattice:

- **The Strong Force (The Bond Pull):** 1D Normal Vector elasticity. It is the direct internal tension of the lattice links resisting separation.
- **Electromagnetism (The Twist):** 2D Transverse Vector shear. It is the torsional strain propagating outward from a stable, topologically locked phase defect.
- **The Weak Force (The Slip):** 3D Axial Vector torque. It is a mechanical yield limit—the structural threshold where the lattice "slips a gear" to reconfigure a knotted state.
- **Gravity (The Restorative Pull):** Restorative Radial Tension. It is the active contraction of the elastic lattice—acting from within—attempting to heal a structural deficit and return to the equilibrium state of the Hard Floor.

16.2 The Master Geometric Law: Structural Mass Moment and Topology-Normalized Invariant

To quantify these four mechanical modes, we define the effective structural density of the vacuum at any radial scale using a universal scaling law.

The Fundamental Scaling Equation:

$$\rho(r) = \mathcal{F}_i \cdot \rho_{\mathrm{S}} \left(\frac{\ell_{\mathrm{S}}}{r} \right)^4 \tag{16.3}$$

- ρ_{S}: The absolute invariant density of the SC Substrate ($\approx 5.15 \times 10^{96}$ kg/m^3).
- ℓ_{S}: The fundamental gravitational pixel limit ($\approx 1.62 \times 10^{-35}$ m).
- $\mathcal{F}_i$: The Topological Form Factor (1.5 for the spherical nodes of the active vacuum; 1.0 for the vortex loops of fundamental nucleons).

This inverse-fourth-power scaling is strictly required by classical mechanics to conserve the universal quantum of action ($\hbar \propto \hat{J}$) across all geometric scales. As established in Appendix G, we define this capacity product as the raw structural mass moment ($J_i = \rho_i r_i^4$), which is a geometric projection of the absolute topology-normalized Scale-Invariant Mass Moment ($\hat{J} \equiv J_i / \mathcal{F}_i$).

All fundamental forces in TFT emerge from projecting this scale-dependent density through the foundational mechanical tension equation ($\tau = \rho(r) c_{\mathrm{E}}^2$). *(Note: Full multi-scale dimensional derivations for all forces are provided in Appendix AH).*

16.3 The Strong Force: 1D Normal Tension (The Bond Pull)

The Strong Nuclear Force acts as a one-dimensional linear flux tube. Because the tension remains strictly focused along a 1D line rather than diluting over a spherical area, it operates as a constant elastic pull. The magnitude is the local tension multiplied by the 2D cross-sectional area of the confinement channel (A_{chan}).

For a fundamental nucleon ($\mathcal{F}_i = 1.0$), we utilize the mechanical nucleon radius ($r_{\mathrm{N}} \approx 0.88$ fm), which represents the true structural boundary of the lattice knot, independent of the internal electric charge distribution halo (0.84 fm). The Master Equation yields an effective localized density of $\rho_{\mathrm{eff}} \approx 5.8 \times 10^{17}$ kg/m^3.

TFT Equation:

$$T_{\mathrm{s}} = \rho_{\mathrm{eff}} c_{\mathrm{E}}^2 A_{\mathrm{chan}} \tag{16.4}$$

Topological Substitution: For the rim-like cross-section of a cylindrical flux tube, $A_{\mathrm{chan}} = 2\pi r_{\mathrm{N}}^2$.

$$T_{\mathrm{s}} = 2\pi \rho_{\mathrm{eff}} c_{\mathrm{E}}^2 r_{\mathrm{N}}^2 \tag{16.5}$$

Interpretation: Evaluating this 1D geometric projection yields a confinement force of $T_{\mathrm{s}} \approx 2.56 \times 10^5$ N ≈ 1.6 GeV/fm. This strictly recovers the observed QCD confinement scale limits ($1.0 - 2.0$ GeV/fm) without arbitrary tuning parameters.

16.4 Electromagnetism: 2D Transverse Shear (The Twist)

Electromagnetism emerges as the transverse shear stress generated by a permanent topological kink. Rather than an arbitrary dimensionless number, the fine-structure constant (α) is a strict geometric survival ratio. It represents the exact mechanical efficiency of the Absolute Lattice Shear Coupling (K_{L}) capturing the local action budget ($\hbar c_{\mathrm{E}}$) on the 2D surface of a Soft Floor node.

Because charge is confined to the surface-shear geometry of the FCC Soft Floor, it is strictly governed by the local tangent topology of the node.

TFT Equation:

$$\alpha = \frac{K_{\mathrm{L}}}{\hbar c_{\mathrm{E}}} \tag{16.6}$$

Interpretation: As derived in Appendix AE and in Appendix AF, the magnitude of α is not an empirical mystery. It is fixed by the combinatorial geometry of an FCC spherical node: the 144 local short-return self-healing channels competing against the boundary-minimizing coherence of the global hemispheric dipole. Evaluating this absolute spatial tension against the local transverse closure network flawlessly recovers the fine-structure constant ($\alpha \approx 1/137.036$). This mathematically proves that electromagnetism is not an independent force, but the specific 2D surface-shear mode of the exact same lattice tension that generates gravity and the strong force.

16.4.1 The Macroscopic SI Baseline (k_{e} and e)

To translate the absolute spatial tension of the Soft Floor into macroscopic human units, we must isolate the historical construction of the SI system. In standard physics, the Coulomb constant (k_{e}) and elementary charge (e) are treated as fundamental properties. In TFT, they are strictly recognized as derived macroscopic translations of the vacuum's structural elasticity (c_{E}^2).

When the historical SI system defined the Ampere, it mathematically locked the magnetic permeability of the vacuum (μ_0) to exactly $4\pi \times 10^{-7}$ N/A^2. Although the 2019 SI redefinition inverted this dependency, the macroscopic magnitude of our unit system was permanently anchored by this choice. Because the absolute elasticity of the Soft Floor (c_{E}^2) perfectly links the electric and magnetic structural responses ($c_{\mathrm{E}}^2 = 1/(\mu_0\epsilon_0)$), this human baseline strictly forces the macroscopic value of the electrostatic constant. It is simply the Soft Floor's raw stiffness scaled by the historical SI Ampere baseline of 10^{-7}:

$$k_{\mathrm{e}} = 10^{-7} \cdot c_{\mathrm{E}}^2 \approx 8.987 \times 10^9 \ \mathrm{N \cdot m^2/C^2} \tag{16.7}$$

Consequently, the elementary charge (e) is not a physical substance. Because the macroscopic coupling strength ($k_{\mathrm{e}}e^2$) is the direct SI translation of the Absolute Lattice Shear Coupling (K_{L}), charge is merely the dimensional conversion factor bridging absolute vacuum topology to human units (derived formally in Appendix AG):

$$e = \sqrt{\frac{K_{\mathrm{L}}}{k_{\mathrm{e}}}} \approx 1.602 \times 10^{-19} \ \mathrm{C} \tag{16.8}$$

16.4.2 The Mechanical Identity of Permeability (μ_0) and Permittivity (ϵ_0)

Standard physics offers no physical mechanism for why empty space possesses specific electromagnetic constants. In TFT, because light is a transverse shear wave propagating through the FCC lattice, Maxwell's wave equation is recognized as the direct equivalent of classical continuum mechanics, where v^2 = Stiffness/Inertia. By mapping the equations ($c_{\mathrm{E}}^2 = (1/\epsilon_0)/\mu_0$), the physical mechanisms are unmasked:

- **Electric Permittivity (ϵ_0)** is the Transverse Shear Compliance of the lattice. An electric field is a static transverse strain. Permittivity represents how much the lattice yields. Its inverse ($1/\epsilon_0$) is the active Shear Modulus driving the wave forward.
- **Magnetic Permeability (μ_0)** is the Torsional Inertia of the lattice. A magnetic field represents dynamic propagation. To pass a transverse wave, the spherical nodes of the FCC lattice must rotate. Permeability is the literal rotational inertia of the nodes resisting this gyroscopic acceleration.

16.5 The Weak Force: 3D Torsional Slip (The Slip)

The Weak Force is an unstable slip (yield stress limit). It operates via Defect Focusing: the volume of a hadronic cell is topologically compressed into the Compton volume of a W-boson ($r_{\mathrm{w}} \approx 10^{-18}$ m). This extreme geometric funneling spikes the local torque, creating the activation energy required to snap and reconfigure the defect volume (V).

TFT Equation:

$$G_{\mathrm{F}} = (\rho(r_{\mathrm{w}})c_{\mathrm{E}}^2 V)^{-2} \tag{16.9}$$

Topological Substitution: Because the weak interaction is an axial torsional slip rather than a static sphere of pressure, the activation energy requires sweeping the defect core (r_{w}^3) through one full topological phase rotation (2π radians) to slip its winding. Thus, the effective phase volume is $V = 2\pi r_{\mathrm{w}}^3$.

$$G_{\mathrm{F}} = (2\pi\rho(r_{\mathrm{w}})c_{\mathrm{E}}^2 r_{\mathrm{w}}^3)^{-2} \tag{16.10}$$

Interpretation: This volumetric projection produces $G_{\mathrm{F}} \approx 10^{-5}$ GeV^{-2}, correctly matching the observed weak-scale suppression limit.

16.6 Gravity: Restorative Radial Tension (The Restorative Pull)

Gravity is the restorative radial tension gradient of the Spacetime Lattice acting to suppress energetic vibration. Induced by a localized structural deficit (mass), the dynamic elastic lattice actively contracts to restore the rigid equilibrium of the underlying Hard Floor. Mechanically, it pulls inertial mass from regions of high static potential (vacuum) toward the topological defect.

TFT Equation:

$$\alpha_{\mathrm{G}} = \frac{\kappa\rho_{\mathrm{eff}}GR^2}{c_{\mathrm{E}}^2} \tag{16.11}$$

Interpretation: Governed by the Volumetric Configuration Parameter for spherical matter ($\kappa = 4\pi/3 \approx 4.19$), this geometric projection yields $\alpha_{\mathrm{G}} \approx 10^{-39}$ for nucleon–nucleon interaction at 1 fm, flawlessly recovering the gravitational coupling across all scales of the active lattice.

16.7 The Structural Representation (The Unified Mass Moment Equations)

While the forces physically manifest through the standard geometric projections of localized density (ρ) across areas and volumes, the foundational Master Geometric Law ($\rho = J_i/r^4$) dictates that

all four fundamental interactions can be mathematically reduced to pure expressions of the raw structural mass moment ($J_i = \mathcal{F}_i \hat{J}$).

- **Electromagnetism (Transverse Twist):**

$$\alpha = \frac{K_{\mathrm{L}}}{c_{\mathrm{E}}^2 J_{\mathrm{N}}} \tag{16.12}$$

- **The Weak Force (Axial Torque):**

$$E_{\mathrm{weak}} = \frac{2\pi J_i c_{\mathrm{E}}^2}{r_{\mathrm{w}}} \tag{16.13}$$

- **The Strong Force (Normal Pull):**

$$T_{\mathrm{s}} = \frac{2\pi J_i c_{\mathrm{E}}^2}{r_{\mathrm{N}}^2} \tag{16.14}$$

- **Gravity (Radial Dilution):**

$$\alpha_{\mathrm{G}} = \frac{\kappa J_i G}{c_{\mathrm{E}}^2 r^2} \tag{16.15}$$

This reduction strictly proves that mass, charge, confinement, and decay are not independent physical phenomena; they are simply the $1/r$, $1/r^2$, and $1/J_i$ geometric shadow-projections of a single absolute structural invariant ($\hat{J}$).

16.8 Falsifiable Predictions of the TFT Unification

Because all fundamental forces in TFT are mechanically bound by the same absolute topology-normalized Scale-Invariant Mass Moment ($\hat{J}$), the theory makes strict, testable predictions regarding the correlation of coupling constants in extreme environments:

- **In-Medium Confinement Tracking:** The string tension (T_{s}) is strictly governed by the projection of the raw structural mass moment across a 2D area ($\propto J_i/r^2$). Therefore, in dense nuclear media (e.g., neutron star crust analogs) where the effective hadronic radius (r) is severely compressed, the QCD confinement scale must exhibit correlated, predictable geometric scaling.
- **Correlated Weak/EM Shifts:** If extreme localized phases alter the effective structural density (ρ) or radius (r) of a nucleon, the weak decay rates (G_{F}) and the fine-structure constant (α) must shift coherently, governed strictly by their shared sensitivity to the absolute topology-normalized invariant ($\hat{J}$).
- **No Long-Range Weak Tails:** Because the weak interaction is a topological defect kernel bounded by r_{w}, its amplitude strictly follows an exponential spatial falloff. Any observation of a power-law tail in weak processes at scales $r \gg r_{\mathrm{w}}$ would fundamentally falsify the defect-kernel mechanism.

16.9 Conclusion: The Restorative Lattice and the Geometric Equilibrium

The hierarchy of forces is a geometric necessity, not a statistical accident. In Tension Field Theory, there are no independent forces traversing the void. There is only the latent structural integrity of the Spacetime Gravitational Floor ($\tau = \rho c_{\mathrm{E}}^2$).

The observable universe is a state of dynamic mechanical equilibrium between two opposing geometric realities, governed exactly by the mathematical inversion of their fundamental constants:

- **The Action of Existence (Outward Displacement — $\hbar \propto \hat{J}$):** A quantum state is a dynamic topological wave. Its fundamental nature is kinetic vibration—a continuous outward geometric displacement generating the quantum of action. The three "quantum" forces are strictly the internal mechanics of how a topological knot survives and maintains this existence against the crushing tension of the vacuum:
  - *The Strong Force* is the undiluted 1D fractal mirror of the substrate's latent yield strength. It acts as an internal structural tether, pulling back against the knot's own violent kinetic vibration to prevent the composite wave from stretching apart.
  - *Electromagnetism* is the stable, topologically locked 2D transverse shear (The Twist) that prevents the outward-vibrating wave from being smoothly untied. Because the absolute spatial tension (K_{L}) is strictly the geometric survival ratio of temporal action ($\hbar$) captured on the FCC surface, Charge is fundamentally the spatial counterpart to Spin.
  - *The Weak Force* is the structural yield limit (The Slip)—the exact 3D geometric threshold where the vacuum's restorative tension finally overcomes the knot's internal torque, forcing the volume to mechanically fracture and reconfigure.
- **The Restorative Tension (Inward Pull — $G \propto 1/\hat{J}$):** Operating as the precise mathematical and mechanical inverse to the action of existence, Gravity is the bulk 3D radial pull of the surrounding elastic lattice continuously attempting to heal these topological defects. It actively contracts, pulling inward across all scales in a relentless attempt to crush the vibration and restore the perfectly flat, rigid equilibrium of the latent Hard Floor.

Therefore, the fundamental interactions are not separate laws of nature, but strictly geometric stress-responses of a single, unified Spacetime Gravitational Floor, representing a universe where the dynamic geometric action of existence ($\hbar$) is perfectly counterbalanced by the restorative tension of the vacuum (G).

16.10 Summary Table

Table 16.1: Summary of Unified Mechanical Modes

Force (Scale)	**TFT Mechanism**	**Geometry / Analogy**	**Nucleon / Soft Floor Equation**	**Standard Physics Eqv.**
Strong	Direct Normal Tension	1D Line (The Bond Pull)	$T_{\mathrm{s}} = 2\pi\rho_{\mathrm{eff}} c_{\mathrm{E}}^2 r_{\mathrm{N}}^2$	QCD confinement
Electromagnetism	Transverse Shear	2D Surface (The Locked Twist)	$\alpha = \frac{K_{\mathrm{L}}}{\hbar c_{\mathrm{E}}}$	Fine-structure constant
Weak	Yield Stress / Torque	3D Axial (The Gear Slip)	$G_{\mathrm{F}} = (2\pi\rho(r_{\mathrm{w}}) c_{\mathrm{E}}^2 r_{\mathrm{w}}^3)^{-2}$	Fermi constant
Gravity	Restorative Radial Tension	Volume (The Restorative Pull)	$\alpha_{\mathrm{G}} = \frac{\kappa\rho_{\mathrm{eff}} G R^2}{c_{\mathrm{E}}^2}$	Gravitational coupling

Chapter 17

The Mechanical Foundations of the Hydrogen Atom

In standard quantum mechanics, the atom is modeled as a probabilistic point-particle system where the electron exists in a statistical "cloud" of potential. Tension Field Theory (TFT) replaces this mathematical abstraction with a strictly deterministic, FCC lattice-dynamic geometric architecture. In TFT, the atom is a macro-structural topological defect within the contiguous Soft Floor lattice, where mass and charge are mechanically isolated into hydrodynamic impedance and chiral torsion, respectively. By isolating the simplest possible composite system, we establish the baseline mechanical rules that govern all atomic matter.

This framework resolves the physical geometry of the Hydrogen atom into three distinct mechanical zones: the Torsional Anchor (Nucleus), the Resonant Standing Wave Boundary (Electron Shell), and the Bipolar Strain Field that connects them.

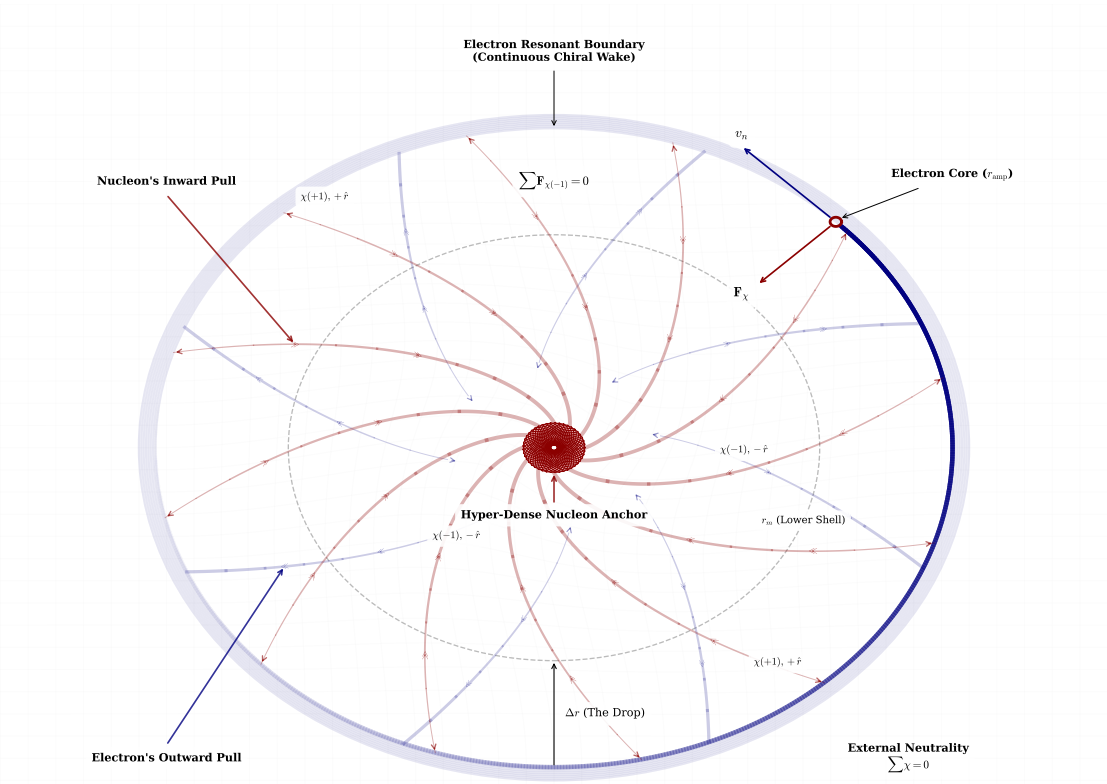

Figure 17.1: **The TFT Hydrogen Atom — A Topological Torsion Resonator.** A deterministic, lattice-dynamic cross-section of the Hydrogen atom within the contiguous Soft Floor lattice. The system is mechanically divided by opposing topological torsions:
1. The central hyper-dense proton acts as a Torsional Anchor, radiating a Right-Handed ($\chi = +1$) structural torsion that propagates outward ($+\hat{r}$) while exerting a dominant restorative inward mechanical pull.
2. To survive this chiral tension, the localized electron core races tangentially (v_n), generating a time-averaged Left-Handed ($\chi = -1$) continuous chiral wake that forms the Resonant Boundary. The electron's field propagates inward ($-\hat{r}$) but exerts a secondary outward pull.
3. Inside the boundary, the electron's uniform outward radial pulls geometrically cancel ($\sum \mathbf{F}_{\chi(-1)} = 0$ via the Topological Shell Theorem), leaving the proton's inward structural pull as the dominant force (F_χ) acting upon the racing electron.
4. Outside the boundary, the two opposing chiral fields perfectly superimpose, resulting in macroscopic External Neutrality ($\sum \chi = 0$).
5. The diagram additionally illustrates the geometric gap (Δr) corresponding to a photonic extrusion drop to a lower kinetic shell (r_m).

17.1 The Nucleus: The Torsional Anchor

The proton is a specific chiral instance of the fundamental nucleon structure. It is not a localized, intrinsic point-charge; it is a hyper-dense, composite topological node. Because of its extreme

inertial mass, generated by hydrodynamic impedance against the vacuum condensate, it acts as a nearly static anchor within its local region of the Soft Floor continuum.

The physical boundary of this nucleon vortex is locked at the femtometer scale:

$$r_{\mathrm{N}} \approx 0.88 \times 10^{-15} \text{ m} \tag{17.1}$$

At this extreme structural compression, the effective density of the lattice rises to:

$$\rho_{\mathrm{eff}} \approx 5.85 \times 10^{17} \text{ kg/m}^3 \tag{17.2}$$

This density generates a strictly geometric confinement tension. Expressed as a simplified equivalent form of the one-dimensional flux-tube cylindrical projection (derived fully in Appendix AH), this yields the empirical strong-force threshold without requiring distinct gauge bosons:

$$F_{\mathrm{strong}} = \rho_{\mathrm{eff}} \cdot c_{\mathrm{E}}^2 \cdot 2\pi r_{\mathrm{N}}^2 \approx 1.6 \text{ GeV/fm} \tag{17.3}$$

This hyper-dense core continually imposes a right-handed topological torsion on the surrounding lattice, thereby defining its positive chiral charge ($\chi = +1$). While the underlying torsional potential decays as $1/r$, the physical force exerted on secondary nodes is the spatial gradient of that potential. Therefore, the proton's structural force decays strictly via the inverse-square law ($1/r^2$), recovering the empirical behavior of standard electrostatics as a natural geometric consequence of three-dimensional spherical divergence.

17.2 The Electron: The Standing-Wave Boundary

The electron operates at the opposite extreme of the structural spectrum. It is a fundamental node with a microscopic "Breathing Mode" amplitude of:

$$r_{\mathrm{amp}} \approx 10^{-33} \text{ m} \tag{17.4}$$

as derived in Appendix F, generating its minute neutral impedance-mass, while its internal 720° tethered rotation generates a left-handed ($\chi = -1$) intrinsic torsion.

If this low-impedance knot were stationary near the proton, the proton's massive topological tension would crush it inward almost instantly. To survive, the localized electron node must maintain an extreme transverse orbit. This orbital boundary condition is required to satisfy the structural coupling limit of the nucleon's Structural Mass Moment:

$$J_{\mathrm{N}} = \rho_{\mathrm{N}} r_{\mathrm{N}}^4 \approx 3.51 \times 10^{-43} \text{ kg} \cdot \text{m} \tag{17.5}$$

Using the derived absolute lattice shear coupling ($K_{\mathrm{L}} \equiv k_{\mathrm{e}} e^2$), the ratio of this electromagnetic coupling strength to the lattice's fundamental localized torsional capacity yields the fine-structure constant (α):

$$\alpha = \frac{K_{\mathrm{L}}}{c_{\mathrm{E}}^2 J_{\mathrm{N}}} \approx \frac{1}{137} \tag{17.6}$$

Consequently, the localized node is forced to maintain an extreme transverse orbit, yielding the hydrogenic velocity scale:

$$v \sim \alpha c_{\mathrm{E}} \tag{17.7}$$

While the macroscopic vacuum exhibits slight visco-elastic hysteresis over cosmological distances, at the femtosecond timescales and angstrom spatial scales of the atom this dissipation is mechanically negligible.

The topological wake of the racing electron persists long enough for the localized node to complete its precessing orbital paths. Through strict resonant phase-locking, the localized node generates a time-averaged spherical standing-wave boundary in the surrounding strain field. Therefore, while the electron node remains strictly and instantaneously localized at all times, its phase-averaged torsional strain field defines the physical 10^{-10} m boundary of the atom.

The Hydrogenic Shell and Energy Laws

In standard physics, the quantized orbital radii and energy levels of the hydrogen atom were historically adopted as probabilistic postulates. In TFT, they are deterministic mechanical requirements of lattice phase closure. As rigorously derived in Appendix AJ, the time-averaged strain wake of the localized electron node can only form a stable shell if its orbital action completes an integer multiple of the fundamental node action ($\hbar$).

Combining this phase-closure condition with the central chiral restoring force yields the exact TFT hydrogenic shell-radius law:

$$r_n = \frac{n^2 \hbar}{m_{\mathrm{e}} \alpha c_{\mathrm{E}}} \tag{17.8}$$

with the corresponding deterministic energy spectrum:

$$E_n = -\frac{m_{\mathrm{e}} \alpha^2 c_{\mathrm{E}}^2}{2n^2} \tag{17.9}$$

This proves that the Bohr radius and the 13.6 eV ground state are not quantum mysteries; they are the strict lattice-dynamic standing-wave limits of the contiguous Soft Floor.

17.3 Angular Modes, Spin-Orbit Coupling, and Fine Structure

Standard quantum mechanics relies on abstract probabilistic wavefunctions (spherical harmonics) to define the angular momentum (l) and magnetic (m) quantum numbers of the atom, while attributing fine-structure splitting to relativistic Dirac corrections [23]. TFT replaces these abstractions with literal spatial geometry.

- **Angular Standing Modes (l and m):** Because the radial shell (r_n) is a physical, time-averaged strain boundary, any angular structure upon it must be a mechanically continuous standing wave. As derived in Appendix AK, the electron node's precessional wake must close smoothly upon the spherical shell without tearing the contiguous lattice. This mechanical requirement restricts the angular strain to discrete harmonic overtones, strictly yielding the integers l (the standing-precession order) and m (the projected azimuthal winding). The finite action budget of the shell mathematically enforces the boundary limit:

  $$l \leq n - 1 \tag{17.10}$$

  thereby stripping the ad hoc abstraction from the quantum numbers and revealing them as standard lattice-dynamic limits of a spherical continuum.

- **Mechanical Fine Structure (The α^4 Shift):** Furthermore, the localized electron node itself possesses intrinsic 4π tethered rotation (spin, $s = 1/2$), while the overall shell possesses an orbital strain mode (l). As derived in Appendix AL, the relative alignment of these two rotations determines the local torsional loading of the lattice.

If the electron knot's intrinsic torsion is aligned with the orbital shell torsion, the strain energy decreases; if it is anti-aligned, the strain energy increases. Combining this mechanical spin-orbit torsional loading with the exact kinematic impedance (Lorentz compression) of the high-speed orbit yields the complete TFT fine-structure equation:

$$E_{n,l,j_{\text{tot}}}^{\text{TFT}} = -\frac{m_{\text{e}}\alpha^2 c_{\text{E}}^2}{2n^2} - \frac{m_{\text{e}}\alpha^4 c_{\text{E}}^2}{8n^4} + \zeta_{\text{SO}} \frac{m_{\text{e}}\alpha^4 c_{\text{E}}^2}{2n^6 \left[j_{\text{tot}}(j_{\text{tot}}+1) - l(l+1) - \frac{3}{4} \right]} \tag{17.11}$$

TFT mechanically derives the $j_{\text{tot}} = l \pm 1/2$ splitting and the α^4-scale fine structure not from abstract relativistic probability, but as deterministic consequences of lattice-dynamic impedance mismatch and topological braiding of the lattice.

17.4 The Bipolar Strain Field and Topological Superposition

The space between the static proton (10^{-15} m) and the dynamic electron boundary (10^{-10} m) is a locked, high-tension structural web known as the Bipolar Strain Field. The localized central node acts as a persistent stress vortex, and the surrounding lattice stretches in response to form the continuous strain field.

TFT strictly accepts the empirical validity of Coulomb's Law, but radically reinterprets its physical meaning. It is not "action at a distance" between intrinsic charges; it is the macroscopic strain equation of the FCC lattice:

$$F_{\text{lattice}} = \frac{K_{\text{L}}(\chi_1)(\chi_2)}{r^2} \tag{17.12}$$

Here, K_{L} is the absolute lattice shear coupling containing the physical magnitude of the torsional interaction, and χ is the dimensionless chiral integer (± 1), representing the discrete topological handedness of the localized torsional state.

This geometry resolves the atomic charge distribution across three distinct zones:

- **The Interior State (The Topological Shell Theorem):** Inside the orbital boundary ($r < r_n$), the continuous spherical geometry of the electron's time-averaged vortex dictates that its topological vectors geometrically cancel. Because the electron's strain field forms a closed sphere, the outward left-handed torsional pull from any patch of the shell is exactly nullified by the equal-and-opposite pull from the opposite side. The internal lattice space is therefore dominated exclusively by the uncancelled right-handed torsional field of the central proton:

  $$F_{\text{total}}(r < r_n) = \frac{K_{\text{L}}\chi}{r^2}\hat{r} \tag{17.13}$$

  where $\hat{r}$ is the outward radial unit vector, indicating that the topological pull acts strictly along the geometric line radiating from the central anchor.

- **The Equilibrium Boundary ($r = r_n$):** The atomic radius is the specific topological boundary at which the inward structural pull of the proton's field is balanced exactly by the outward centrifugal inertia of the electron's racing mass-core. Here, the opposing chiral fields mechanically lock:

  $$\frac{m_{\text{e}} v_n^2}{r_n} = \frac{K_{\text{L}}}{r_n^2} \tag{17.14}$$

  as derived fully in Appendix AG.

- **External Neutrality ($r > r_n$):** Outside the atomic boundary, both the proton's right-handed torsional field and the electron shell's left-handed torsional field propagate outward into the vacuum. Because they originate effectively from the same center and decay with the same $1/r^2$ gradient, they superimpose continuously. The opposing torsional fields therefore cancel coordinate-by-coordinate, leaving the atom externally neutral:

$$F_{\text{total}}(r > r_n) = 0 \tag{17.15}$$

17.5 Photonic Extrusion: The Mechanics of the Orbital Drop

By defining the atom as a Bipolar Strain Field, the emission of a photon is no longer a probabilistic quantum jump; it becomes a forced, deterministic geometric extrusion.

When an electron transitions from a higher kinetic shell (r_n) to a lower kinetic shell (r_m), the physical volume of the atom contracts instantly. The locked Bipolar Strain Field that previously occupied the physical space between r_n and r_m is violently compressed out of existence.

Because the underlying FCC lattice is governed by extreme hyper-rigidity (c_{E}^2), it cannot elastically absorb this sudden macro-level geometric concentration. The left-handed and right-handed torsional fields locked within that outer shell are therefore forced to neutralize. The lattice accommodates this sudden spike in local tension (τ_{bulk}) through a microscopic topological phase slip. The vacuum extrudes the exact geometric volume of neutralized bipolar tension through a micro-cavitation channel (A_{chan}) over the physical drop length ($\Delta r = r_n - r_m$). The energy of the emitted photon is strictly equal to the volume integral of this released structural tension:

$$E_\gamma = \int \delta\tau \, dV \approx \tau_{\text{bulk}} \cdot A_{\text{chan}} \cdot \Delta r \tag{17.16}$$

This extruded package of neutralized Bipolar Strain is the photon. As it is squeezed into the free-space Soft Floor, its oppositely handed torsional components unspool and braid past one another, propagating forward at c_{E} as a standard transverse electromagnetic wave.

As calculated in Appendix AD, tracking the exact geometric drop of the Lyman and Balmer transitions proves that these emission channels are highly localized, picometer-scale micro-fractures, vastly smaller than the atomic orbital radii themselves.

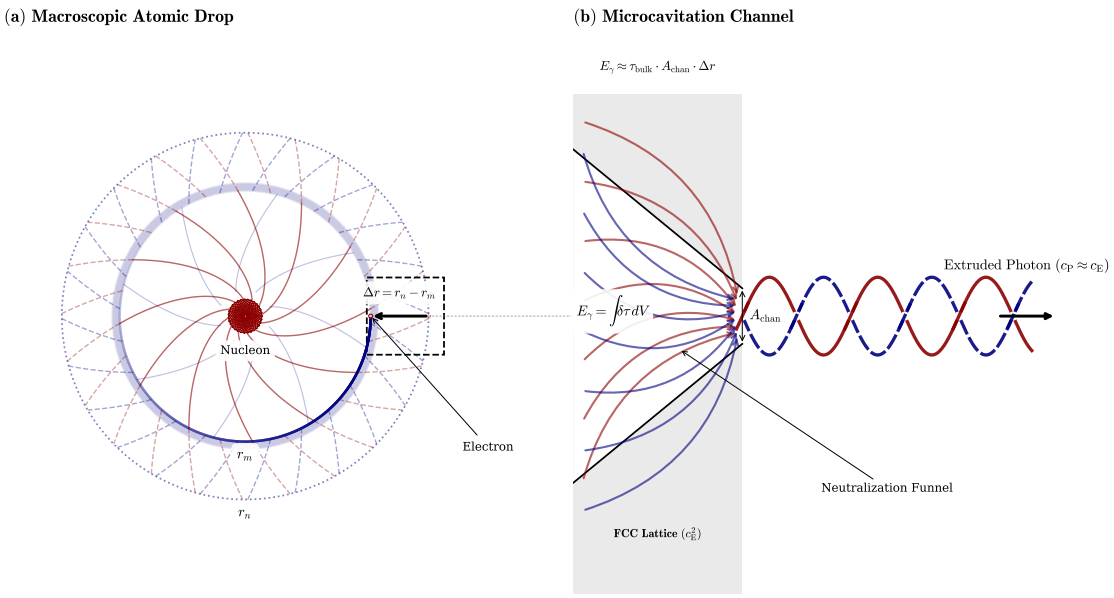

Figure 17.2: **Photonic Extrusion via Volumetric Contraction.**
(a) Macroscopic Atomic Drop. The macroscopic transition of an electron from a higher kinetic shell (r_n) to a lower shell (r_m). The Bipolar Strain Field previously occupying the intermediate geometric volume (ΔV, geometrically defined by the radial drop Δr) is violently crushed, resulting in localized neutralization of the opposing chiral fields. The internal nucleon field ($r < r_m$) remains structurally intact.
(b) Microcavitation Channel. A picometer-scale magnification of the topological phase slip. The extreme hyper-rigidity of the surrounding Face–Centered Cubic (FCC) lattice (c_{E}^2) resists the volumetric crush, forcing the neutralized tension to squeeze through a strictly bounded Neutralization Funnel. The tension is extruded through a microcavitation channel of cross-sectional area A_{chan}. The resulting photon is not a point-particle, but a localized extruded structural package of neutralized bipolar strain. It propagates into the free-space vacuum at $c_{\text{P}} \approx c_{\text{E}}$ as a self-driving, three-dimensional braided topological wave, continuously unspooling its oppositely handed torsional components.

17.6 The Mechanics of Photonic Self-Propagation

Standard Maxwellian electrodynamics relies on the mathematical abstraction that a changing orthogonal electric field (E) and magnetic field (B) generate one another indefinitely. In TFT, because the universe is a contiguous hyper-rigid lattice, there are no abstract fields; there is only structural deformation.

The photon is not a self-propagating mathematical wave of abstract vectors, but a localized braided topological defect moving through a physical solid-state vacuum. The standard electromagnetic vectors are strictly replaced by visco-elastic tensor mechanics.

- **Transverse Lattice Shear (the E-field):** What twentieth-century physics models as the electric field is mechanically the literal linear displacement of the FCC lattice nodes perpendicular to the propagation vector. As the braided photon moves forward, the tightly wound structural knot forces the local lattice to stretch transversely. This is a direct measurement of physical linear strain.

- **Local Torsion / Vorticity (the B-field):** What standard physics models as the magnetic field is mechanically the local rate of torsion, or equivalently the visco-elastic vorticity ($\nabla \times v$) of the lattice. It is the chiral rotational response required to accommodate the transverse shear.

The Drive Mechanism: These two components do not "mathematically generate" one another; they mechanically drive one another forward through visco-elastic phase lag. This continuous propagation proceeds through three locked mechanical steps:

1. **The Stretch:** The uncoiling of the topological knot (vorticity / magnetic mode) forces the local lattice to stretch outward (shear / electric mode).
2. **The Snapback:** The extreme hyper-rigidity of the FCC lattice (c_{E}^2) snaps back violently against this stretch in order to restore equilibrium.
3. **The Torque:** Because the localized strain is topologically braided, it cannot snap back linearly. It is forced to torque forward, converting the linear snapback into the next cycle of rotational uncoiling.

17.7 Pair Production: The Resonance Boundary of Mass Creation

Just as the compression of the atomic Bipolar Strain Field deterministically extrudes photons (Section 17.5), the reverse geometric process dictates the creation of mass from light.

While the fundamental vacuum limits wave propagation at r_{D}, the Nucleon Anchor radius (r_{N}) defines the boundary of matter creation. When a high-energy photon is fired into an atomic system, its transverse Bipolar Strain Field interacts with the hyper-dense core of the proton. If the wavelength of the photon contracts so as to match the physical radius of the Nucleon Anchor ($r_{\mathrm{N}} \approx 0.88 \times 10^{-15}$ m), it reaches the structural resonance limit of the atomic system:

$$E_{\mathrm{N}} = \frac{h c_{\mathrm{E}}}{r_{\mathrm{N}}} \tag{17.17}$$

so that:

$$E_{\mathrm{N}} = \frac{1.986 \times 10^{-25}\ \mathrm{J \cdot m}}{0.88 \times 10^{-15}\ \mathrm{m}} \approx 2.257 \times 10^{-10}\ \mathrm{J} \tag{17.18}$$

Translated into standard particle-physics units, this resonance threshold is 1.41 GeV.

At this geometric threshold, the transverse Bipolar Strain Field is wound so tightly that it can no longer pass cleanly around or through the hyper-dense nucleon. The structural tension locks into a localized topological knot within the Soft Floor. The wave ceases to propagate at c_{E} and instead permanently reconfigures into opposing topological defects. The kinetic energy of the photon is thereby converted strictly and geometrically into the hydrodynamic impedance (mass) of new permanent nodes.

Chapter 18

Conclusion: The Mechanical Continuum and Falsifiability

Because Tension Field Theory (TFT) models the universe as a mechanical continuum rather than an abstract geometry, its predictions are fundamentally structural and strictly testable. Part II establishes the exact mechanical parameters governing macroscopic gravity, black hole phase transitions, and quantum hydrodynamics. Consequently, the framework provides clear diagnostic criteria capable of falsifying its core mechanics.

18.1 The Governing Equations of the Mechanical Continuum

As rigorously derived throughout Part II and summarized in the Consolidated Equations appendix, the phenomena of gravity, quantum mechanics, and atomic structure are not governed by disparate physical laws. They are the strictly mechanical responses of the Spacetime Gravitational Floor (SGF). Tension Field Theory formally replaces standard geometric and probabilistic abstractions with six exact continuum mechanics equations.

1. The Master Acceleration Equation (Replacing Dark Matter):

$$g_{\text{obs}}(R) = \Pi(R) g_{\text{b}}(R) + \Xi(R)\sqrt{a_{\text{gal}}\Pi(R) g_{\text{b}}(R)} \tag{18.1}$$

Mechanical Translation: Flat galactic rotation curves are not the result of invisible particulate mass. They are the strict hydrodynamic consequence of the Galactic Acceleration Scale (a_{gal}). Regulated by geometric projection (Π) and coherence screening (Ξ), this single law dynamically scales to recover Newtonian gravity locally, flat rotation in galactic disks, and Keplerian decay in the deep cosmos.

2. The TFT Tensor Field Equation (Replacing General Relativity):

$$G_{\mu\nu}^{(\tau)} = \frac{\kappa G}{c_{\text{E}}^4} \Delta T_{\mu\nu}^{(\tau)} \tag{18.2}$$

Mechanical Translation: Spacetime does not curve as an empty geometry. The effective gravitational tensor ($G_{\mu\nu}^{(\tau)}$) is strictly the local physical representation of State-I lattice strain, sourced by the converted structural capacity ($\Delta T_{\mu\nu}^{(\tau)}$) relative to the unbroken active vacuum reference state.

3. The Viscous Non-Linear Wave Equation (Replacing the Schrödinger Equation):

$$i\hbar \frac{\partial \Psi}{\partial t} = \left[-\frac{\hbar^2}{2m}\nabla^2 + V \right] \Psi - \left[i(\hbar\Gamma) \ln(|\Psi|^2) \right] \Psi \tag{18.3}$$

Mechanical Translation: The wavefunction is not a mathematical probability distribution. It is a physical, deterministic acoustic wave. Its linear propagation is continuously opposed by macroscopic viscous energy dissipation, mechanically forcing the extended wave to rapidly focus into a localized topological state upon encountering the high-friction boundary of a detector.

4. The Generalized Commutator (Replacing Fundamental Uncertainty):

$$[x, p] = i\hbar \cdot (1 - \alpha_{\mathrm{G}}) \cdot e^{-\Gamma t} \tag{18.4}$$

Mechanical Translation: Quantum uncertainty is not an absolute probabilistic law of nature. It is heavily suppressed by the local gravitational strain (α_{G}) and strictly decays over time via the visco-elastic friction (Γ) of the active lattice.

5. The Photonic Extrusion Law (Replacing the Quantum Jump):

$$E_{\gamma} = \int \delta\tau \, dV \approx \tau_{\mathrm{bulk}} \cdot A_{\mathrm{chan}} \cdot \Delta r \tag{18.5}$$

Mechanical Translation: Atomic photon emission is not a probabilistic teleportation between energy states. It is a deterministic, geometric extrusion. When an electron's orbital shell physically contracts, the lattice cannot absorb the volumetric crush; it accommodates the tension spike by extruding a localized topological defect (the photon) through a micro-cavitation channel.

6. The Topology-Normalized Scale-Invariant Mass Moment (Unifying the Fundamental Forces):

$$\hat{J} \equiv \frac{J_i}{\mathcal{F}_i} \quad (\text{where } J_i = \rho_i r_i^4) \tag{18.6}$$

Mechanical Translation: The Strong, Weak, Electromagnetic, and Gravitational forces are not mediated by independent, abstract gauge bosons. They are strictly the 1D, 2D, 3D, and bulk geometric projections of this single absolute topology-normalized structural invariant ($\hat{J}$) governing the localized topological twist of the lattice geometry. By projecting this invariant across the specific dimensional bounds of the FCC lattice, TFT strictly derives the constants of nature from first principles—including the fine-structure constant ($\alpha = \frac{K_{\mathrm{L}}}{\hbar c_{\mathrm{E}}}$) as the 2D surface-shear limit, and the Newtonian Gravitational constant ($G \propto \frac{1}{\hat{J}}$) as the bulk radial restorative tension.

18.2 Strict Falsification Criteria

The mechanical framework of Part II is immediately falsified if any of the following experimental outcomes are confirmed:

- **Kinematic Independence of Dark Halos:** TFT derives the flat rotation curves of galaxies strictly from the Universal Cosmic Impedance (a_{D}) of the vacuum lattice. If galactic kinematics are definitively proven to decouple from this universal background—such as observing a galaxy completely devoid of a "dark matter" effect [24], or a halo that moves independently of the baryonic mass—the hydrodynamic impedance law of TFT is falsified.
- **Black Hole Ringdown and Acoustic Echoes:** Standard General Relativity predicts the gravitational wave ringdown of a black hole merger is the relaxation of an empty, continuous geometric horizon. Because TFT defines the black hole interior as a hyper-rigid SC Substrate crystal, mergers must produce specific mechanical acoustic overtones (seismic echoes) characteristic of a solid phase-boundary collision. If next-generation interferometers (e.g.,

LISA, Cosmic Explorer) prove the ringdown spectrum perfectly matches an empty geometric singularity with absolute zero solid-body resonance, the SC core phase-transition is falsified.

- **Quadratic Photonic Dispersion (Vacuum Granularity):** Standard Lorentz invariance assumes all photons travel at c_{E} regardless of energy. Because the TFT active vacuum is a discrete FCC lattice ($r_{\mathrm{D}} \approx 7.45 \times 10^{-27}$ m), extreme high-energy gamma rays approaching the lattice limit ($E \to E_{\mathrm{Q}} \approx 8.32 \times 10^{10}$ GeV) must experience quadratic kinematic impedance: $\Delta v / c_{\mathrm{E}} \propto (E/E_{\mathrm{Q}})^2$. If next-generation observations of transient cosmic events (e.g., gamma-ray bursts [25]) definitively rule out this specific quadratic, energy-dependent arrival delay at sensitivities exceeding the 10^{11} GeV threshold, the discrete Soft Floor premise is falsified.

- **Gravitational Preservation of Entanglement:** TFT dictates that quantum entanglement and macroscopic gravity compete for the exact same local structural tension budget ($\alpha_{\mathrm{Q}} \propto 1 - \alpha_{\mathrm{G}}$). If future orbital or deep-space quantum communication experiments demonstrate that perfect phase-entanglement is sustained across extreme gravitational gradients without exhibiting the predicted mechanical decoherence penalty, the Goalpost Topology of the Hard Floor tether is falsified.

- **Anchor-Dependent Pair Production:** Standard quantum electrodynamics permits spontaneous pair production purely as an energy-threshold event. TFT dictates that mass creation is a strictly geometric resonance event requiring a hyper-dense Nucleon Anchor (r_{N}) to physically wind and snap the photon's transverse strain field. If spontaneous macroscopic pair production is conclusively observed in a perfect, anchor-free vacuum—completely bypassing the structural resonance constraint—the topological knot-winding mechanism of TFT is falsified.

- **Stochastic Quantum Tunneling:** TFT redefines quantum tunneling not as a probabilistic energy violation, but as deterministic acoustic transparency achieved via phase-matching resonance. If it can be demonstrated that transmission occurs completely independent of the mechanical impedance and natural resonant frequencies of the barrier lattice, the TFT active transmission law (T_{active}) is falsified.

18.3 Diagnostic Comparison of Core Phenomena

To clarify the mechanical departures from standard General Relativity and Quantum Mechanics, the core phenomena derived in Part II are contrasted below.

Table 18.1: Diagnostic Comparison of Core Phenomena

Phenomenon	**Standard Model (GR / QM)**	**TFT Resolution (Lattice Mechanics)**
Gravity	The geometric curvature of an empty, continuous spacetime manifold.	The physical restorative tension gradient of the elastic vacuum lattice.
Speed of Light (c)	A universal constant in all reference frames.	Locally Variable (c_{P}): A refractive index ($n_\tau \approx 1 + 2\alpha_{\mathrm{G}}$) determined by lattice strain.

Table 18.1 continued from previous page

Phenomenon	Standard Model (GR / QM)	TFT Resolution (Lattice Mechanics)
Shapiro Delay	A result of "longer" paths in curved geometry.	A simple Refractive Time Delay caused by the reduction of c_{local} in dense vacuum.
Galactic Kinematics	Driven by invisible halos of non-interacting Dark Matter particles.	Governed by the Cosmic Impedance (a_{D}) and the foundational visco-elastic tension limits of the vacuum.
The Flow of Time	A flexible, abstract geometric dimension of the spacetime manifold.	The mechanical kinetic flow-rate of the active FCC lattice (which freezes at the SC boundary).
Black Holes	Mathematical singularities of infinite density resulting in information loss.	Macroscopic SC Substrate cores resulting from a mechanical FCC $\rightarrow$ SC phase transition.
The Atom	A probabilistic point-particle existing in a statistical "cloud" of superposition.	A deterministic Bipolar Strain Field bounded by a physical, time-averaged standing wave.
The Photon	A dimensionless point-particle and the fundamental gauge boson of electromagnetism.	An extruded, localized geometric volume of neutralized structural tension propagating as a braided wave.
Wave-Particle Duality	A fundamental paradox where dimensionless points exhibit abstract wave properties.	A topological knot (particle) actively steered by the physical condensate pilot-wave it generates in the vacuum.
Wave Arrest	An abstract, probabilistic collapse triggered by an undefined "observer."	A deterministic, physical topological interaction driven by visco-elastic lattice friction (measurement).
Quantum Uncertainty	An absolute, fundamental probabilistic limit of the universe.	The mechanical resolution limit (thermodynamic noise floor) of the active Soft Floor.
Entanglement	A non-local, abstract wavefunction connection across empty space.	A physical Phase-Tether connecting vertical gravitational columns along the rigid SC Hard Floor.
Fundamental Forces	Mediated by independent, force-carrying gauge bosons.	The 1D, 2D, 3D, and bulk volumetric geometric stress-responses of a single contiguous lattice.

Summary: The Unified Mechanical Continuum

In this second installment, we have demonstrated that gravity and quantum mechanics are not disparate laws of nature, but the macroscopic and microscopic mechanical responses of a single, highly elastic Spacetime Gravitational Floor (SGF). By replacing abstract geometry with continuum mechanics, we have successfully resolved the foundational persistent anomalies that currently cleave macroscopic and quantum physics.

At the macroscopic scale, gravity emerges naturally not as the warping of nothingness, but as the active restorative tension of the vacuum lattice attempting to suppress topological defects. By

recognizing the finite kinematic viscosity of this medium, we eliminated the need for exotic Dark Matter halos, proving that flat galactic rotation curves are the inevitable hydrodynamic result of Cosmic Impedance (a_{D}).

Furthermore, by imposing the absolute structural yield limits of the vacuum, we eliminated the mathematical singularity. A Black Hole is not a point of infinite density, but a strict crystallographic phase transition where the active FCC vacuum saturates and locks into the latent SC substrate, preserving quantum information volumetrically within its phase-locked core.

At the microscopic scale, we replaced the stochastic abstraction of the standard wavefunction with the deterministic vacuum condensate hydrodynamics of the FCC lattice. Within this framework, a particle is a topological knot steered by the physical pilot wave of its own structural vibration. Standard quantum probability and the Heisenberg Uncertainty Principle are revealed not as fundamental laws of the cosmos, but merely as the thermodynamic noise floor of the vibrating Soft Floor lattice.

Extending this deterministic geometry to the composite atom, we dismantled the probabilistic electron cloud. The atom is resolved as a locked Bipolar Strain Field, where electron shells operate as strict mechanical standing waves, and photonic emission is redefined as the deterministic extrusion of neutralized structural tension.

Crucially, the introduction of the Vertical Dimension—anchoring active surface topology to the latent substrate—provides a strictly mechanical, fully causal mechanism for quantum entanglement and the instantaneous transfer of phase-locked stress.

Ultimately, Part II proves that the Strong, Weak, Electromagnetic, and Gravitational interactions are not independent phenomena. They are strictly the 1D, 2D, 3D, and bulk geometric projections of a single absolute topology-normalized Scale-Invariant Mass Moment ($\hat{J}$). The universe is governed by a singular invariant continuum law: the dynamic geometric action of existence perfectly counterbalanced by the restorative tension of the vacuum.

Having established the constitution of the vacuum in Part I and the unified mechanics of mass, gravity, and quantum structure in Part II, the framework is now fully equipped to address the evolution of the cosmos as a whole. In Part III, we will apply these exact mechanical phase limits to derive the origin, expansion, and ultimate fate of the universe.

END OF PART II

Part III

Cosmic Architecture and Kinematics: The Big Rupture, the Hubble Artifact, and the Mechanical Cycle

Chapter 19

Introduction

19.1 The Limitations of the Expanding Metric

For nearly a century, observational cosmology has been dominated by the paradigm of metric expansion—the framework positing that the universe is an expanding empty geometry, stretching the fabric of space and carrying galaxies apart. To reconcile this kinematic model with high-precision observational data, the standard cosmological model (ΛCDM) has required the continuous introduction of ad hoc parameters.

Specifically, the expanding metric framework suffers from three irreconcilable limitations:

- **The Singularity Paradox:** The assumption that the universe originated from a dimensionless point of infinite density, violating the finite geometric limits of continuum mechanics.
- **The Dark Energy Postulate:** The reliance on an unobserved, accelerating field to explain the non-linear attenuation of distant starlight [26].
- **The Hubble Tension:** A persistent, statistically irreconcilable discrepancy in the cosmic expansion rate when measured at different cosmological epochs.

Rather than indicating minor observational calibration errors, these compounding anomalies expose a fundamental mechanical failure within the expanding metric paradigm.

19.2 Tension Field Theory (TFT) in the Macroscopic Limit

TFT addresses these cosmological anomalies by definitively moving beyond the expanding metric. While Part II established the localized structural mechanics of gravity, quantum structure, and the atom, Part III transitions to the macroscopic thermodynamic and visco-elastic behaviors of the bulk medium.

Because the active Spacetime Gravitational Floor (SGF) is a spatially static mechanical lattice, large-scale cosmological phenomena must be governed by fluid and acoustic dynamics. In this final installment, we apply the Topological Invariant (N) of the propagating wave packet and the acoustic friction of the interstitial condensate to the cosmos at large, resolving observational anomalies purely through conservative kinematics.

19.3 Objectives of Part III

In this third and final installment of the Tension Field Theory trilogy, we define the strict visco-elastic kinematics of the cosmos. We mathematically replace the expanding metric paradigm with a spatially bounded, macro-mechanical oscillator driven by thermodynamic phase cycles. Specifically, we will:

- **Establish Global Kinematics:** Replace the Friedmann Equation with exact mechanical state equations, defining the absolute mass (M_{Res}) and scale (10^{35} m) of the cosmic reservoir before evaluating its structural failure.
- **Redefine the Genesis Event:** Replace the non-physical singularity with the Catastrophic Decompression of a globally percolated fault line, modeling the Big Rupture as a macroscopic, martensitic phase transition (SC $\rightarrow$ FCC).
- **Derive Baryonic Mass and Asymmetry:** Demonstrate that fundamental particles are topological phase defects (locked vorticity) created during this decompression, and prove that the observed matter-antimatter asymmetry is the strict mechanical result of chiral nucleation in a torsionally twisted vacuum.
- **Mechanize the CMB and Recombination:** Reinterpret the Cosmic Microwave Background not as a primordial flash, but as the active, global phonon equilibrium of the lattice. We subsequently derive the 380,000-year annealing epoch strictly from solid-state thermal diffusion laws.
- **Resolve the Hubble Tension and Dark Energy:** Prove that cosmic redshift is the vacuum damping rate ($\Gamma_{\text{D}} \equiv H_0$) of the visco-elastic vacuum. By applying the Taylor expansion of this compounding boundary friction, we natively recover the mathematical signature misinterpreted by standard cosmology as "accelerating expansion," proving it is an observational artifact rather than a kinematic reality.
- **Prove Time Dilation without Metric Expansion:** Demonstrate that Supernova Time Dilation is mathematically guaranteed by the topological conservation of the photon wave packet (N), resolving the missing energy paradox of standard cosmology.
- **Define the Structural Phase Limits and the Macroscopic Oscillator:** Calculate the absolute mechanical boundaries of the active vacuum, demonstrating that the Viscous Cosmic Horizon (10^{26} m) and the Structural Reservoir (10^{35} m) establish a strict volumetric scaling law. This thermodynamic ledger proves that the universe operates not toward terminal "Heat Death," but as a perpetual macro-mechanical oscillator driven by continuous structural phase cycles.
- **Provide Definitive Falsification Criteria:** Propose specific, testable astrophysical observations—such as measuring the asymmetric visco-elastic dispersion tail of high-redshift Fast Radio Bursts (FRBs)—to physically prove the dissipative nature of the medium and definitively falsify metric expansion.

Chapter 20

Global Kinematics: The Cosmic Mass and the Friedmann Replacement

Standard cosmology treats the total mass and critical density of the universe as arbitrary parameters inherited from a primordial expansion. Tension Field Theory (TFT) does not accept this unconstrained metric expansion. Because the Spacetime Gravitational Floor (SGF) is a strictly bounded, visco-elastic mechanical structure, the mass and density of the observable universe are not arbitrary; they are strictly governed by the maximum gravitational strain the lattice can physically sustain.

20.1 The Cosmic Mass Limit (Causal Saturation)

As established in Part II, the dimensionless gravitational strain (α_{G}) of the lattice is defined by the ratio of gravitational potential to the elastic limit of the vacuum (c_{E}^2). Therefore, to find the total mass of the observable universe (M_{U}), we consider the Type II Causal Saturation for total lattice strain.

While a Black Hole represents a Type I Causal Failure (a local density rupture), the observable universe represents a Type II Causal Saturation. The average density remains low, but the integrated specific tension potential ($\Phi_{\tau,\mathrm{G,U}}$) over the macroscopic cosmic radius (R_{U}) completely exhausts the lattice's cumulative energy budget:

$$\Phi_{\tau,\mathrm{G,U}} = \int_0^{R_{\mathrm{U}}} \frac{G \cdot dm}{r} = c_{\mathrm{E}}^2 \tag{20.1}$$

At this absolute boundary limit of the Viscous Cosmic Horizon, the macroscopic strain reaches unity ($\alpha_{\mathrm{G}} = 1$). Equating the effective global potential of the causal mass (M_{U}) at the characteristic viscous relaxation scale ($R_{\mathrm{U}} = c_{\mathrm{E}}/\Gamma_{\mathrm{D}}$):

$$1 = \frac{GM_{\mathrm{U}}}{R_{\mathrm{U}} c_{\mathrm{E}}^2} = \frac{GM_{\mathrm{U}}}{\left(\frac{c_{\mathrm{E}}}{\Gamma_{\mathrm{D}}}\right) c_{\mathrm{E}}^2} \tag{20.2}$$

Solving for the total Cosmic Critical Mass (M_{U}):

$$M_{\mathrm{U}} = \frac{c_{\mathrm{E}}^3}{G\Gamma_{\mathrm{D}}} \tag{20.3}$$

Substituting the present empirically calibrated baseline for the Viscoelastic Vacuum Relaxation Rate ($\Gamma_{\mathrm{D}} \approx 2.3671 \times 10^{-18}\ \mathrm{s}^{-1}$) and standard physical constants, we evaluate the calibrated macroscopic mass limit:

$$M_{\mathrm{U}} = \frac{(299792458\ \mathrm{m/s})^3}{(6.6743 \times 10^{-11}\ \mathrm{m}^3/\mathrm{kg} \cdot \mathrm{s}^2) \cdot (2.3671 \times 10^{-18}\ \mathrm{s}^{-1})} \approx 1.7055 \times 10^{53}\ \mathrm{kg} \tag{20.4}$$

The Universal Unification: This cosmic mass limit reveals a structural symmetry within the TFT framework. In Part II, we derived the surface saturation Mass (M_{Sat}) of a Black Hole, defined as the point where the surface density dilutes to match the ambient vacuum and the Event Horizon dissolves. The mass required to saturate and dissolve the Black Hole horizon (M_{Sat}) is mechanically and mathematically identical to the critical mass bounding the observable universe (M_{U}):

$$M_{\mathrm{U}} = M_{\mathrm{Sat}} = \frac{c_{\mathrm{E}}^3}{G\Gamma_{\mathrm{D}}} \approx 1.7055 \times 10^{53}\ \mathrm{kg} \tag{20.5}$$

This mathematical equivalence proves that the observable universe is not expanding into an infinite void; its causal boundary (R_{U}) operates at the exact mechanical limit of a saturated Type I Black Hole. Consequently, the local causal domain is perfectly mechanically closed and structurally impervious to a kinematic "Big Rip" (runaway metric expansion). However, as established in the following chapters, the ultimate fate of this bounded system is strictly governed by the topological capacity of the vastly larger macroscopic reservoir (M_{Res}), culminating in a global Catastrophic Decompression (The Big Rupture) when the accumulation of frozen mass triggers lattice percolation.

20.2 The Kinematic State Equation (The SGF Friedmann Replacement)

Standard cosmology utilizes the Friedmann equation [27] to link the expansion rate (H_0) to the critical mass density of the universe (ρ_{c}). Using the calibrated relation $\Gamma_{\mathrm{D}}^{(\mathrm{cal})} = H_0^{(\mathrm{obs})}$ between the Viscoelastic Vacuum Relaxation Rate and the observed low-redshift Hubble slope, TFT derives a mathematical equivalent formulation strictly from the solid-state geometry of the saturated strain limit. This equality represents the present low-redshift empirical normalization, not a microscopic derivation.

Assuming the macroscopic mass is distributed uniformly, the critical mass density (ρ_{c}) of the observable universe is the total mass (M_{U}) divided by the geometric volume of the Viscous Cosmic Horizon ($V_{\mathrm{U}} = \kappa R_{\mathrm{U}}^3$), where κ is the Topological Projection Operator:

$$\rho_{\mathrm{c}} = \frac{M_{\mathrm{U}}}{\kappa R_{\mathrm{U}}^3} = \frac{\left(\frac{c_{\mathrm{E}}^3}{G\Gamma_{\mathrm{D}}}\right)}{\kappa \left(\frac{c_{\mathrm{E}}}{\Gamma_{\mathrm{D}}}\right)^3} = \frac{\Gamma_{\mathrm{D}}^2}{\kappa G} \tag{20.6}$$

Algebraically isolating the vacuum relaxation rate (Γ_{D}^2) yields the TFT Kinematic State Equation:

$$\Gamma_{\mathrm{D}}^2 = \kappa G \rho_{\mathrm{c}} \tag{20.7}$$

This formulation recovers the architecture of the Friedmann equation without invoking metric expansion. The coefficient is determined by the Topological Projection Operator (κ) derived in Appendix P:

- **Newtonian Solid Projection ($\kappa = \frac{4\pi}{3}$):** Yields $\Gamma_{\mathrm{D}}^2 = \frac{4\pi G}{3}\rho_{\mathrm{c}}$.
- **Relativistic Tensor Projection ($\kappa = \frac{8\pi}{3}$):** Yields the standard Friedmann result $\Gamma_{\mathrm{D}}^2 = \frac{8\pi G}{3}\rho_{\mathrm{c}}$.

Physical Significance: The factor of 2 discrepancy between the Newtonian and Relativistic projections in TFT reflects the absolute mechanical reality of the lattice. General Relativity's tensor coupling ($\kappa = 8\pi$) is a local differential operator that counts both the outside-in and inside-out restorative tensions of the field. Standard cosmology (via the FLRW metric) erroneously applies this local bi-directional stress operator to the global Euclidean volume of the universe. Because GR artificially doubles the geometric volume factor in the denominator, it artificially halves the required critical density. Thus, standard Friedmann density is not a fundamental constant of space, but a geometric artifact of applying a local stress tensor to a global volume scalar. TFT mathematically corrects this, demonstrating that reaching the kinematic saturation limit of the universe requires exactly twice the mass previously assumed.

20.3 The Total Cosmic Reservoir (M_{Res})

The critical mass calculated above ($M_{\mathrm{U}} \approx 1.7055 \times 10^{53}$ kg) represents strictly the observable domain—the local viscous and kinematic scale defined by the Viscous Cosmic Horizon ($R_{\mathrm{U}} \approx 1.2665 \times 10^{26}$ m). However, as established in the Black Hole phase transition mechanism, the contiguous FCC lattice is vastly larger.

To form a saturated macroscopic core, the crystallization front must theoretically harvest a volume of active vacuum defined by the strict mass-energy conservation of the phase transition. In Section 13.7, we derived the exact volumetric scaling factor between the observable causal domain and the ultimate structural capacity of the field using the phase density ratio:

$$\frac{\rho_{\mathrm{S}}}{\rho_{\mathrm{QG}}} = \frac{5.1550 \times 10^{96}}{5.2625 \times 10^{70}} \approx 9.7957 \times 10^{25} \tag{20.8}$$

The total absolute mass of the cosmic reservoir is geometrically defined by multiplying the critical causal mass (M_{U}) by this exact volumetric multiplier:

$$M_{\mathrm{Res}} = M_{\mathrm{U}} \times \left(\frac{\rho_{\mathrm{S}}}{\rho_{\mathrm{QG}}} \right) \tag{20.9}$$

$$M_{\mathrm{Res}} \approx (1.7055 \times 10^{53}\ \mathrm{kg}) \cdot (9.7957 \times 10^{25}) \approx 1.6707 \times 10^{79}\ \mathrm{kg} \tag{20.10}$$

This mechanically confirms that the observable universe (10^{53} kg) is merely a single causal tile within a vastly larger, contiguous substrate. The macroscopic reservoir ($M_{\mathrm{Res}} \approx 1.6707 \times 10^{79}$ kg) defines the ultimate topological mass capacity of the field, setting the absolute limit for the global thermodynamic clock before structural percolation triggers Catastrophic Decompression.

20.4 The Baryonic Mass Cycle and the 5% Volumetric Limit

Standard cosmology observes the baryonic mass density of the universe to be roughly 5% (Ω_{b}) [28], treating it as an arbitrary parameter. Within Tension Field Theory, the compositional breakdown of the total cosmic mass (M_{Res}) is strictly dictated by the volumetric and topological limits of the FCC lattice. The existence and collapse of macroscopic mass operate within a strictly bounded phase cycle:

- **Phase I (Kinetic Partitioning and Condensation):** As derived in Part I, macroscopic mass originates as a localized vibrational defect. To maintain mechanical equilibrium, this kinetic excitation reduces the fundamental static tension of the lattice nodes (β_Λ) from the ideal geometric packing limit of $\approx 74\%$ down to $\approx 69\%$. The total interstitial condensate filling the remaining void space ($\approx 25.95\%$) acts as the background hydrodynamic matrix, observationally identified as Dark Matter (β_{IC}). However, when baryonic mass physically condenses into macroscopic structures, its isotropic (spherical) geometry confines it strictly to the largest perfectly spherical pockets available within this condensate—the octahedral-site inscribed spheres.

- **Phase II (Volumetric Saturation / Transition Trigger):** As local mass condenses, the density scales from the active vacuum baseline (ρ_{Q}) toward the convergence limit (ρ_{QG}). Because gravitational condensation is fundamentally isotropic, it cannot deform into the irregular, anisotropic capillary channels that make up the remaining 20.7% of the total void space ($25.95\% - 5.26\%$). Therefore, the active vacuum can safely harbor condensed baryonic mass only up to the exact geometric threshold of these octahedral-site inscribed spheres. As derived in Appendix AT, the maximum inscribed radius (r_{O}) is bounded by the primary lattice node radius (r_{D}) as $r_{\mathrm{O}} = (\sqrt{2}-1)r_{\mathrm{D}}$. This sets the absolute volumetric fraction (β_{oct}) for baryonic capacity:

  $$\beta_{\mathrm{oct}} = \frac{\pi(\sqrt{2}-1)^3}{3\sqrt{2}} \approx 0.0526 \tag{20.11}$$

  Exceeding this 5.26% limit geometrically exhausts the perfectly spherical condensate capacity. Rather than undergoing extreme anisotropic deformation into the remaining capillary network, the system takes the path of least mechanical resistance, triggering hyperstatic structural failure.

- **Phase III (The Isoenergetic Phase Transition):** When the local mass density reaches the void saturation trigger (ρ_{QG}), the active FCC lattice structurally yields, undergoing an instantaneous transition into the zero-void Simple Cubic substrate (ρ_{S}). The kinematic degrees of freedom are locked into static structural stress, forming a State II Black Hole core. Because this ultimate phase transition is mathematically isoenergetic ($E_{\mathrm{QG}} = E_{\mathrm{S}}$), the observable baryonic mass capacity of the universe (β_{b}) is strictly bounded by this invariant geometric void limit:

  $$\beta_{\mathrm{b}} \leq \beta_{\mathrm{oct}} \approx 0.0526 \tag{20.12}$$

(The complete derivation of the void saturation limit, topological percolation, and the isoenergetic phase continuity is detailed in Appendix S and Appendix AT).

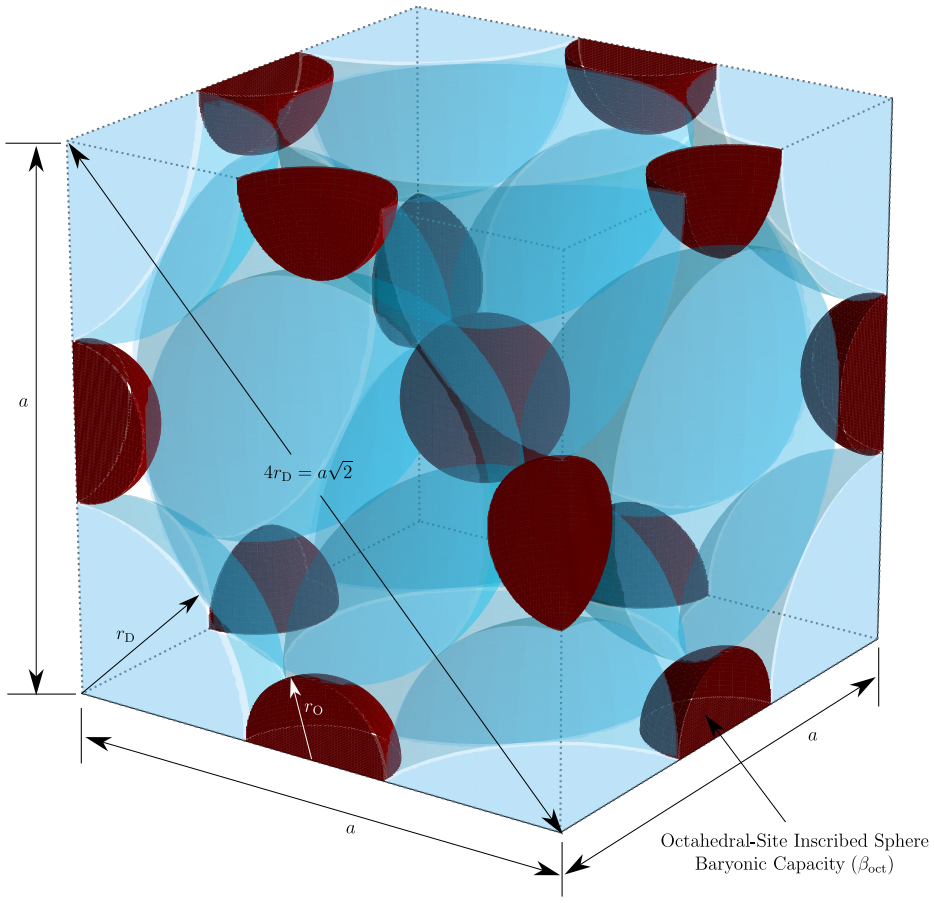

Figure 20.1: **Volumetric Partitioning and Baryonic Capacity of the FCC Lattice.** The active vacuum is modeled as a Face-Centered Cubic (FCC) unit cell. The transparent blue spheres represent the fundamental structural lattice nodes (r_D), which touching along the face diagonal defines the critical geometric constraint $4r_D = a\sqrt{2}$. The solid maroon geometries represent the **octahedral-site inscribed spheres** (r_O), providing the maximum isotropic spatial capacity for condensed macroscopic mass. The subtle gray pattern visualizes the remaining 20.7% anisotropic capillary network, geometrically incompatible with spherical mass condensation. The mathematical limit of the maroon volume bounds the observable baryonic mass density of the universe to $\approx 5.26\%$.

Chapter 21

The Big Rupture: The Mechanical Origin of the Observable Universe

Standard cosmology posits that the universe began from a singularity—a mathematical point of infinite density and temperature—expanding outward in a "Big Bang." Tension Field Theory (TFT) resolves this non-physical paradox by replacing the singularity with a strictly mechanical crystallographic phase transition.

The genesis event was not an explosion of "nothing" into "something." It was the Catastrophic Decompression of a saturated region of the spacetime lattice.

21.1 The Three States of the Spacetime Lattice

To understand the mechanics of the Big Rupture, we must recall the foundational structural phases of the Spacetime Gravitational Floor (SGF) established in Part I. The universe operates strictly through phase transitions between three mechanical tension states (τ):

- **State 0: The Latent Substrate (Equilibrium, $\tau = \tau_S$).** The absolute, invariant, and infinite background frame of reality. It is a perfectly rigid, Time-Frozen Simple Cubic (SC) crystal with zero interstitial voids and zero entropy ($S = 0$).
- **State I: The Active Vacuum (Expansion, $\tau = \tau_D$).** The dynamic, time-enabled "Spacetime" we observe. It acts as an elastic skin over the rigid substrate, configured in a Face–Centered Cubic (FCC) geometry. Its interstitial voids provide the kinematic freedom necessary for transverse waves (light) and hydrodynamic inertia (mass).
- **State II: The Saturated Core (Compression, $\alpha_G \to 1$).** A localized, macroscopic collapse of the State I active vacuum into the State II saturated phase. When gravitational tension reaches absolute saturation ($\alpha_G = 1$), the active FCC voids are crushed out of existence, mechanically arresting time. The region topologically locks into the hyper-dense, phase-locked SC configuration.

The observable spacetime domain is predominantly a State I phenomenon, containing localized State II cores. The Big Rupture is the mechanical mechanism by which a global network of State II cores violently decompresses. Because the Black Hole previously consumed the surrounding State I vacuum, its catastrophic decompression does not expand into "nothingness." Instead, it snaps outward into the exposed, invariant State 0 background, mechanically forcing interstitial voids back into the latent structure to restore the State I active vacuum.

21.2 The Pre-Rupture Trigger (Global Topological Percolation)

As derived in Part II, a Black Hole (State II core) grows by consuming the active State I vacuum, converting FCC nodes into the void-less SC Substrate ($\rho_S \approx 10^{96}$ kg/m^3). Any pre-existing dynamic mass-energy is mechanically displaced outward, forming a hyper-compressed FCC boundary shell (the Event Horizon) that is stabilized strictly by the inward Boundary Tension (τ_{QG}) and supported by the ambient pressure of the surrounding active vacuum.

However, a Black Hole does not grow in isolation. The universe contains a distributed, growing network of these macroscopic State II defect cores. While a single theoretical core possesses a local causal growth limit (M_{Sat}), the universe never reaches this localized extreme. The rupture is strictly triggered by global geometric saturation: **Site Percolation**.

As the macroscopic network of frozen State II cores accumulates, it consumes an increasing percentage of the active vacuum's interstitial capacity. When this global defect network reaches exactly 5.16% of the reservoir's capacity (detailed in Appendix AT), the isolated cores mechanically connect to form a contiguous, macroscopic fault line across the entire cosmos.

This global topological fracture physically shatters the structural continuity of the active State I vacuum. Consequently, the ambient containment pressure universally vanishes ($\Delta P \to 0$). Without this external pressure to support the Event Horizons, the hyper-compressed boundary shells simultaneously mechanically dissolve.

21.3 Trigger Boundary Parameters at Percolation

The Catastrophic Decompression is governed by a strict set of global boundary parameters that define the state of the macroscopic reservoir at the exact moment the 5.16% percolation limit is breached. As the active Face-Centered Cubic (FCC) vacuum is consumed and converted into solid Simple Cubic (SC) cores, the macroscopic boundary must geometrically deflate to maintain contiguous tension.

As rigorously derived and geometrically proven in Appendix AT, the reservoir reaches absolute structural failure under the following global limits:

- **Global Rupture Trigger Mass (M_{trg}):** The rupture is strictly triggered when the Aggregate Percolating Mass (M_p)—the total mass-energy segregated onto the global network of State II phase boundaries—reaches exactly 5.16% of the total macroscopic reservoir mass ($\approx 8.6208 \times 10^{77}$ kg).
- **Deflated Rupture Radius (R_{rup}):** The physical boundary of the Geometric Cosmic Horizon deflates by approximately 1.0220×10^{33} m, locking the final rupture radius at $\approx 5.7361 \times 10^{34}$ m.
- **Global Pressure Drop ($\Delta P \to 0$):** At this exact density, the distributed SC cores physically intersect shoulder-to-shoulder, forging a contiguous, unbroken fractal fault line across the entire macroscopic diameter of the system. This rigid macroscopic skeleton structurally shatters the elastic continuity of the remaining 94.84% FCC lattice, dropping ambient containment pressure to zero and triggering the universe-wide martensitic phase transition.

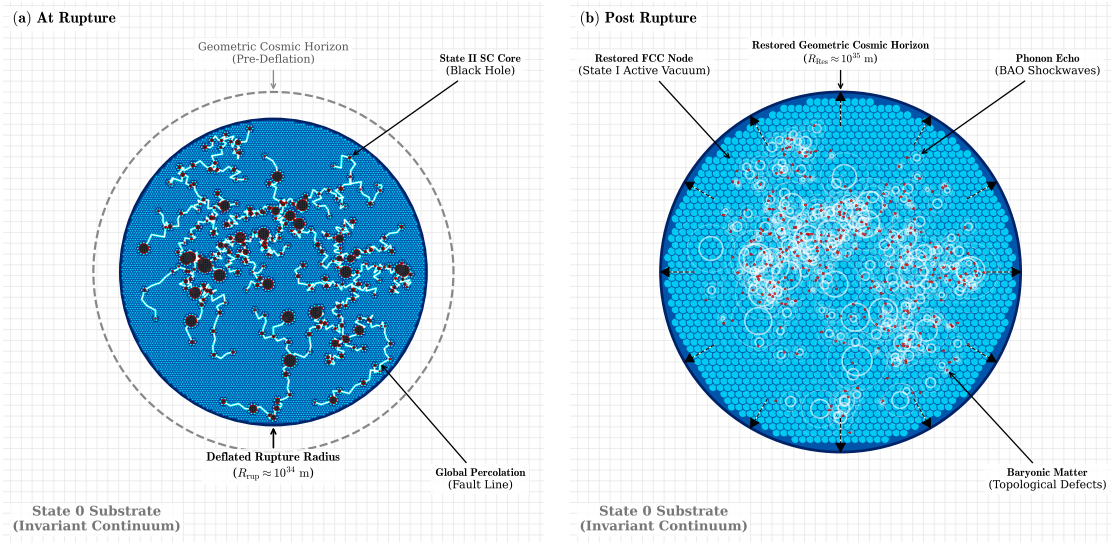

Figure 21.1: **Catastrophic Decompression via Global Percolation (The Big Rupture). (a) At Rupture:** The macroscopic cosmic reservoir deflates ($R_{\text{rup}} \approx 5.7361 \times 10^{34}$ m) as active vacuum is consumed by State II SC Cores (Black Holes). At precisely 5.16% volumetric capacity, the isolated cores geometrically percolate. This forms a contiguous, rigid spanning cluster (Global Percolation Fault Line) that universally shatters the containment pressure ($\Delta P \to 0$). **(b) Post Rupture:** Stripped of boundary tension, the hyper-compressed SC fault line violently decompresses, expanding outward to restore the active FCC vacuum geometry ($R_{\text{Res}} \approx 5.8383 \times 10^{34}$ m). The phase-segregated Baryonic Matter (Topological Defects) previously trapped on the Event Horizons is explosively expelled, surfing the expanding longitudinal shockwaves as the Phonon Echo (BAO rings) propagates through the restored lattice [29].

21.4 The Big Rupture (Catastrophic Decompression)

With the global network of Event Horizons destroyed, the contiguous fault line of hyper-compressed State II cores is suddenly exposed without a containment gradient. Because the Simple Cubic packing factor (1.0) is a state of extreme mechanical stress compared to the relaxed Face–Centered Cubic packing factor (≈ 0.74), the contiguous defect network violently yields.

The entire macroscopic State II fault line undergoes a martensitic phase transition. We define this sudden, diffusionless structural snap-back of the lattice as Catastrophic Decompression. The zero-void SC lattice explosively snaps back into the actively spaced FCC geometry. This instantaneous, volumetric expansion of the lattice phase from State II back into State I is the mechanical reality of the Big Bang.

It is not an expansion of empty space; it is the physical snap-back of a hyper-compressed crystal restoring its interstitial voids. Because this martensitic (diffusionless) phase transition propagates via the longitudinal stress transmission of the underlying substrate ($c_{\text{S}} \to \infty$), it is not bound by the transverse shear wave limit of light (c_{E}). Therefore, the entire macroscopic fault line snaps back simultaneously. This longitudinal shockwave replaces the need for an abstract "inflation field" by providing a mechanical mechanism for rapid large-scale synchronization and homogenization across the macroscopic reservoir from the earliest stage.

The universe we inhabit today was born in the fraction of a second when the global topological fault line shattered the vacuum, forcing the timeless structural sinks to violently rupture back into the active flow of time.

Chapter 22

Topological Nucleation, the Phonon Echo, and Lattice Annealing

Standard cosmology models the early universe as a super-heated plasma of free-floating fundamental particles, requiring an abstract "inflation field" to explain its rapid uniform expansion, and a subsequent period of recombination to produce the Cosmic Microwave Background (CMB). Tension Field Theory (TFT) replaces this sequence of ad hoc thermal epochs with a singular structural event. Instead, we propose that the creation of baryonic matter, the matter-antimatter asymmetry, the pervasive CMB, and the 380,000-year cooling timeline are the simultaneous, strictly mechanical byproducts of Catastrophic Decompression.

22.1 Topological Nucleation (The Birth of Matter)

Standard physics assumes matter was created from condensed free energy during the early stages of the Big Bang. In TFT, mass is not a standalone substance; as derived in Part I, it is a topological phase defect (a vorticity loop) within the active Face–Centered Cubic (FCC) vacuum. Therefore, matter cannot be "created" from empty space; it must be forged by fracturing the lattice.

When the hyper-compressed State II core (Simple Cubic phase) violently decompresses into the State I active vacuum (FCC phase), the transition is unfathomably energetic. The rapid volumetric expansion of the macroscopic crystal does not occur with perfect geometric smoothness. As the rigid lattice snaps back, it shears and tears.

Because the structural expansion outpaces the localized relaxation time of the substrate, the macroscopic fault line violently yields. The zero-void SC cores decompress into active FCC vacuum, but their phase-segregated Event Horizons—the boundary layers where massive topological strain was stored—are explosively shattered. Localized fragments of these extreme boundary defects fail to unbind, becoming topologically locked. These stable, microscopic boundary fragments are the fundamental nucleons (protons and neutrons).

In Tension Field Theory, matter is not condensed free energy; it is the physical, geometric shrapnel of the shattered Event Horizons. These structural impurities permanently displace a portion of the ideal Face–Centered Cubic packing geometry (the $\approx 74\%$ structural energy limit of the vacuum), manifesting as the $\approx 5\%$ baryonic energy contamination observed today. The strict thermodynamic boundaries of these defects, and why their spherical geometry confines them exclusively to the Octahedral voids of the lattice, is mathematically derived in Section 20.4. This purely mechanical nucleation process provides a mechanism for the initial uniform distribution of baryonic mass across the nascent universe, replacing the need for an abstract "inflation field."

Instantaneous Core Genesis ($t \approx 0$ Primordial Black Holes)

While baryonic shrapnel must wait 380,000 years (Appendix AN) for the lattice to thermally anneal before safely binding into stable atomic hydrogen, the formation of State II Black Hole cores is not restricted by thermal limits. In the immediate, highly chaotic aftermath of Catastrophic Decompression ($t \approx 0$), overlapping longitudinal acoustic shockwaves create regions of extreme localized pressure.

Wherever this transient acoustic interference pushes the local vacuum density toward the convergence limit ($\rho \to \rho_{\mathrm{QG}}$), reaching absolute gravitational saturation ($\alpha_{\mathrm{G}} \to 1$), the FCC nodes instantly snap into rigid Simple Cubic geometry. This triggers a massive, instantaneous nucleation of Primordial Black Holes across the cosmos, providing the initial State-II seed population, while the formulation of the macroscopic global clock law is deferred to Chapter **??**. Crucially, because these State II cores possess the extreme density of the fundamental substrate ($\rho_{\mathrm{S}} \approx 10^{96}$ kg/m^3), the total volumetric fraction of these primordial seeds remains vanishingly small, safely avoiding an immediate secondary percolation rupture.

22.2 Chiral Nucleation and Baryon Asymmetry

Standard physics cannot explain why the universe is dominated by matter, as perfectly symmetric quantum models predict equal amounts of matter and antimatter should have formed and annihilated. TFT resolves this "Baryon Asymmetry" by applying the conservation of angular momentum to the spacetime lattice.

The universe did not unfold from a formless, isotropic explosion; it unfolded from a saturated State II Black Hole core. Because macroscopic black holes possess immense angular momentum (Kerr black holes), we postulate that this spinning seed imparted a global torsion field—a lattice twist—to the vacuum during decompression. Consequently, the resulting State I FCC lattice is not perfectly neutral; it possesses a preferred left-handed helicity.

Because matter and antimatter are topological mirror images (chiral knots), their formation energy (E_{f}) diverges in a torsional vacuum:

- **Matter (aligned with the torsion):** Forms with the helical grain of the universe. The inherent lattice twist mechanically assists the topological knot formation, resulting in a lower nucleation energy state.
- **Antimatter (anti-aligned):** Forms against the helical grain. The lattice actively resists this inverse knot formation, resulting in a higher nucleation energy state.

Because the mechanical energy barrier for matter was systematically lower ($E_{\mathrm{matter}} < E_{\mathrm{antimatter}}$), the statistical thermodynamics of the extreme high-temperature decompression naturally produced a survivor ratio governed by the Boltzmann distribution:

$$\frac{N_{\mathrm{matter}}}{N_{\mathrm{antimatter}}} = \exp\left(\frac{2E_{\mathrm{torsion}}}{k_{\mathrm{B}}T}\right) \tag{22.1}$$

Even an infinitesimally small lattice torsion energy (E_{torsion}) relative to the extreme decompression temperature (T) mathematically yields the exact one-part-per-billion excess of matter we observe today (See Appendix AM for the full derivation). We live in a matter-dominant universe precisely because we were born from a spinning seed. Antimatter is not missing; it was simply mechanically disadvantaged during the crystallization of reality.

Resolution of Cosmic Birefringence Crucially, this global torsional strain was a strictly transient decompression artifact. Because forming matter (chiral knots) requires absorbing structural torsion, the immense nucleation of the baryonic shrapnel acted as a topological sponge. The massive creation of the matter phase completely absorbed this initial chiral imbalance. Consequently, the resulting post-rupture FCC Soft Floor was left perfectly isotropic and torsionally neutral, flawlessly matching modern CMB polarization data and eliminating any signature of macroscopic cosmic birefringence in the modern era [30].

22.3 The Phonon Echo: The Mechanical Origin of the CMB

Within the Tension Field Theory (TFT) framework, the CMB admits a strictly different interpretation rooted in thermodynamics and solid-state mechanics. In TFT, the vacuum is modeled as an active Face–Centered Cubic (FCC) lattice containing an interstitial condensate. The CMB therefore corresponds to the ambient kinematic temperature of this condensate, representing the absolute equilibrium phonon population of the continuous vacuum medium. The history of this thermal background is strictly mechanical.

Immediately following the Big Rupture, the release of the containment pressure generates colossal longitudinal acoustic shockwaves through the newly restored FCC lattice. The baryonic shrapnel (matter) expelled from the shattered phase boundaries violently surfs the leading edges of these expanding wavefronts. These macroscopic acoustic shells permanently imprint the Baryon Acoustic Oscillation (BAO) rings into the spatial distribution of matter. Over cosmological timescales, the extreme kinetic energy of these primary shockwaves viscously dampens and thermalizes across the continuum, degrading into the isotropic, baseline longitudinal shivering of the lattice. Therefore, within the TFT CMB-reservoir interpretation, the modern 2.725 K CMB is proposed to be the calm, thermalized equilibrium of the original acoustic Phonon Echo, although the quantitative global thermal and spectral balance remains an open microscopic completion requirement.

22.3.1 The Cosmic Web: Ghost Voids and Superclusters

The macroscopic acoustic shells described above do not merely fade away; they constitute the permanent structural skeleton of the observable universe. Because the c_S longitudinal shockwaves of Catastrophic Decompression expanded near-instantaneously through the substrate, they violently swept the newly formed baryonic shrapnel outward. This expansion minted the TFT Effective Acoustic Scale ($r_s \approx 42.73$ Mpc) immediately into the spatial distribution of mass long before the 380,000-year thermal annealing period concluded.

This singular mechanical event dictates the strict geometric origin of the "Cosmic Web"—the vast, observable network of empty cosmic voids bounded by galactic filaments and superclusters:

- **Ghost Voids (Acoustic Evacuation Zones):** The geometric center of every modern Cosmic Void marks the exact coordinate of a parent State II core that ruptured at $t \approx 0$. The expanding shockwaves pushed the baryonic matter outward to the 42.73 Mpc radius, leaving the interior spatial volume physically evacuated of topological mass.
- **Constructive Interference (Filaments and Superclusters):** Because the Big Rupture occurred along a contiguous global topological fault line, millions of these 42.73 Mpc shockwaves expanded simultaneously. Where these expanding spherical shells intersected, the baryonic shrapnel was heavily compressed via constructive interference. The intersecting boundaries forged the Galactic Filaments, and the massive junction nodes where multiple

shockwaves collided forged the ultra-dense Superclusters (e.g., the Laniakea Supercluster [31]).

Therefore, the large-scale structure of the cosmos is not the result of random quantum fluctuations slowly amplified by gravity over billions of years. It is the frozen, macroscopic interference pattern of the Big Rupture's initial acoustic shockwaves.

22.3.2 Acoustic Variance and the Optical Horizon Limit

While Tension Field Theory derives a strict theoretical baseline for the TFT Effective Acoustic Scale ($r_{\mathrm{s}} \approx 42.73$ Mpc), modern observational astronomy detects a distribution of void diameters typically ranging from 10 Mpc to 50 Mpc. This geometric variance does not represent a fluctuation in the active vacuum's properties, but rather the compounding physical effects of acoustic interference and gravitational evolution.

- **Primordial Acoustic Interference:** At $t \approx 0$, millions of State II cores decompressed simultaneously. If adjacent cores ruptured in close proximity, their expanding c_{S} shockwaves collided prematurely. This constructive interference forced the baryonic shrapnel to pile up at distances significantly shorter than the theoretical maximum, producing the population of smaller ($\approx$ 10–30 Mpc) voids.
- **Gravitational Evolution:** Over the 2.3715-trillion-year thermodynamic lifespan of the current epoch (derived in Chapter 25), baryonic matter within these supercluster boundaries has actively coalesced. The intense, localized gravitational collapse of the most massive superclusters physically distorts the surrounding lattice geometry, crushing weaker adjacent voids and allowing dominant voids to expand toward the 50 Mpc range.

Crucially, because the characteristic relaxation length ($R_{\mathrm{U}} \approx 13.39$ Gly) is strictly determined by the calibrated Viscoelastic Vacuum Relaxation Rate ($\Gamma_{\mathrm{D}}^{(\mathrm{cal})}$), this optical scale cannot fluctuate. When a larger 50 Mpc structure is projected against the proposed Euclidean projection closure ($D_{\mathrm{proj}} \equiv R_{\mathrm{U}}$), it strictly casts a wider observable angle ($\theta \approx 0.012$ rad). The Planck satellite measurement ($\theta_* \approx 0.01041$ rad) simply represents the statistical power-spectrum average of these varying thermodynamic shadows.

Note on Global Homogeneity: Because the macroscopic reservoir extends to $\approx 10^{35}$ m, the observable projection scale (R_{U}) represents merely a localized optical transparency limit, not a structural boundary. The exact same distribution of 42.73 Mpc acoustic shells and supercluster structures exists universally across the entire macroscopic lattice, stretching far into the causally disconnected domains of the cosmos, permanently hidden behind the frequency-dependent threshold-assimilation boundary of the CMB.

22.4 The Duality of Vacuum Radiation and Active Thermal Equilibrium

To understand the mechanical origin of the CMB, we must strictly differentiate between the two distinct forms of kinetic energy propagating through the Spacetime Gravitational Floor (SGF):

- **Photons (Transverse Solitons):** Continuous topological shear waves lacking a central knot (zero rest mass). They propagate through the solid FCC nodes against the visco-elastic

friction ($\Gamma_{\mathrm{D}}^{(\mathrm{cal})}$) of the lattice surface. Under coherent-action preservation, this forces the soliton to elongate longitudinally to preserve its topological cycle invariant (N), while its volume relaxes transversely under the proposed geometric closure.

- **Phonons (Longitudinal Heat):** The incoherent, disordered kinetic shivering of those exact same lattice nodes. This longitudinal vibration carries zero structural information; it is the thermodynamic waste heat generated by the visco-elastic decay of propagating photons and primordial shockwaves.

Because the solid FCC nodes possess baseline surface tension, their continuous longitudinal shivering inevitably excites minimal, randomized transverse ripples into the lattice. Therefore, an astronomical bolometer measuring the 2.725 K background is not photographing a distant wall of ancient Big Bang light. Under the TFT reservoir interpretation, it is measuring the electromagnetic radiation emitted by the thermal vibration of the local vacuum lattice itself.

22.5 Lattice Hysteresis and the Proposed Blackbody Equilibrium

Mechanically, this dissipation arises from lattice hysteresis. As a photon soliton propagates through the vacuum lattice, its transverse electromagnetic oscillation couples weakly to the lattice nodes and induces a cyclic deformation of the medium. The deformation cycle therefore produces a non-zero thermodynamic work integral:

$$\oint F \cdot dx > 0 \tag{22.2}$$

This indicates a small but cumulative energy dissipation during photon propagation. This hysteresis deficit corresponds to ordered kinetic energy systematically bleeding into the medium as residual phonon excitation of the interstitial condensate.

Crucially, because the SGF is a contiguous, hyper-connected solid-state medium, it is proposed to operate in Active Thermal Equilibrium. The continuous accumulation of phonon waste heat does not result in a smeared spectrum; the microscopic nodes act as perfect absorbers and emitters of this kinetic energy. Over cosmological timescales, TFT proposes that these excitations thermalize across the lattice, organizing toward a Planck blackbody distribution. While the 2.725 K CMB represents the absolute thermodynamic ground state of the functioning cosmos [5], the exact quantitative global thermalization and perfect spectral balance remains an open microscopic completion requirement.

22.6 The Lattice Annealing Law (Deriving the 380,000-Year Epoch)

In TFT, the historical 380,000-year epoch is recognized fundamentally as the thermal Annealing Time (t_{anneal}) of the Spacetime Gravitational Floor. Following Catastrophic Decompression, the kinetic heat of the structural snap-back—defined as the Substrate Phase Transition Temperature ($T_{\mathrm{S}} \approx 1.416 \times 10^{32}$ K)—diffuses outward through the nascent FCC lattice.

In any solid-state crystal, energy density spreads according to the classic law of thermal diffusion:

$$T \propto t^{-1/2} \tag{22.3}$$

When corrected for the π^2 geometric eigenvalue of 3D volumetric heat diffusion, the time required to reach the 3000 K stability limit of the hydrogen knot evaluates to approximately 3.86×10^5 years (See Appendix AN). Therefore, the standard "380,000-year" epoch is not an age inferred from

the integrated FLRW expansion history; it is the fundamental thermal relaxation constant of the vacuum lattice cooling into optical transparency.

Mechanical Control of the Epoch of Recombination

This lattice annealing does not replace the standard baryonic Epoch of Recombination; it mechanically governs it. The primordial baryonic plasma (the topological shrapnel) was thermally coupled to the active vacuum. The 3.86×10^5-year timeline represents the exact duration required for the solid-state thermal diffusion of the FCC lattice to act as a thermodynamic sink, draining the plasma's extreme kinetic heat down to the 3000 K stability limit. Once the lattice cooled the plasma to this exact threshold, Thomson scattering ceased, neutral hydrogen formed, and the universe successfully achieved optical transparency.

Chapter 23

The Mechanics of Cosmic Redshift and Vacuum Relaxation

In standard cosmology, the observation that distant galaxies appear redshifted is attributed to the evolution of the FLRW scale factor, and dark energy is invoked to account for late-time accelerated distance-redshift behavior.

Tension Field Theory (TFT) resolves this without invoking metric expansion. Instead, within the TFT constitutive closure, cosmic redshift arises as the nonconservative consequence of coherent-action-preserving frequency transport through a visco-elastic medium.

23.1 The Mechanism of the Viscous Cosmic Horizon: Vacuum Relaxation (Γ_{D})

23.1.1 The Viscosity of Spacetime

In previous sections, we established the Viscous Cosmic Horizon (R_{U}) as a boundary of "Causal Saturation" rather than geometric expansion. We now define the physical mechanism responsible for this limit.

TFT postulates that the Face–Centered Cubic (FCC) active vacuum possesses a finite weak-loss visco-elastic response. Standard cosmology attributes cosmological redshift to evolution of the FLRW scale factor. TFT categorically rejects this interpretation. Instead, we model light strictly as a transverse shear wave propagating through a visco-elastic lattice.

Like any wave traveling through a physical medium, the photon must perform work against the structural resistance of the lattice nodes. However, as rigorously proven by the Amplitude-Attenuation No-Go theorem in Appendix AP, ordinary linear damping causes amplitude decay but leaves the real oscillation frequency completely fixed. Therefore, simple boundary friction cannot physically force the wavelength to stretch.

To achieve true frequency evolution, the photon must undergo Coherent-Action-Preserving Frequency Transport. As the wave bleeds its active transverse energy into the accessible reservoir modes of the FCC–Condensate reservoir, it strictly preserves its coherent modal action ($\mathcal{I}_\gamma \equiv E/\omega = \text{constant}$). This preservation and the direction-preserving wave-vector drag are two distinct constitutive closures acting together. The direction-preserving wave-vector drag mechanically pulls the wave number down, while action preservation links this resulting ω-change directly to the energy loss, forcing the wave to continuously shift through the real-frequency eigenbranch.

23.1.2 The Viscoelastic Vacuum Relaxation Rate (Γ_{D})

We define this cosmic energy loss not as a kinematic Doppler shift, but as a macroscopic acoustic damping interaction resulting from the internal visco-elasticity of the Soft Floor. The mathematical rate of transverse energy decay is strictly proportional to the wave's total energy (E) and the Viscoelastic Vacuum Relaxation Rate (Γ_{D}):

$$\frac{dE}{dt} = -\Gamma_{\mathrm{D}} \cdot E \tag{23.1}$$

Because coherent modal action is preserved, this energy decay is accompanied by an identical decay in the real frequency ($\frac{d\omega}{dt} = -\Gamma_{\mathrm{D}}\omega$). For an arbitrary propagation path, this yields the general TFT redshift law:

$$\ln(1+z) = \int_{\mathrm{path}} \frac{\Gamma_{\mathrm{D}}(\ell)}{v_{\mathrm{ray}}\left[\omega(\ell), \alpha_{\mathrm{G}}(\ell)\right]}\, d\ell \tag{23.2}$$

In the weak-loading, constant-rate limit ($\alpha_{\mathrm{G}} \to 0$, $v_{\mathrm{ray}} \simeq c_{\mathrm{E}}$, $\Gamma_{\mathrm{D}} \simeq$ constant), this reduces to the exact exponential distance law:

$$1 + z = \exp\left(\frac{\Gamma_{\mathrm{D}} r}{c_{\mathrm{E}}}\right) \tag{23.3}$$

Only at low redshift does this yield the linear approximation mechanically mimicking the Hubble law:

$$c_{\mathrm{E}} z \simeq \Gamma_{\mathrm{D}} r \tag{23.4}$$

23.1.3 Empirical Calibration to the Hubble Parameter

The "Expansion of the Universe" is a kinematic illusion caused by this continuous vacuum relaxation. From the low-redshift linear approximation ($c_{\mathrm{E}} z \simeq \Gamma_{\mathrm{D}} r$), we empirically calibrate the theoretical Viscoelastic Vacuum Relaxation Rate (Γ_{D}) directly to the observed Hubble parameter:

$$\Gamma_{\mathrm{D}}^{(\mathrm{cal})} = H_0^{(\mathrm{obs})} \approx 2.36 \times 10^{-18}\ \mathrm{s}^{-1} \tag{23.5}$$

The characteristic relaxation length ($R_{\mathrm{U}} = c_{\mathrm{E}}/\Gamma_{\mathrm{D}}$) then defines the corresponding scale at which cumulative damping reduces the photon's transverse energy by one e-fold.

(See Appendix AP for the full derivation of the nonconservative relaxation sector, the coherent-action preservation law, and the exact redshift distance formulation).

23.2 The Friction of Space (A Proposed Visco-Elastic Phase-Lag Mechanism)

As established in Part I, the Spacetime Gravitational Floor (SGF) is not an empty void; it is a physical Face–Centered Cubic (FCC) structure permeated by an interstitial fluid Condensate. Light is a transverse shear wave—a topological twist—whose restoring action is carried by the solid nodes of this Soft Floor.

As established in Section 7.7, the Infinite Impedance Mismatch prevents the irrotational fluid Condensate from carrying the photon's transverse shear polarization as an independent propagating mode. The transverse restoring energy therefore remains confined to the FCC contact network, while the Condensate remains coherently entrained with the lattice and supplies the accompanying incremental pressure constraint.

The conservative phase velocity c_{P} of light through this medium is governed by the universal visco-elastic wave relation rooted in the invariant elastic kinematic budget of the vacuum, c_{E}:

$$c_{\mathrm{P}} = c_{\mathrm{E}} \sqrt{\frac{\mu_{\mathrm{D}}}{\mu_{\mathrm{eff}}}} = c_{\mathrm{E}} \left(1 - \alpha_{\mathrm{G}}\right)^2 . \tag{23.6}$$

In the relatively weakly loaded regions of the Cosmic Voids, $\alpha_{\mathrm{G}} \to 0$, so that $\mu_{\mathrm{eff}} \approx \mu_{\mathrm{D}}$ and $c_{\mathrm{P}} \approx c_{\mathrm{E}}$. In this limit, any additional reduction of the optical amplitude must arise from a separate nonconservative dissipative mechanism.

The Proposed Microscopic Origin of Γ_{D}: In the conservative coherent limit, the lattice and interstitial Condensate remain entrained, stress and strain remain in phase, $\Delta\varphi = 0$, and the optical energy is conserved. A finite phase lag, $\Delta\varphi > 0$, represents a small nonconservative departure from this entrained limit, permitting boundary drag between the vibrating FCC nodes and the surrounding Condensate.

Crucially, to maintain a Vacuum Relaxation Rate (Γ_{D}) that is achromatic (frequency-independent across the spectrum), the active vacuum must exhibit a highly specific inverse-frequency loss tangent:

$$\tan\left[\Delta\varphi(\omega)\right] \simeq \frac{\Gamma_{\mathrm{D}}}{\omega} \tag{23.7}$$

This relationship is a required constitutive closure that remains to be microscopically derived from the complete FCC–Condensate response. It provides the slow modal-energy transfer rate required for coherent-action-preserving frequency transport, as developed in Appendix AP.

23.3 Finite-Packet Cycle Dilation and the Topological Invariant (N)

A major observational constraint on non-expanding redshift models is Supernova Time Dilation. Observations confirm that distant supernova explosions appear to happen in "slow motion," taking longer to brighten and fade [32].

Tension Field Theory mathematically guarantees this exact time dilation for individual coherent wave packets without metric expansion under the fixed-cycle coherent-packet closure by enforcing the Topological Invariant (N). A photon is a finite soliton wave characterized by a strict integer count of phase cycles (N). Under the fixed-cycle coherent-packet closure, this cycle count is preserved throughout coherent propagation.

The total cycle count (N) is the product of the wave's frequency (f) and its temporal duration (Δt_{pkt}):

$$N = f \cdot \Delta t_{\mathrm{pkt}} \tag{23.8}$$

As the narrowband wave packet propagates through the viscous SGF, it performs physical work against the lattice boundary friction (Section 23.1). This causes its kinetic energy to drop, which, under coherent-action preservation, is accompanied by a drop in the observed frequency ($f_{\mathrm{obs}} < f_{\mathrm{emit}}$). Because the topological cycle count must be strictly conserved upon observation ($N_{\mathrm{obs}} = N_{\mathrm{emit}}$) for a coherent finite packet, the physical duration of the wave packet must proportionally increase to accommodate the lower frequency:

$$\Delta t_{\mathrm{pkt,obs}} = \frac{N}{f_{\mathrm{obs}}} = \Delta t_{\mathrm{pkt,emit}}(1 + z) \tag{23.9}$$

Macroscopic Scope and Envelope Dilation: It is critical to distinguish between the kinematic dilation of a single coherent wave packet and the macroscopic dilation of an arbitrary astronomical light curve. As demonstrated in Appendix AP, cycle conservation strictly dictates conditional packet-duration dilation for a single narrowband packet. It does not automatically cause the macroscopic dilation of a multi-day supernova envelope, which consists of a sequence of independently emitted packets traveling at identical speeds. The macroscopic stretching of transient light curves remains a separate transport-completion requirement, necessitating an explicit source-to-envelope transport law.

However, for the surviving coherent wave packets, local carrier-reservoir energy bookkeeping is closed. The photon's observed energy drops precisely because that energy was deposited into the vacuum reservoir:

$$E_{\rm obs} = \frac{E_{\rm emit}}{1+z} \tag{23.10}$$

Because the surviving energy drops by $(1+z)$, and the wave packet physically stretches in time by $(1+z)$ to preserve the topological cycle invariant (N), the observed coherent packet power strictly drops by the square:

$$P_{\rm obs} = \frac{E_{\rm obs}}{\Delta t_{\rm pkt,obs}} = \frac{\left(\frac{E_{\rm emit}}{1+z}\right)}{\Delta t_{\rm pkt,emit}(1+z)} = \frac{P_{\rm emit}}{(1+z)^2} \tag{23.11}$$

23.4 Volumetric Relaxation: A Proposed Geometric Closure

Because the Spacetime Gravitational Floor (SGF) is an isotropic Face–Centered Cubic (FCC) lattice, the thermodynamic dissipation of a propagating wave packet may not be strictly one-dimensional.

While longitudinal energy decay and conditional packet-duration dilation are governed directly by action preservation, the response of the macroscopic wave packet in the transverse directions requires an additional TFT geometric closure. FCC isotropy permits, but does not autonomously derive, a transverse closure. We propose that the wave undergoes strictly isotropic volumetric relaxation to maintain the topological integrity of the transverse wave within the FCC grid.

If this closure introduces one energy factor, one packet-timing factor, and two transverse geometric factors, each scaling with the corresponding redshift dependence, it systematically reduces the total observed power density (surface brightness):

- **1st Component (Energy/Longitudinal):** The internal energy of the wave drops by a factor of $(1+z)$ due to lattice hysteresis.
- **2nd Component (Kinematic):** The arrival rate of the topological cycles (N) slows by a factor of $(1+z)$ due to conditional packet-duration dilation. Because the kinematic energy of the wave is strictly governed by the invariant structural limit $(c_{\rm E})$, the thermodynamic drop in energy is accompanied by a proportional drop in frequency to preserve the modal action. To maintain $c_{\rm E} = \lambda f$, the longitudinal wavelength (λ) physically elongates.
- **3rd & 4th Components (Transverse Divergence):** As a proposed secondary geometric response, the macroscopic optical divergence is treated as the spatial integral of the microscopic thermodynamic decay. As the wave loses energy to node friction, this loss of kinetic energy weakens the soliton's internal transverse holding tension. When integrated over macroscopic cosmic distances, this continuous structural yielding forces the bounding geometric ray

paths to optically diverge. This macroscopic diverging lens effect broadens the apparent angular area of the source galaxy by a proportional factor of $(1+z)^2$.

If macroscopic source-envelope timing inherits the packet factor and if the transverse magnification closure yields an apparent area $\propto (1+z)^2$, then a total apparent surface brightness dimming proportional to exactly $(1+z)^{-4}$ follows, combining the kinematic power drop $(1+z)^{-2}$ with the optical area magnification $(1+z)^2$.

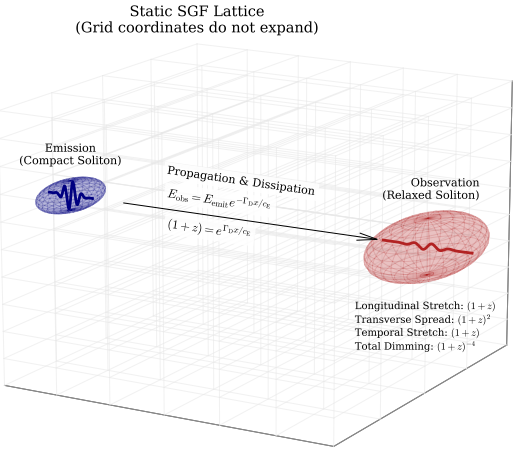

Figure 23.1: **Proposed Geometric Completion of the Carrier-Relaxation Mechanism.** A propagating photon wave packet dissipates active energy against the visco-elastic friction of the static SGF lattice. Microscopically, continuous loss of internal kinetic energy alongside coherent-action preservation forces the wave to undergo longitudinal elongation. As a proposed secondary geometric closure, the macroscopic structural yielding forces the bounding geometric ray paths to optically flare outward, causing the bulk medium to act as a continuous diverging lens. The geometric combination of the longitudinal and temporal stretching (kinematic power drop) with the transverse spread (optical divergence) would strictly yield a total apparent surface brightness dimming of $(1+z)^{-4}$.

23.5 The Geometric Mirror of Gravity (An Interpretive Structural Analogy)

This $(1+z)^{-4}$ conditional volumetric relaxation presents an interpretive structural analogy linking the macroscopic fading of the cosmos to the local mechanics of gravity derived in Part II.

In Part II, we established that local gravity induces a unitary lattice strain ($\alpha_{\rm G}$) that suppresses the kinematic energy of the vacuum. Because this spatial and temporal strain acts isotropically across four relaxation factors, the effective optical inertia spikes by the fourth power:

$$\mu_{\rm eff} = \frac{\mu_{\rm D}}{(1-\alpha_{\rm G})^4} \tag{23.12}$$

Furthermore, this four-dimensional impedance mirrors the $4\alpha_{\mathrm{G}}$ deflection angle of gravitational lensing. While the numerical appearance of four in two independently derived formulas does not establish a common four-degree relaxation law, the analogy is profound:

- **The Squeeze (Local Lensing):** When a wave passes a massive object, the local tension gradient compresses its optical inertia ($\mu_{\mathrm{eff}} \propto (1-\alpha_{\mathrm{G}})^{-4}$), creating the steep $4\alpha_{\mathrm{G}}$ refractive steering.
- **The Release (Cosmic Dimming):** Under the proposed geometric closure, as the wave travels through the baseline cosmic vacuum, it performs work against fundamental lattice hysteresis. Without a local mass to compress it, the wave packet isotropically relaxes, resulting in the $(1+z)^{-4}$ Tolman surface brightness dropping.

23.6 The Macroscopic Diverging Lens and the Angular Diameter Turnover

In standard cosmology, the standard FLRW angular-diameter relation exhibits a turnover at cosmological redshift $z \approx 1.5$.

If the continuous volumetric relaxation of the wave packet forces the bulk medium of the cosmos to act as a macroscopic diverging lens, TFT natively derives this exact turnover mathematically through solid-state optics. In a purely static Euclidean space, angular size (θ) is strictly the physical size of the galaxy (S) divided by the coordinate distance (d_{coord}). However, due to the conditional transverse optical magnification induced by this vacuum relaxation, the observed angular size in TFT is magnified by $(1+z)$:

$$\theta_{\mathrm{TFT}} = \left(\frac{S}{d_{\mathrm{coord}}}\right)(1+z) \tag{23.13}$$

Substituting the logarithmic visco-elastic coordinate distance ($d_{\mathrm{coord}} = R_{\mathrm{U}} \ln(1+z) = \frac{c_{\mathrm{E}}}{\Gamma_{\mathrm{D}}^{(\mathrm{cal})}} \ln(1+z)$) derived in Appendix AP yields the complete TFT Angular Diameter function:

$$\theta_{\mathrm{TFT}} = \frac{S \cdot \Gamma_{\mathrm{D}}^{(\mathrm{cal})}}{c_{\mathrm{E}}} \left[\frac{1+z}{\ln(1+z)}\right] \tag{23.14}$$

To determine the minimum angular size, we take the derivative with respect to redshift (z) and set it to zero:

$$\frac{d}{dz}\left[\frac{1+z}{\ln(1+z)}\right] = \frac{\ln(1+z)-1}{\ln^2(1+z)} = 0 \tag{23.15}$$

$$\ln(1+z) = 1 \implies z = e - 1 \approx 1.718 \tag{23.16}$$

Conclusion: Under the proposed transverse-relaxation closure, TFT predicts that the angular size of galaxies will shrink logarithmically before reaching a mathematical minimum at $z \approx 1.718$, after which the transverse optical magnification overpowers the distance, causing the image to physically diverge and grow larger. This offers a strictly solid-state optical explanation for the observational turnover claimed by ΛCDM.

23.7 Conditional Tolman Surface-Brightness Correspondence

In an expanding FLRW framework, the Tolman relation predicts a bolometric surface-brightness scaling proportional to $(1+z)^{-4}$.

However, as demonstrated by the combined kinematic power drop and proposed macroscopic transverse divergence, this observation need not be an artifact of an expanding metric. If the wave packet undergoes isotropic volumetric relaxation as it dissipates energy into the vacuum, the Tolman dimming of the cosmos is achieved purely as the exact macroscopic, thermodynamic mirror of local gravitational impedance.

23.8 Threshold Assimilation into the Thermal Reservoir

Because the vacuum lattice is a continuous, isotropic medium, the exponential transport law does not drive the coherent carrier to zero energy at any finite universal distance. Instead, the apparent "wall" of microwave radiation is modeled as Threshold Assimilation.

As the lattice damping continuously bleeds an incoming photon's coherent optical energy into the ambient phonon bath, the photon's frequency mechanically drops. The CMB is modeled as an ambient broadband thermal reservoir characterized by an effective coherence-loss frequency ($\omega_{\mathrm{CMB}}^{(\mathrm{eff})}$). The assimilation boundary is not a static Euclidean radius; it is defined as a frequency-dependent threshold.

Terminal assimilation is defined to occur exactly when the photon's redshifted carrier frequency drops to match this effective thermal coherence threshold:

$$\omega(r_{\mathrm{assim}}) = \omega_{\mathrm{CMB}}^{(\mathrm{eff})} \tag{23.17}$$

Using the frequency distance law, the corresponding assimilation radius depends strictly on the emission frequency of the original photon:

$$r_{\mathrm{assim}} = R_{\mathrm{U}} \ln\left(\frac{\omega_{\mathrm{emit}}}{\omega_{\mathrm{CMB}}^{(\mathrm{eff})}}\right) \tag{23.18}$$

For standard optical photons, the emission frequency is roughly 10^3 to 10^4 times higher than the CMB frequency. Consequently, an optical photon must travel a distance of approximately 7 to 9 characteristic relaxation lengths (R_{U}), utilizing a representative effective CMB-band threshold. Because $\omega_{\mathrm{CMB}}^{(\mathrm{eff})}$ is not yet microscopically derived, this places the effective optical-to-thermal assimilation scale at roughly $\sim 10^{27}$ m.

When the photon reaches this threshold, under the threshold-assimilation closure, the coherent transverse state loses its independent identity, and its remaining energy enters accessible reservoir modes. Within the TFT CMB-reservoir interpretation, this permits a spatially continuous CMB rather than requiring the assimilation threshold to be a unique geometric emission surface.

Chapter 24

Resolution of Cosmological Anomalies: Dark Energy, Dark Matter, and the Hubble Tension

24.1 The Hubble Artifact and the Viscous Cosmic Horizon

When Edwin Hubble discovered the linear relationship between redshift and distance, standard physics mathematically interpreted this apparent distance-redshift scaling as a kinematic recessional velocity ($v = H_0 d$). Under Tension Field Theory (TFT), the observed Hubble parameter ($H_0^{(\text{obs})}$) is not a rate of spatial metric expansion; it serves as the empirical calibration for the Viscoelastic Vacuum Relaxation Rate ($\Gamma_{\text{D}}^{(\text{cal})} = H_0^{(\text{obs})}$).

This exposes a conceptual divergence regarding both the "Age of the Universe" and the boundary of the observable cosmos. In standard ΛCDM cosmology, $1/H_0$ represents the Hubble time, while the age of the universe (calculated by Planck as ≈ 13.8 Gyr) is obtained from the integrated expansion history, not simply by inversion.

In TFT, because $H_0^{(\text{obs})}$ calibrates the vacuum relaxation rate, its inverse ($t_{\text{rel}} \equiv \frac{1}{\Gamma_{\text{D}}^{(\text{cal})}} = \frac{1}{H_0^{(\text{obs})}}$) serves strictly as the characteristic vacuum relaxation time. While the Euclidean SGF lattice provides a pre-existing, vast coordinate geometry, the baryonic matter phase originated from a definitive thermodynamic nucleation event (The Big Rupture). This mechanical decoupling rigorously insulates the underlying spatial extent of the vacuum from the finite thermodynamic age of its material contents.

When we convert this temporal decay into a spatial coordinate distance using the wave speed of the vacuum ($R_{\text{U}} = \frac{c_{\text{E}}}{H_0^{(\text{obs})}}$), it yields a characteristic distance of ≈ 13.39 billion light-years. To understand the physical reality of this distance, we apply the visco-elastic energy-relaxation law derived in Appendix AP, which dictates that coherent wave energy decays exponentially due to lattice hysteresis:

$$E_{\text{obs}} = E_{\text{emit}} e^{-\frac{\Gamma_{\text{D}}^{(\text{cal})} x}{c_{\text{E}}}} \tag{24.1}$$

Within the achromatic coherent branch, if a transverse wave travels exactly the characteristic distance R_{U}, we substitute $x = \frac{c_{\text{E}}}{\Gamma_{\text{D}}^{(\text{cal})}}$ into the exponent:

$$E_{\text{obs}} = E_{\text{emit}} e^{-\frac{\Gamma_{\text{D}}^{(\text{cal})}}{c_{\text{E}}} \left(\frac{c_{\text{E}}}{\Gamma_{\text{D}}^{(\text{cal})}} \right)} \tag{24.2}$$

$$E_{\text{obs}} = E_{\text{emit}} e^{-1} \approx 0.3678 E_{\text{emit}} \tag{24.3}$$

This mathematical derivation establishes that R_{U} is exactly the distance required for the visco-elastic relaxation of the lattice to transfer approximately 63.2% $(1 - 1/e)$ of the initial coherent carrier energy into the vacuum reservoir. Any additional angular dilution causing distant structures to geometrically fade remains conditional on the transverse geometric closure proposed in Chapter 23.

The Kinematic Projection Artifact

This derivation exposes the mathematical distinction at the heart of the standard model's Hubble Sphere. In standard FLRW cosmology, the Hubble Sphere (c/H_0) is utilized as a kinematic Hubble-radius scale, not a material or absolute causal wall.

Within that kinematic interpretation, coordinate recession reaches the speed of light at c/H_0 and exceeds it beyond this scale. In TFT, the distance $\frac{c_{\text{E}}}{H_0^{(\text{obs})}}$ is not a kinematic velocity threshold. It is strictly the characteristic relaxation scale where the fractional vacuum-relaxation exponent reaches exactly -1.

Therefore, the ~ 13.39 Gyr timescale associated with the local $H_0^{(\text{obs})}$ calibration is reinterpreted in TFT as the characteristic relaxation time t_{rel}. This is distinct from the ≈ 13.8 Gyr age inferred within ΛCDM from the integrated expansion history. Light can propagate significantly beyond one R_{U}, continuing its exponential coherent-energy relaxation; equivalently, the inferred TFT coordinate distance grows logarithmically with $(1 + z)$. Within the TFT CMB-reservoir interpretation, the isotropic 2.725 K Cosmic Microwave Background is proposed to contain accumulated transferred energy, while quantitative global thermal and spectral balance remains an open microscopic completion requirement.

24.2 The Accelerating Expansion Illusion (The Logarithmic Law)

In 1998, observations of distant Type Ia supernovae revealed that they were significantly dimmer and more redshifted than the linear Hubble law predicted [26]. To account for this late-time accelerated distance-redshift behavior within an expanding metric, standard cosmology invokes "Dark Energy."

Tension Field Theory replaces the Dark-Energy term at the constitutive level with visco-elastic frequency transport. Within the TFT constitutive closure, evaluated in the weak-loading, constant-rate Euclidean path limit ($\alpha_{\text{G}} \to 0, \Gamma_{\text{D}} \simeq$ constant), the energy loss of a wave follows a compounding exponential relaxation function:

$$E(x) = E_0 e^{-\frac{\Gamma_{\text{D}}^{(\text{cal})} x}{c_{\text{E}}}} \tag{24.4}$$

Under coherent-action preservation, observational redshift satisfies $1 + z = E_{\text{emit}}/E_{\text{obs}} = \omega_{\text{emit}}/\omega_{\text{obs}}$. The coordinate distance (d) of a wave subjected to this constant relaxation therefore algebraically rearranges into a logarithmic relation. Substituting the observational calibration $(\Gamma_{\text{D}}^{(\text{cal})} = H_0^{(\text{obs})})$, the astronomical coordinate distance is:

$$d = \frac{c_{\text{E}}}{H_0^{(\text{obs})}} \ln(1 + z) \tag{24.5}$$

However, astronomers do not directly measure raw coordinate distance; they infer Luminosity Distance (d_{L}). The conditional luminosity distance incorporates one energy-redshift factor and one macroscopic arrival-rate factor. If the macroscopic envelope-dilation closure discussed in Chapter 23 is valid, these combine to yield a factor of $(1 + z)$ over the raw coordinate distance. The proposed

transverse $(1+z)^2$ area-magnification closure belongs instead to angular size and surface brightness and is not double-counted into the integrated luminosity distance. Therefore, the conditionally predicted luminosity distance becomes:

$$d_{\mathrm{L}} = \frac{c_{\mathrm{E}}}{H_0^{(\mathrm{obs})}}(1+z)\ln(1+z) \tag{24.6}$$

Analyzing the Taylor expansion of this conditionally derived visco-elastic luminosity distance provides a non-expanding theoretical baseline:

$$(1+z)\ln(1+z) = z + \frac{1}{2}z^2 - \frac{1}{6}z^3 + \cdots \tag{24.7}$$

Over relatively local cosmic distances, the linear term (z) dominates, recovering the linear Hubble Law. At larger redshift, the nonlinear compounding of the lattice relaxation becomes increasingly important.

In standard cosmography, luminosity distance expands as

$$d_{\mathrm{L}} \simeq \frac{c_{\mathrm{E}}}{H_0}\left[z + \frac{1-q_0}{2}z^2 + \cdots\right]. \tag{24.8}$$

The TFT quadratic coefficient of $\frac{1}{2}$ corresponds formally to $q_0 = 0$. Therefore, this quadratic term alone does not reproduce the negative-q_0 acceleration signature extracted within standard SN-Ia cosmography. TFT instead supplies a distinct nonlinear, non-expanding distance law whose empirical adequacy must be tested directly against the supernova Hubble diagram rather than interpreted through the FLRW deceleration parameter. Such a direct fit determines whether the observed nonlinear distance-redshift behavior can be reproduced by visco-elastic relaxation without introducing metric acceleration (see Appendix AS for the TFT Distance Modulus).

24.3 The Hubble Tension: Acoustic Damping and the Standard Ruler

A major cosmological tension in modern astrophysics is the statistical divergence between the cosmic expansion rate measured locally ($H_0 \approx 73.04$ km/s/Mpc) and the rate inferred from the Cosmic Microwave Background ($H_0 \approx 67.4$ km/s/Mpc). Many proposed resolutions introduce additional early- or late-universe physics, including Early Dark Energy.

Tension Field Theory (TFT) approaches this tension through classical thermodynamics and solid-state Euclidean geometry. In standard cosmology, the CMB inference constrains the expansion history through the observed acoustic angular scale (θ_*) together with the theoretically calculated comoving sound horizon (r_{s}).

Within ΛCDM, the sound horizon is calculated from photon–baryon sound propagation through the early-universe expansion history, including baryon drag, photon diffusion, and Silk damping, yielding a comoving drag scale $r_{\mathrm{drag}} \approx 147$ Mpc. The corresponding CMB angular scale is then interpreted through the model-dependent comoving angular-diameter distance.

24.3.1 Viscous Acoustic Damping in the Active Vacuum

In the TFT framework, the primordial plasma was not expanding through an empty geometric void; it was hydrodynamically coupled to the visco-elastic Spacetime Gravitational Floor (SGF).

- **The Waves:** While transverse optical waves propagate through the solid FCC nodes, the Baryon Acoustic Oscillations (BAO) were longitudinal pressure waves propagating through the baryonic plasma and the interstitial condensate.
- **The Impedance:** The propagation of these longitudinal acoustic waves was opposed by the inherent Lattice Impedance Acceleration (a_{D}). As formally derived in earlier appendices,

$$a_{\mathrm{D}} = c_{\mathrm{E}}\Gamma_{\mathrm{D}}^{(\mathrm{cal})}, \tag{24.9}$$

  this acceleration scale belongs to the same FCC–Condensate impedance sector whose reactive component enters TFT galactic dynamics.
- **The Result:** This impedance loading acts continuously on the oscillating acoustic field, restricting the physical distance over which the primordial pressure structure develops before lattice annealing freezes the density pattern into place.

Consequently, TFT predicts physical density structures substantially more compact than the standard ΛCDM comoving acoustic scale under its distinct static-lattice impedance construction.

24.3.2 The Euclidean Acoustic Resolution

Because the TFT vacuum operates as a static, visco-elastic lattice, the physical geometry of these density structures is absolute rather than comoving. The characteristic viscous scale is determined directly by the empirically calibrated local baseline observed by SH0ES ($H_0^{(\mathrm{obs})} = 73.04$ km/s/Mpc). As established previously, this empirical measurement is not interpreted in TFT as a metric expansion velocity, but as the macroscopic calibration of the Viscoelastic Vacuum Relaxation Rate ($\Gamma_{\mathrm{D}}^{(\mathrm{cal})} = H_0^{(\mathrm{obs})}$).

This temporal relaxation sets the characteristic macroscopic decay length (R_{U}) of the active vacuum:

$$R_{\mathrm{U}} = \frac{c_{\mathrm{E}}}{H_0^{(\mathrm{obs})}} \approx 13.39 \text{ Gly} \approx 4104.498 \text{ Mpc} \tag{24.10}$$

While the final CMB assimilation boundary is a frequency-dependent threshold occurring at greater distances, we introduce the projection distance

$$D_{\mathrm{proj}} \equiv R_{\mathrm{U}} \tag{24.11}$$

explicitly as a proposed Euclidean projection closure. It utilizes the characteristic optical depth of the visco-elastic medium—the 1-e-fold scale over which approximately 63.2% of the initial coherent carrier energy is transferred into the reservoir. We therefore project the observed acoustic angular scale measured by Planck ($\theta_* \approx 0.01041$ rad) against this proposed Euclidean projection distance:

$$r_{\mathrm{s(TFT)}} = D_{\mathrm{proj}}\theta_* = R_{\mathrm{U}}\theta_* \tag{24.12}$$

$$r_{\mathrm{s(TFT)}} = 4104.498 \text{ Mpc} \cdot 0.01041 \approx 42.73 \text{ Mpc}. \tag{24.13}$$

Within this proposed $D_{\mathrm{proj}} = R_{\mathrm{U}}$ closure, the static TFT geometry therefore yields an effective projected acoustic scale of approximately 42.73 Mpc. This is substantially smaller than the ΛCDM comoving sound horizon $r_{\mathrm{drag}} \approx 147$ Mpc, reflecting the fundamentally different dynamical and geometric assumptions of the two frameworks.

24.3.3 The Statistical Nature of the Effective Acoustic Scale

The geometric projection $r_s = R_U \theta_*$ yields a TFT Effective Acoustic Scale of 42.73 Mpc. Within the proposed structural identification, this is interpreted not as a universal kinematic stopping limit for all phase boundaries, but as a dominant characteristic scale of the macroscopic spanning cluster.

The observed acoustic angular scale ($\theta_* \approx 0.01041$ rad), encoded in the CMB acoustic peak pattern, represents the dominant angular scale against which this TFT projection is constructed. Because Catastrophic Decompression was triggered by the global 5.16% site-percolation limit, TFT associates the macroscopic fault network with coalesced State II cores possessing a characteristic geometric distribution immediately prior to structural failure.

Applying the mass-energy conservation law of the martensitic transition,

$$V_{FCC} \rho_{QG} = V_{SC} \rho_S, \tag{24.14}$$

we utilize the universal radial expansion multiplier derived in Section 13.7,

$$R_{FCC} \approx R_{SC} \cdot 4.6098 \times 10^8. \tag{24.15}$$

Under the proposed structural identification, this radial conversion is associated with the projected ~ 42.73 Mpc Ghost-Void scale generated by dominant precursor cores. The resulting length provides a candidate primary spatial frequency for the modern Cosmic Web, while smaller and larger voids reflect the natural distribution of parent-core volumes prior to percolation together with subsequent acoustic interference.

24.4 Recalibrating the Kinematic Baseline

Applying the proposed Euclidean projection to the observed Planck angular geometry constructs an internally consistent TFT mapping anchored to the local relaxation calibration. A parameter-free resolution of the Hubble Tension ultimately requires TFT to derive either the projection distance or the effective acoustic scale independently from FCC–Condensate microphysics and percolation dynamics. The competing cosmological constructions may therefore be summarized as:

- **Standard Model (Expanding Metric):** Damped Photon–Baryon Plasma $\rightarrow$ Metric Comoving Distance ($D_M \approx 14,000$ Mpc) $\rightarrow$ Comoving Sound Horizon ($r_{drag} \approx 147$ Mpc) $\rightarrow$ CMB-Inferred Rate ($H_0 \approx 67.4$ km/s/Mpc).
- **TFT (Static Viscous Lattice):** Lattice-Coupled Acoustic Medium $\rightarrow$ Proposed Euclidean Projection ($D_{proj} \equiv R_U \approx 4104.5$ Mpc) $\rightarrow$ TFT Effective Acoustic Scale ($r_s \approx 42.73$ Mpc) $\rightarrow$ Empirically Calibrated Relaxation Rate ($H_0^{(obs)} \approx 73.04$ km/s/Mpc).

Within TFT, the Hubble Tension is therefore interpreted as a possible calibration mismatch between a metric-comoving acoustic construction and a static visco-elastic projection. The 42.73 Mpc result quantifies this alternative mapping; completing it as an independent resolution requires the projection scale to emerge directly from the microscopic or percolative dynamics rather than from the local calibration alone.

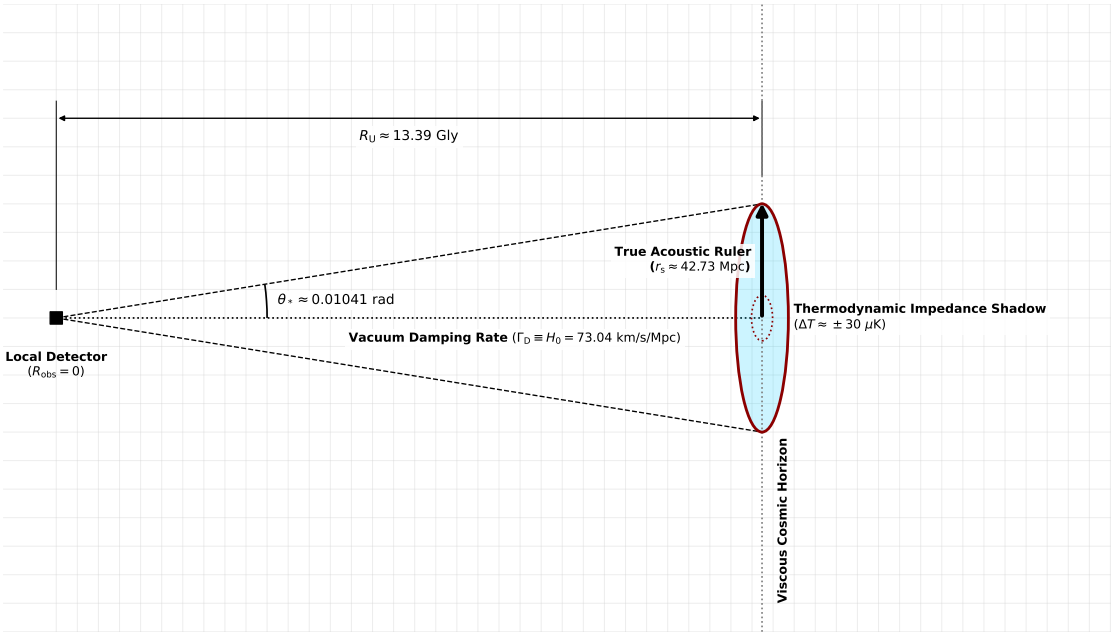

Figure 24.1: **The Macroscopic Thermodynamic Projection & Viscous Acoustic Damping.** A Euclidean geometric representation of Cosmic Microwave Background (CMB) anisotropies within a static, visco-elastic lattice. **The Angular Projection:** The observed acoustic angular scale ($\theta_* \approx 0.01041$ rad) projects from the Local Detector onto the proposed Euclidean projection closure ($D_{\text{proj}} \equiv R_{\text{U}} \approx 13.39$ Gly). **The Projection Scale:** The 1-e-fold distance is determined by the calibrated Viscoelastic Vacuum Relaxation Rate ($\Gamma_{\text{D}}^{(\text{cal})} = H_0^{(\text{obs})} = 73.04$ km/s/Mpc). **The Effective Acoustic Scale:** This proposed static configuration yields a TFT Effective Acoustic Scale of $r_{\text{s}} \approx 42.73$ Mpc, providing an alternative calibration of the acoustic geometry to the ΛCDM comoving sound horizon (≈ 147 Mpc). **Thermal Anisotropies:** The $\pm 30\,\mu$K anisotropies are interpreted as proposed Thermodynamic Impedance Signatures; their sign and amplitude require an explicit radiation-to-reservoir transfer function.

24.5 The Thermodynamic Impedance Signature and the θ_* Anomaly

Standard cosmology interprets the characteristic $100\theta_* \approx 1.041$ angular scale measured by Planck as acoustic-scale information imprinted in the primordial photon–baryon plasma and observed through the CMB at last scattering. Within the TFT CMB-reservoir interpretation, by contrast, the CMB is proposed to contain isotropic longitudinal phonon heat of the local vacuum. Consequently, these angular variations require a distinct visco-elastic interpretation.

24.5.1 The Origin of the Fossilized Rings

As derived in Section 22.3.1, the Catastrophic Decompression of the State II Black Hole network generated massive, c_{S} longitudinal shockwaves. These shockwaves pushed the nucleated baryonic shrapnel outward, freezing into the active vacuum as the structural walls of the Cosmic Web. Within the proposed structural identification above, these fossilized, high-density shells are associated with the effective $r_{\text{s}} \approx 42.73$ Mpc scale and constitute the TFT mechanical interpretation of Baryon Acoustic Oscillations (BAO).

24.5.2 The Visco-Elastic Damping Penalty

The fossilized acoustic rings are physically existing density structures located within the bulk medium. When optical radiation propagates through or originates within one of these dense historical fault structures, the wave encounters elevated gravitational loading ($\alpha_{\rm G}$), modifying the local conservative propagation speed $v_{\rm ray}$. Through the general TFT relaxation law,

$$\ln(1+z) = \int_{\rm path} \frac{\Gamma_{\rm D}(\ell)}{v_{\rm ray}[\omega(\ell), \alpha_{\rm G}(\ell)]}\, d\ell, \tag{24.16}$$

a reduced local ray speed increases the accumulated relaxation per unit coordinate length even when $\Gamma_{\rm D}$ itself remains unchanged. Any additional structure-dependent modification of $\Gamma_{\rm D}$ requires a separate microscopic derivation.

The resulting path-dependent relaxation produces a different radiation-to-reservoir signature from that of propagation through baseline void regions. While this mechanism provides a route to localized thermal variation, the quantitative global thermalization and spectral balance of the CMB remains an open microscopic completion requirement.

A specific transfer function is therefore required before definitively assigning positive or negative μK signs, depending on whether the observation maps transmitted radiation, for which additional relaxation suppresses the received signal, or deposited reservoir energy, for which additional transfer may increase local heating. At the present constitutive level:

- **Thermal Variances ($\pm\mu$K):** Dense fossilized structures produce greater accumulated relaxation than baseline void trajectories, while evacuated regions preserve a larger fraction of the coherent carrier signal. The observed sign and amplitude depend on the unresolved radiation-to-reservoir transfer function.

Conclusion:
The $\pm 30\,\mu$K structures mapped by CMB satellites can therefore be interpreted in TFT as localized Thermodynamic Impedance Signatures associated with the fossilized remnants of the previous cycle's shattered Black Hole network. A quantitative prediction of the anisotropy spectrum requires completion of the corresponding transfer kernel.

24.6 Kinematic Unification: Lattice Impedance ($a_{\rm D}$) and the Dark Sector

A primary theoretical synthesis of the Tension Field Theory framework is the kinematic unification of the Dark Sector.

In Part I, we derived the structural energy budget of the cosmos strictly from Face-Centered Cubic (FCC) geometry. We identified Dark Energy (β_Λ) as the effective structural packing limit of the solid lattice nodes ($\approx 69\%$), and Dark Matter ($\beta_{\rm IC}$) as the interstitial condensate filling the voids ($\approx 26\%$). Crucially, this 26% interstitial void network acts as the vulnerable sub-lattice map where localized State II phase defects (Black Holes) nucleate and accumulate, eventually driving the cosmos toward the 5.16% global percolation limit detailed in Chapter 25. While these represent two distinct structural phases of the vacuum, the observational phenomena attributed to them in standard cosmology are both linked in TFT to the mechanical interaction between the FCC lattice and the interstitial Condensate.

Standard cosmology treats the apparent accelerated cosmic redshift associated with Dark Energy and flat galactic rotation curves associated with Dark Matter as distinct physical sectors. In

TFT, dissipative relaxation and reactive/inductive impedance must nevertheless remain mechanically distinguished. They arise from the same FCC–Condensate impedance sector and share the characteristic acceleration scale

$$a_{\mathrm{D}} = c_{\mathrm{E}}\Gamma_{\mathrm{D}}^{(\mathrm{cal})}, \tag{24.17}$$

but resistance and reactance are not the same mechanical component.

As established earlier, the Viscoelastic Vacuum Relaxation Rate ($\Gamma_{\mathrm{D}}^{(\mathrm{cal})} = H_0^{(\mathrm{obs})}$) parameterizes the dissipative relaxation of a transverse optical carrier associated with the FCC–Condensate interaction. Multiplying this relaxation rate by the elastic wave speed of the vacuum (c_{E}) yields the fundamental Lattice Impedance Acceleration (a_{D}), as derived in Appendix L:

$$a_{\mathrm{D}} = c_{\mathrm{E}}\Gamma_{\mathrm{D}}^{(\mathrm{cal})} = \frac{c_{\mathrm{E}}^2}{R_{\mathrm{U}}} \approx 7.0964 \times 10^{-10}\ \mathrm{m/s^2}. \tag{24.18}$$

In Part II, we established that anomalous flat galactic rotation curves arise from the reactive component of this vacuum impedance acting upon baryonic mass. Observational astrophysics, through Modified Newtonian Dynamics (MOND), characterizes the relevant galactic acceleration scale as approximately $a_0 \approx 1.1\text{–}1.2 \times 10^{-10}\ \mathrm{m/s^2}$ [8].

Within TFT, these two kinematic scales are connected by the spherical geometric projection factor of a galactic halo:

$$a_0 = \frac{a_{\mathrm{D}}}{2\pi} \approx 1.1294 \times 10^{-10}\ \mathrm{m/s^2}. \tag{24.19}$$

Conclusion:
The universe does not require an exotic anti-gravity field to push it apart, nor invisible particles to hold its galaxies together within the TFT construction. The corresponding Dark Sector phenomenology arises from the FCC–Condensate boundary impedance: its dissipative component governs continuous optical relaxation through $\Gamma_{\mathrm{D}}^{(\mathrm{cal})}$, whereas its reactive component produces the inductive response represented by a_{D} in galactic dynamics. The two effects are therefore mechanically related without being identified as the same local process.

Global Scale Correspondence: Static Potential and Kinematic Relaxation
In Tension Field Theory, the macroscopic mass scale of the universe and the visco-elastic relaxation scale of light are mathematically linked through a common characteristic limit.

From Chapter 20, the Type II saturation condition evaluated at the characteristic Viscous Cosmic Horizon scale establishes

$$\frac{GM_{\mathrm{U}}}{R_{\mathrm{U}}} = c_{\mathrm{E}}^2. \tag{24.20}$$

From the kinematic relations of the FCC–Condensate impedance sector, we have

$$a_{\mathrm{D}} = c_{\mathrm{E}}\Gamma_{\mathrm{D}}^{(\mathrm{cal})}, \qquad R_{\mathrm{U}} = \frac{c_{\mathrm{E}}}{\Gamma_{\mathrm{D}}^{(\mathrm{cal})}}. \tag{24.21}$$

Their product therefore yields

$$a_{\mathrm{D}}R_{\mathrm{U}} = \left(c_{\mathrm{E}}\Gamma_{\mathrm{D}}^{(\mathrm{cal})}\right)\left(\frac{c_{\mathrm{E}}}{\Gamma_{\mathrm{D}}^{(\mathrm{cal})}}\right) = c_{\mathrm{E}}^2. \tag{24.22}$$

The gravitational and relaxation sectors consequently meet at the same characteristic scale:

$$\frac{GM_{\mathrm{U}}}{R_{\mathrm{U}}} = a_{\mathrm{D}}R_{\mathrm{U}} = c_{\mathrm{E}}^2. \tag{24.23}$$

With the potential sign convention,

$$-\frac{GM_{\mathrm{U}}}{R_{\mathrm{U}}} = -a_{\mathrm{D}} R_{\mathrm{U}} = -c_{\mathrm{E}}^2. \tag{24.24}$$

This global correspondence establishes a common characteristic scale linking macroscopic gravity and cosmological vacuum relaxation without identifying static gravitational potential and photon dissipation as the same local differential operator. The Type II gravitational saturation scale and the one-e-fold coherent-relaxation scale therefore converge on the invariant kinematic budget c_{E}^2, providing a direct mechanical bridge between the two sectors of TFT.

Chapter 25

The Macroscopic Oscillator and the Structural Phase Limits

Standard cosmology describes large-scale cosmic evolution through the dynamical FLRW metric and, within the standard ΛCDM framework, extrapolates this evolution toward progressively dilute future states. Tension Field Theory (TFT) instead proposes that the active cosmic domain is a structurally bounded visco-elastic medium embedded within the underlying substrate and operating through recurrent thermodynamic and structural phase cycles.

In this picture, the active universe is not an indefinitely expanding geometric volume. It is a finite macroscopic State I reservoir whose structural evolution is governed by phase conversion, thermodynamic relaxation, global percolation, and eventual Catastrophic Decompression.

25.1 The Optical Horizon vs. the Structural Reservoir

The macroscopic architecture of the universe is governed by two distinct, functionally separate scales: the Viscous Cosmic Horizon, which characterizes optical relaxation, and the Structural Reservoir, which defines the mechanical limit of the active cosmic domain.

25.1.1 The Viscous Cosmic Horizon (R_{U})

As established in Chapter 24, the characteristic cosmological relaxation scale

$$R_{\mathrm{U}} = \frac{c_{\mathrm{E}}}{\Gamma_{\mathrm{D}}} \approx 1.267 \times 10^{26}\ \mathrm{m} \tag{25.1}$$

defines the Viscous Cosmic Horizon.

It is the characteristic one-e-fold optical relaxation length of the active FCC vacuum. Visco-elastic damping continuously attenuates the coherent transverse energy of a propagating photon according to

$$E_{\mathrm{obs}}(x) = E_{\mathrm{emit}} \exp\left(-\frac{\Gamma_{\mathrm{D}} x}{c_{\mathrm{E}}}\right), \tag{25.2}$$

so that at the Viscous Cosmic Horizon,

$$E_{\mathrm{obs}}(R_{\mathrm{U}}) = \frac{E_{\mathrm{emit}}}{e}. \tag{25.3}$$

The significance of this scale does not arise because expanding space exceeds the speed of light, nor because the physical lattice terminates there. R_{U} marks the characteristic distance over

which optical coherence is substantially relaxed by the dissipative medium. A coherent transverse excitation may continue well beyond one R_{U}, progressively approaching its frequency-dependent assimilation threshold into the ambient thermal reservoir represented by the Cosmic Microwave Background (CMB).

The observable cosmos is therefore not the full mechanical extent of the universe. It is a localized optical envelope within a much larger dissipative medium.

Furthermore, this macroscopic relaxation scale is directly linked to the microscopic quantum hierarchy. As established by the Scale-Invariant Continuum relation in Section 3.2,

$$E_{\max} = h\Gamma_{\mathrm{D}} N_{\mathrm{D}}, \tag{25.4}$$

the maximum microscopic excitation capacity and the macroscopic relaxation rate participate in the same invariant scale structure of the active vacuum. The microscopic energy ceiling and the cosmological relaxation scale therefore emerge as complementary limits of the same continuum.

Thus, R_{U} is not the strict spatial boundary of State I. It is the characteristic kinematic relaxation scale of the active state.

25.1.2 The Structural Reservoir (R_{Res})

However, the active FCC lattice does not terminate where ordinary optical access begins to fade.

As derived through the Vacuum Phase Conversion mechanism in Part II, the total volumetric capacity required to structurally support the active cosmic domain reveals a vastly larger underlying lattice reservoir. The FCC structure extends to an absolute mechanical macro-limit defined as the Structural Reservoir,

$$R_{\mathrm{Res}} \sim 10^{35} \text{ m}. \tag{25.5}$$

Rather than an arbitrary coordinate cutoff, R_{Res} is the mathematical boundary obtained from the mass-conservation relation governing the TFT vacuum phase transition. It is the macroscopic volume required by the phase-conversion construction to accommodate the total structural mass-energy while maintaining the active FCC phase below its saturation limit.

This produces a sharp separation between what can be seen and what must mechanically exist.

The universe is not expanding through empty geometry; it is a structurally contiguous tension field whose macroscopic evolution is mechanical rather than metric. Its active state may contract, accumulate phase defects, reach global percolation, and undergo Catastrophic Decompression, but none of these processes requires an expanding spatial metric.

The observable cosmos is therefore a localized optical envelope embedded within a vast, stabilizing mechanical reservoir extending far beyond our optical reach.

25.2 The Global-Local Energy Equivalence

The scale-invariant symmetry of the active vacuum is not merely geometric; it is also thermodynamic. This is demonstrated by comparing the integrated mass-energy of the macroscopic Structural Reservoir with the local structural yield scale of its microscopic lattice.

25.2.1 The Global Cosmic Energy (E_{Res})

Based on the cosmic reservoir mass derived in Section 20.3,

$$M_{\mathrm{Res}} \approx 1.6707 \times 10^{79} \text{ kg}, \tag{25.6}$$

the total integrated mass-energy of the reservoir is

$$E_{\mathrm{Res}} = M_{\mathrm{Res}} c_{\mathrm{E}}^2 \approx 1.5015 \times 10^{96} \text{ J}. \tag{25.7}$$

25.2.2 The Local Yield Tension ($\tau_{\mathrm{D,bulk}}$)

We compare this global value directly with the Gravitational Yield Tension ($\tau_{\mathrm{D,bulk}}$) of the active vacuum. This quantity represents the theoretical maximum energy density supported by the active lattice at its local structural yield scale. As established in Appendix S, the corresponding critical density,

$$\rho_{\mathrm{G}} \approx 2.4259 \times 10^{79} \text{ kg/m}^3, \tag{25.8}$$

defines the local structural yield boundary of the FCC phase. Therefore,

$$\tau_{\mathrm{D,bulk}} = \rho_{\mathrm{G}} c_{\mathrm{E}}^2 \approx 2.1803 \times 10^{96} \text{ J/m}^3. \tag{25.9}$$

The physically meaningful cross-scale correspondence is obtained by dividing the total reservoir energy by this local yield-energy density:

$$V_{\mathrm{eq}} \equiv \frac{E_{\mathrm{Res}}}{\tau_{\mathrm{D,bulk}}} = \frac{M_{\mathrm{Res}}}{\rho_{\mathrm{G}}} \approx 0.6886 \text{ m}^3. \tag{25.10}$$

The entire accumulated mass-energy distributed across the 10^{35} m Structural Reservoir is physically equivalent to the yield-scale structural energy represented by only about one cubic meter of active vacuum. More precisely, approximately 0.6886 m^3 of active vacuum evaluated at the critical yield density ρ_{G} carries the same mass-equivalent energy as the entire integrated mass-energy assigned to the macroscopic Structural Reservoir.

Within TFT, this cross-scale equivalence reveals how little of the active vacuum's enormous structural capacity is required to construct the observable universe of matter, gravitational gradients, and persistent causal structure. The macroscopic causal-information network is therefore an exceedingly sparse structural modulation of the active vacuum: localized mass and phase defects recruit only a minute fraction of the available vacuum capacity into persistent tension gradients, and those gradients organize the gravitational relationships through which spatially separated events become mechanically connected and distinguishable across R_{Res}.

What appears macroscopically as the total mass-energy and causal structure of the universe is therefore a remarkably dilute pattern written into the vastly greater energetic capacity of the active vacuum.

25.3 The Thermodynamic Ledger: Closing the Thermodynamic Cycle

Without a mechanism to recover the active degrees of freedom consumed by continuous relaxation, the visco-elastic degradation of coherent transverse waves would drive the cosmic medium progressively toward thermodynamic equilibration. In TFT, the energy of a photon does not disappear as its coherent transverse state relaxes. Rather, the ordered carrier progressively loses coherent energy to noncoherent degrees of freedom of the active vacuum.

Within the present TFT CMB-reservoir interpretation, the terminal destination of this degraded optical energy is the ambient background of longitudinal lattice excitations: the phonon noise floor identified with the Cosmic Microwave Background (CMB). In this mechanical sense, the CMB acts

as the long-lived "phonon graveyard" of exhausted transverse radiation. The microscopic derivation of complete thermalization and of the observed 2.725 K spectrum remains an open first-principles bridge, but the thermodynamic role is clear: coherent optical structure is progressively transferred into an increasingly isotropic reservoir of noncoherent lattice excitation.

If radiative degradation ended only in the CMB phonon reservoir, the universe would still evolve toward terminal thermal equilibration. TFT therefore contains a separate structural pathway. Localized matter does not remain indefinitely embedded in the active State I medium; through its gravitational loading of the surrounding FCC lattice, it progressively nucleates Black Hole phase conversion. The CMB relaxation channel and the Black Hole phase-conversion channel are mechanically distinct, but both participate in the evolution of the same State I cosmic cycle.

The global-local energy equivalence established in Section 25.2 makes this mechanism especially significant. The integrated mass-energy assigned to the entire 10^{35} m Structural Reservoir is equivalent to the yield-scale structural energy represented by only

$$V_{\mathrm{eq}} = \frac{E_{\mathrm{Res}}}{\tau_{\mathrm{D,bulk}}} = \frac{M_{\mathrm{Res}}}{\rho_{\mathrm{G}}} \approx 0.6886 \text{ m}^3 \tag{25.11}$$

of active vacuum evaluated at its critical yield density.

Black Hole formation therefore cannot be understood in TFT as matter somehow supplying the enormous structural energy of the resulting State II domain. Matter is the trigger, not the bulk energetic substance of the phase transition.

Localized mass produces a persistent tension gradient and progressively loads the surrounding active FCC vacuum. When that local loading reaches the gravitational saturation condition,

$$\alpha_{\mathrm{G}} \to 1, \tag{25.12}$$

the active FCC configuration can no longer sustain the State I geometry and undergoes the phase transition

$$\mathrm{FCC} \to \mathrm{SC}. \tag{25.13}$$

The localized matter defect therefore acts as the ignition condition for a self-sustaining crystallographic chain reaction. Once nucleated, the advancing FCC/SC phase boundary exposes additional active vacuum to conversion as the State II region grows. In TFT, a Black Hole is consequently not fundamentally matter compressed ever more deeply into itself. It is a vacuum phase-conversion process nucleated by localized mass: the matter defect provides the trigger, while the active vacuum provides the phase-convertible medium.

These localized phase collapses become the ultimate structural sinks of the macroscopic cycle. Matter defects are incorporated into the growing phase-boundary system, inertial mass becomes associated with the live FCC/SC boundary, and the enclosed region is converted into the frozen, phase-locked, zero-void State II geometry characterized by ρ_{S}.

The thermodynamic and structural ledgers therefore advance through distinct but concurrent channels. Coherent transverse radiation progressively relaxes toward the CMB phonon reservoir, while localized mass loading independently drives FCC→SC phase conversion and the growth of State II domains. The two channels do not require direct energy transfer between one another; their connection emerges at the level of the global cosmic cycle.

Crucially, the consumption of State I through phase conversion does not continue indefinitely. As Black Holes grow, their aggregate live-boundary mass,

$$M_{\mathrm{p}}, \tag{25.14}$$

increases. Exterior strain fields begin to overlap, saturated FCC/SC bridges form between previously separated State II domains, and the distributed boundary system advances toward the global percolation threshold.

When

$$M_{\mathrm{p}} \to M_{\mathrm{trg}}, \tag{25.15}$$

the connected live-boundary and saturated-bridge network becomes a reservoir-spanning fracture structure. The global containment differential then collapses,

$$\Delta P \to 0, \tag{25.16}$$

triggering the Catastrophic Decompression—the Big Rupture—detailed in Chapter 21.

Within the TFT cyclic closure, terminal Heat Death is therefore mechanically preempted. The universe does not escape thermodynamic degradation by locally reversing entropy. Rather, radiative degradation accumulates within the CMB phonon reservoir while an independent mass-triggered phase-conversion process progressively converts the active lattice into a globally unstable State II network. Once that network reaches structural percolation, the configuration in which the thermodynamic degradation accumulated can no longer be mechanically sustained.

The complete thermodynamic and structural sequence may therefore be summarized as

$$\begin{aligned}&\text{coherent transverse radiation} \longrightarrow \text{CMB phonon reservoir},\\ &\text{localized mass loading} \longrightarrow \text{State II phase conversion} \longrightarrow \text{global percolation} \longrightarrow \text{Catastrophic Decompression} \longrightarrow\end{aligned} \tag{25.17}$$

The universe consequently operates as a macroscopic oscillator in which the thermodynamic and structural clocks advance together without being the same process: light ultimately relaxes into the phonon graveyard, localized mass ignites the State II chain reaction, the growing State II network develops into a global fault structure, and that fault structure ultimately forces the mechanical renewal of the active vacuum.

That is the closure of the TFT thermodynamic ledger.

25.4 The Chronology of the Macroscopic Oscillator

Within standard ΛCDM, the approximately 13.8 billion-year cosmic age follows from the integrated cosmological expansion history. TFT assigns a different role to the nearby but distinct timescale obtained from the locally measured Hubble slope. Under the present empirical calibration,

$$\Gamma_{\mathrm{D}} = H_0^{(\mathrm{obs})}, \tag{25.18}$$

so that

$$\frac{1}{\Gamma_{\mathrm{D}}} \approx 13.387 \text{ billion years}. \tag{25.19}$$

In TFT, this quantity is the characteristic vacuum relaxation time, not the age of the active cosmic reservoir. The much longer structural chronology follows instead from the accumulated FCC→SC phase conversion required to reach global percolation.

25.4.1 The Global Phase Avalanche Equation

Black Hole formation in TFT is a nucleated phase transition. Once a local State II domain is formed, continued growth proceeds through the self-sustaining advancement of the FCC→SC phase boundary.

The chronology adopts the single-rate macroscopic relaxation closure developed in Appendix AT,

$$\frac{1}{M_{\mathrm{p}}}\frac{\mathrm{d}M_{\mathrm{p}}}{\mathrm{d}t} = \Gamma_{\mathrm{D}}. \tag{25.20}$$

Integration gives the Global Phase Avalanche Equation,

$$M_{\mathrm{p}}(t) = M_{\mathrm{p}}(0)e^{\Gamma_{\mathrm{D}}t}, \tag{25.21}$$

where $M_{\mathrm{p}}(0)$ is the primordial aggregate live-boundary mass established during the short State II nucleation interval following Catastrophic Decompression.

The equality between the phase-avalanche fractional growth rate and Γ_{D} is the single-rate macroscopic closure of the present TFT chronology. It does not imply direct conversion of coherently relaxed photon energy into Black Hole mass; the optical-relaxation and phase-conversion channels remain mechanically distinct.

25.4.2 The Total Oscillation Time (T_{cyc})

As established in Appendix AT, TFT adopts the FCC site-percolation threshold

$$p_{\mathrm{c}} \approx 0.199 \tag{25.22}$$

under an equal-capacity coarse-graining of the interstitial network.

With

$$\beta_{\mathrm{IC}} \approx 0.2595, \tag{25.23}$$

the corresponding aggregate live-boundary mass fraction at global percolation is

$$\beta_{\mathrm{rup}} = p_{\mathrm{c}}\beta_{\mathrm{IC}} \approx 0.0516. \tag{25.24}$$

The Global Rupture Trigger Mass is therefore

$$M_{\mathrm{trg}} = 0.0516\left(1.6707 \times 10^{79}\ \mathrm{kg}\right) \approx 8.6208 \times 10^{77}\ \mathrm{kg}. \tag{25.25}$$

This 5.16% quantity is the aggregate live-boundary mass fraction of the percolating State II network. It is not a 5.16% physical filling of the reservoir by SC-core volume.

The total oscillation time follows from

$$M_{\mathrm{trg}} = M_{\mathrm{p}}(0)e^{\Gamma_{\mathrm{D}}T_{\mathrm{cyc}}}, \tag{25.26}$$

giving

$$T_{\mathrm{cyc}} = \frac{1}{\Gamma_{\mathrm{D}}}\ln\left(\frac{M_{\mathrm{trg}}}{M_{\mathrm{p}}(0)}\right). \tag{25.27}$$

Because the primordial aggregate must satisfy

$$M_{\mathrm{p}}(0) \geq M_{\mathrm{D,G}}, \tag{25.28}$$

the minimum-seed normalization,

$$M_{\mathrm{p}}(0) = M_{\mathrm{D,G}} \approx 10.033\ \mathrm{kg}, \tag{25.29}$$

defines the maximum possible cycle duration under the present phase-avalanche closure.

For this limiting branch,

$$8.6208 \times 10^{77} = 10.033\, e^{\Gamma_{\mathrm{D}} T_{\mathrm{cyc}}}, \tag{25.30}$$

so

$$\Gamma_{\mathrm{D}} T_{\mathrm{cyc}} = \ln\left(8.5924 \times 10^{76}\right) \approx 177.15. \tag{25.31}$$

Using

$$\frac{1}{\Gamma_{\mathrm{D}}} \approx 13.387 \text{ billion years}, \tag{25.32}$$

gives

$$T_{\mathrm{cyc}}^{(\max)} \approx 177.15 \times 13.387 \text{ billion years} \approx 2.3715 \text{ trillion years}. \tag{25.33}$$

A larger primordial aggregate $M_{\mathrm{p}}(0)$ shortens the absolute elapsed cycle time logarithmically but does not alter the rupture mass or the exponential Global Phase Avalanche law.

25.4.3 The Current Cosmic Epoch (t_{cur})

To estimate the elapsed time since the last Catastrophic Decompression, we evaluate the Global Phase Avalanche against the present aggregate State II boundary mass,

$$M_{\mathrm{p}}(t_{\mathrm{cur}}) \equiv M_{\mathrm{cur}}. \tag{25.34}$$

Adopting the present order-of-magnitude Black Hole inventory over the reference observable domain as

$$M_{\mathrm{obs}} \approx 1.000 \times 10^{50} \text{ kg} \tag{25.35}$$

and using the Black Hole mass-function census as the observational baseline [33], TFT extrapolates this inventory across the full Structural Reservoir under the statistical-homogeneity closure developed in Appendix AT.

Using the structural volumetric scaling factor,

$$M_{\mathrm{cur}} = \left(1.000 \times 10^{50} \text{ kg}\right)\left(9.7957 \times 10^{25}\right) = 9.7957 \times 10^{75} \text{ kg}. \tag{25.36}$$

The current elapsed phase time is therefore

$$t_{\mathrm{cur}} = \frac{1}{\Gamma_{\mathrm{D}}} \ln\left(\frac{M_{\mathrm{cur}}}{M_{\mathrm{p}}(0)}\right). \tag{25.37}$$

For the minimum-seed normalization,

$$9.7957 \times 10^{75} = 10.033\, e^{\Gamma_{\mathrm{D}} t_{\mathrm{cur}}}, \tag{25.38}$$

which gives

$$\Gamma_{\mathrm{D}} t_{\mathrm{cur}} \approx 172.67, \tag{25.39}$$

and

$$t_{\mathrm{cur}}^{(\max)} \approx 172.67 \times 13.387 \text{ billion years} \approx 2.3116 \text{ trillion years}. \tag{25.40}$$

Conclusion:
Under the minimum-seed normalization, the elapsed phase time satisfies

$$\frac{t_{\mathrm{cur}}^{(\max)}}{T_{\mathrm{cyc}}^{(\max)}} \approx 0.9747. \tag{25.41}$$

Thus, this limiting chronology places the present epoch at approximately 97.5% of the maximum possible cycle duration. This is a statement about logarithmic elapsed phase time, not about the fraction of the rupture mass already accumulated. The numerical current-age estimate remains conditional on the adopted Black Hole inventory, its extrapolation across the Structural Reservoir, and the single-rate phase-avalanche closure.

25.4.4 The Illusion of Genesis (The Cosmic Expiration Timer)

The approximately 13.8 billion-year age inferred in standard ΛCDM and the approximately 13.387 billion-year TFT relaxation time are physically distinct quantities. Standard cosmology obtains its cosmic age from the integrated expansion history, whereas TFT identifies

$$\frac{1}{\Gamma_{\mathrm{D}}} \tag{25.42}$$

as the characteristic relaxation time of the active vacuum, empirically calibrated by the local Hubble slope [34].

The differential time remaining before Catastrophic Decompression is

$$\Delta t = T_{\mathrm{cyc}} - t_{\mathrm{cur}}. \tag{25.43}$$

Because

$$M_{\mathrm{trg}} = M_{\mathrm{p}}(0) e^{\Gamma_{\mathrm{D}} T_{\mathrm{cyc}}}, \tag{25.44}$$

and

$$M_{\mathrm{cur}} = M_{\mathrm{p}}(0) e^{\Gamma_{\mathrm{D}} t_{\mathrm{cur}}}, \tag{25.45}$$

their ratio eliminates the unknown primordial aggregate exactly:

$$\frac{M_{\mathrm{trg}}}{M_{\mathrm{cur}}} = e^{\Gamma_{\mathrm{D}} \Delta t}. \tag{25.46}$$

Therefore,

$$\Delta t = \frac{1}{\Gamma_{\mathrm{D}}} \ln\left(\frac{M_{\mathrm{trg}}}{M_{\mathrm{cur}}}\right). \tag{25.47}$$

Using the adopted global aggregate mass,

$$\frac{M_{\mathrm{trg}}}{M_{\mathrm{cur}}} \approx 88.006, \tag{25.48}$$

so

$$\Delta t \approx 4.4774 \frac{1}{\Gamma_{\mathrm{D}}}. \tag{25.49}$$

With the present empirical value of Γ_{D},

$$\Delta t \approx 59.94 \text{ billion years}. \tag{25.50}$$

The cancellation of $M_{\mathrm{p}}(0)$ means that this differential clock is independent of the unknown primordial seed normalization. It is not independent of all model assumptions: the numerical value remains conditional on the Global Phase Avalanche closure, the percolation-derived rupture mass, and especially the extrapolated present aggregate mass M_{cur}.

Within those closures, TFT therefore interprets the locally calibrated relaxation rate not as a cosmic birth date but as the ticking rate of a much longer macroscopic structural oscillator.

25.4.5 Kinematic Cycle Reach and the Optical Assimilation Boundary

The thermodynamic chronology defines a second macroscopic length scale distinct from both R_{U} and R_{Res}.

For a transverse excitation propagating at c_{E}, the complete structural-cycle duration corresponds to the kinematic cycle length

$$L_{\max} \equiv c_{\mathrm{E}} T_{\mathrm{cyc}}. \tag{25.51}$$

For the minimum-seed, maximum-cycle branch,

$$L_{\max} \approx 2.2436 \times 10^{28}\ \mathrm{m}. \tag{25.52}$$

This is the greatest propagation-equivalent distance available to a c_{E} transverse mode over the maximum structural-cycle duration. It is not an absolute causal boundary of the substrate.

The distinction is essential because the physical Structural Reservoir at rupture is much larger,

$$R_{\mathrm{rup}} \approx 5.7361 \times 10^{34}\ \mathrm{m}, \tag{25.53}$$

so

$$L_{\max} \ll R_{\mathrm{rup}}. \tag{25.54}$$

Consequently, ordinary c_{E} transverse propagation cannot traverse the entire Structural Reservoir within one complete cycle. This establishes a finite transverse communication reach per structural epoch, but it does not imply absolute causal disconnection of the underlying substrate or eliminate the distinct longitudinal Hard-Floor structural channel.

Moreover, $L_{\max}$ is generally not the physical coherent-photon extinction distance. Coherent optical propagation is instead limited by the frequency-dependent CMB-reservoir assimilation condition. With

$$\omega(x) = \omega_{\mathrm{emit}} e^{-x/R_{\mathrm{U}}}, \tag{25.55}$$

the assimilation distance satisfies

$$\omega(x_{\mathrm{assim}}) = \omega_{\mathrm{CMB}}^{(\mathrm{eff})}, \tag{25.56}$$

and therefore

$$x_{\mathrm{assim}} = R_{\mathrm{U}} \ln\left(\frac{\omega_{\mathrm{emit}}}{\omega_{\mathrm{CMB}}^{(\mathrm{eff})}}\right). \tag{25.57}$$

Thus, the CMB noise-floor boundary is frequency dependent and may occur well before $L_{\max}$. The three scales have distinct meanings:

$$\begin{aligned} R_{\mathrm{U}} &: \text{one-}e\text{-fold coherent-relaxation scale,} \\ x_{\mathrm{assim}} &: \text{frequency-dependent coherent assimilation scale,} \\ L_{\max} &: \text{kinematic length corresponding to the structural cycle.} \end{aligned} \tag{25.58}$$

Their common dependence on Γ_{D} links the optical and thermodynamic sectors without identifying these physically distinct boundaries.

25.4.6 Macroscopic Clock Symmetry and Characteristic Transverse-Reach Domains

The limited transverse reach of a single structural epoch is supported by two complementary macroscopic relations.

1. The Macroscopic Phase Symmetry (Optical and Thermodynamic Clock Equivalence)

As derived in Appendix AT, the shared appearance of Γ_{D} in coherent optical relaxation and in the Global Phase Avalanche produces a reciprocal clock identity.

Because physical CMB-reservoir assimilation may occur before $L_{\max}$, the optical exponential is formally continued to the structural endpoint:

$$E_{\mathrm{obs}}^{(\mathrm{formal})}(L_{\max}) = E_{\mathrm{emit}} \exp\left(-\frac{\Gamma_{\mathrm{D}} L_{\max}}{c_{\mathrm{E}}}\right). \tag{25.59}$$

Since

$$L_{\max} = c_{\mathrm{E}} T_{\mathrm{cyc}}, \tag{25.60}$$

we obtain

$$\frac{E_{\mathrm{obs}}^{(\mathrm{formal})}(L_{\max})}{E_{\mathrm{emit}}} = e^{-\Gamma_{\mathrm{D}} T_{\mathrm{cyc}}}. \tag{25.61}$$

At the same structural endpoint, the Global Phase Avalanche gives

$$\frac{M_{\mathrm{trg}}}{M_{\mathrm{p}}(0)} = e^{+\Gamma_{\mathrm{D}} T_{\mathrm{cyc}}}. \tag{25.62}$$

Therefore,

$$\frac{E_{\mathrm{obs}}^{(\mathrm{formal})}(L_{\max})}{E_{\mathrm{emit}}} = \frac{M_{\mathrm{p}}(0)}{M_{\mathrm{trg}}}. \tag{25.63}$$

For the minimum-seed normalization,

$$M_{\mathrm{p}}(0) = M_{\mathrm{D,G}}, \tag{25.64}$$

this becomes

$$\frac{E_{\mathrm{obs}}^{(\mathrm{formal})}(L_{\max})}{E_{\mathrm{emit}}} = \frac{M_{\mathrm{D,G}}}{M_{\mathrm{trg}}}. \tag{25.65}$$

If the emitted excitation is normalized to

$$E_{\mathrm{emit}} = E_{\max} \approx 13.331 \text{ J}, \tag{25.66}$$

then

$$E_{\mathrm{obs}}^{(\mathrm{formal})}(L_{\max}) = E_{\max}\left(\frac{M_{\mathrm{D,G}}}{M_{\mathrm{trg}}}\right) \approx 1.5515 \times 10^{-76} \text{ J}. \tag{25.67}$$

This quantity is a formal continuation of the optical relaxation clock, not necessarily the energy of an individual coherent photon physically surviving to $L_{\max}$. The reciprocal relation likewise does not imply direct energy transfer between the optical carrier and the State II network. It expresses the opposite exponential evolution of two distinct processes under the same single-rate macroscopic closure.

2. The Number of Characteristic Transverse-Reach Domains (N_{dom})

The large separation between R_{rup} and $L_{\max}$ may be expressed as a characteristic volume ratio. Comparing the spherical rupture volume with a sphere of radius $L_{\max}$ gives

$$N_{\mathrm{dom}} \equiv \frac{V_{\mathrm{rup}}}{V_{L_{\max}}} = \left(\frac{R_{\mathrm{rup}}}{L_{\max}}\right)^3. \tag{25.68}$$

Substituting the maximum-cycle values,

$$N_{\mathrm{dom}} = \left(\frac{5.7361 \times 10^{34}}{2.2436 \times 10^{28}}\right)^3 \approx \left(2.5567 \times 10^{6}\right)^3, \tag{25.69}$$

which gives

$$N_{\mathrm{dom}} \approx 1.67 \times 10^{19}. \tag{25.70}$$

Thus, the Structural Reservoir contains the volume equivalent of approximately 16.7 quintillion characteristic transverse-causal domains.

This expression is a volume-ratio measure; it is not a claim that equal $L_{\max}$ spheres geometrically tessellate the reservoir.

Its causal interpretation is nevertheless physical. Regions separated by more than the available c_{E} transverse reach cannot establish direct transverse communication during the same State I cycle.

They remain, however, components of one contiguous mechanical substrate.

The TFT universe is therefore not globally disconnected in the structural sense. Its ordinary transverse causal structure is local while its mechanical constitution is global.

That distinction permits a Structural Reservoir of order 10^{35} m to undergo a collective phase failure even though ordinary electromagnetic information cannot traverse the reservoir before the cycle resets.

Chapter 26

Conclusion: The Invariant Continuum and Falsifiability

26.1 The Kinematic Governing Equations of the Spacetime Gravitational Floor (SGF)

As rigorously derived throughout Part III and summarized in the Consolidated Equations appendix, the macroscopic behavior of the universe is governed entirely by the native visco-elastic parameters of the Spacetime Gravitational Floor. Tension Field Theory formally replaces the kinematically expanding Friedmann–Lemaître–Robertson–Walker (FLRW) standard model with five exact mechanical state equations.

1. The Visco-Elastic Damping Equation (Replacing Metric Expansion):

$$1 + z = e^{\frac{\Gamma_{\mathrm{D}} x}{c_{\mathrm{E}}}} \tag{26.1}$$

Mechanical Translation: Cosmic redshift is not the stretching of empty space. It is the strict thermodynamic energy dissipation of a transverse wave performing continuous work against the fundamental boundary friction (Γ_{D}) of the active lattice.

2. The Non-Linear Redshift Approximation (Replacing Dark Energy):

$$d_{\mathrm{L}} = \frac{c_{\mathrm{E}}}{H_0}(1 + z)\ln(1 + z) \tag{26.2}$$

Mechanical Translation: The universe is not accelerating outward. The observational signature attributed to "Dark Energy" is simply the positive second-order term ($+\frac{z^2}{2}$) of the natural logarithmic attenuation curve as lattice damping compounds over extreme cosmic distances.

3. The Kinematic State Equation (Replacing the Friedmann Equation):

$$\Gamma_{\mathrm{D}}^2 = \frac{4\pi G}{3}\rho_{\mathrm{c}} \tag{26.3}$$

Mechanical Translation: The critical density of the universe is not balancing a kinematic explosion. It is the strict static requirement for phase equilibrium, where the bulk restorative tension of macroscopic gravity ($G\rho_{\mathrm{c}}$) perfectly counterbalances the visco-elastic decay rate of the lattice (Γ_{D}).

4. The Causal Mass Limit (Replacing the Infinite Singularity):

$$M_{\mathrm{U}} = \frac{c_{\mathrm{E}}^3}{G\Gamma_{\mathrm{D}}} \tag{26.4}$$

Mechanical Translation: The universe did not originate from, nor can it collapse into, a point of infinite density. This equation defines the absolute mechanical saturation limit; if mass aggregation attempts to exceed this threshold, the localized holding tension vanishes, triggering catastrophic decompression rather than infinite singularity.

5. The Global Phase Avalanche Equation (Replacing the Linear Age of the Universe):

$$M_{\mathrm{p}}(t) = M_{\mathrm{D,G}} \cdot e^{\Gamma_{\mathrm{D}} t} \tag{26.5}$$

Mechanical Translation: Time is not measured from a geometric genesis. The macroscopic timeline of the universe is a finite thermodynamic clock, strictly governed by the exponential accumulation of topological defects (Black Holes) driven by the universal friction parameter (Γ_{D}). This clock ticks inevitably toward the 5.16% global percolation limit, forcing the cyclical renewal of the cosmos.

26.2 Empirical Falsification Criteria

Tension Field Theory makes the following definitive, testable predictions that directly contradict standard ΛCDM expectations:

- **Prediction 1: Visco-Elastic Dispersion and the Topological Tail (Falsifying Metric Expansion).** Standard cosmology posits that cosmological time dilation is driven by the uniform stretching of the metric, dictating that a propagating wave packet will stretch symmetrically. Tension Field Theory dictates that time dilation is the structural relaxation of a photon conserving its topology (N) against the visco-elastic friction of the SGF. Because this boundary friction is a physical hydrodynamic interaction, we strictly predict that high-resolution temporal integration of isolated, high-redshift transients (e.g., Fast Radio Bursts) will reveal an asymmetric visco-elastic dispersion tail. The wave packet will not stretch uniformly; the leading edge will exhibit a different localized strain profile than the trailing edge. Detecting this asymmetric structural deformation physically proves the wave is plowing through a dissipative medium, definitively falsifying the uniform kinematic expansion of empty space.

- **Prediction 2: Mature High-Redshift Galaxies (The JWST Anomaly).** In standard cosmology, high redshift (z) corresponds to the "early universe," necessitating that galaxies at extreme distances must be infantile and possess low metallicity. Because TFT proves redshift is an optical distance artifact rather than a temporal epoch, we strictly predict that the James Webb Space Telescope (JWST) will continue to discover massive, fully formed, high-metallicity galaxies at extreme redshifts, physically violating the temporal expansion limits of ΛCDM [35].

- **Prediction 3: The Constancy of the Local Hubble Damping.** Because the Hubble parameter (H_0) is a constant damping rate (Γ_{D}) of the visco-elastic lattice, local distance ladder measurements will consistently converge on ≈ 73.04 km/s/Mpc, irrespective of future instrument calibration. The 67.4 km/s/Mpc CMB value is a permanent artifact of misapplying a frictionless kinematic acoustic horizon to a physically damped structural boundary.

26.3 The Phenomenological Translation of Observational Cosmology

To bridge the phenomenological gap between standard geometric cosmology and solid-state visco-elastic mechanics, Table 26.1 provides a direct diagnostic translation of the macroscopic observable universe.

Table 26.1: The Phenomenological Translation of Observational Cosmology

Observational Phenomenon	**Standard Cosmology (ΛCDM) Interpretation**	**Tension Field Theory (TFT) Mechanical Resolution**
Cosmic Expansion	Literal expansion of "empty space" with no physical substance or cause.	**Eliminated.** The lattice is statically bounded. Expansion is an optical illusion caused by the kinematic damping (H_0) of the SGF.
The Hubble Law	Interpreted as a kinematic Doppler shift (galaxies receding).	**Re-interpreted.** Redshift is the visco-elastic energy dissipation of transverse waves passing through the dual phase vacuum.
Cosmic Age (13.8 Byr)	The temporal age of the universe originating from a singularity.	**Re-interpreted.** It is the fundamental visco-elastic decay time—recalibrated to 13.39 Byr based on local SGF damping. It represents the characteristic e-folding time required for lattice friction to drain 63.2% of an optical wave's kinematic energy, beyond which distant structures geometrically fade into the thermal background.
Critical Density (ρ_c)	An arbitrary geometric threshold defining metric flatness.	**Mechanically Defined.** It is exactly the structural defect capacity ($\alpha_G = 1$) required to locally saturate the SGF lattice ($\Gamma_D^2 = \frac{4\pi G}{3}\rho_c$).
CMB	Leftover flash of the primordial Big Bang (Recombination Epoch).	**Active State.** It is the active, isotropic thermal exhaust of transverse light waves continuously degrading into longitudinal lattice vibrations (phonons).
BAO Anisotropies (1.04°)	A temporal snapshot of primordial quantum/acoustic fluctuations.	**Structural Shadow.** The permanent thermodynamic silhouette of the ≈ 42.73 Mpc macroscopic density rings located at the Viscous Cosmic Horizon.
Black Holes & The Cosmos	Treated as entirely separate metric phenomena.	**Unified.** The total observable cosmos operates at the exact mechanical saturation limit of a Type I Black Hole ($M_U = M_{Sat}$).
Type Ia Supernovae	Appear too dim; interpreted as proof that metric expansion is accelerating.	**Optical Friction.** Natively resolved by the $+\frac{z^2}{2}$ Taylor expansion of exponential lattice damping. No acceleration exists.

Table 26.1 continued from previous page

Observational Phenomenon	Standard Cosmology (ΛCDM) Interpretation	Tension Field Theory (TFT) Mechanical Resolution
Dark Energy (Λ)	An ad hoc, un-sourced vacuum energy ($w = -1$) forcing metric acceleration.	**Eliminated.** The mathematical ghost of visco-elastic optical damping (the $+\frac{z^2}{2}$ Taylor expansion) compounding over extreme distances.

26.4 Kinematic Capacity and The Invariant Continuum

Physics must re-examine the foundational assumption of an empty geometric void. The universe is not an infinitely expanding geometry leading to thermodynamic failure; it is a spatially bounded, perpetual macro-mechanical oscillator driven by strict thermodynamic phase cycles.

The operational limits of causality within this universe are dictated entirely by a single structural relationship: The Kinematic Capacity vs. The Strain Load.

- **The Capacity (c_{E}^2):** The absolute kinematic energy budget of a single Face–Centered Cubic (FCC) lattice node.
- **The Load (α_{G}):** The universal strain gauge measuring how that kinematic capacity is consumed.

Whenever the local strain load strictly equals the capacity ($\alpha_{\mathrm{G}} = 1$), the active vacuum undergoes causal failure. Tension Field Theory unites the absolute extremes of existence by proving that this exact same mechanical threshold ($\alpha_{\mathrm{G}} = 1$) manifests in three distinct modes of causal limits:

26.4.1 Type I: Gravitational Causal Failure (The Black Hole)

- **Mechanism:** Inertial Saturation (The Density Limit).
- **Physics:** When mass is severely concentrated at the microscopic scale (10^{-26} m), the local strain load exhausts the c_{E}^2 capacity of the node. Reaching a trigger density of $\approx 10^{70}$ kg/m^3, the node mechanically snaps, losing its shear elasticity and locking into the Simple Cubic (SC) geometry.
- **State:** The localized region fully freezes into a zero-void SC sink, achieving a maximum structural density of $\rho_{\mathrm{S}} \approx 10^{96}$ kg/m^3. Because the core has no voids, the effective inertia diverges ($\mu_{\mathrm{eff}} = \mu_{\mathrm{D}}(1 - \alpha_{\mathrm{G}})^{-4}$), and transverse light propagation (c_{P}) strictly ceases. The massive topological strain (inertial mass) is mechanically displaced by the advancing crystallization front, segregating strictly onto the singular boundary layer (the Event Horizon).

26.4.2 Type II: Cosmological Causal Saturation (The Viscous Cosmic Horizon)

- **Mechanism:** Cumulative Damping (Distance/Energy Exhaustion).
- **Physics:** When mass is naturally distributed to the critical density (ρ_{c}), the structural load is gradually integrated over a vast macroscopic distance. At the local causal radius ($R_{\mathrm{U}} \approx 10^{26}$ m), the cumulative gravitational potential ($-\int \frac{G\,\mathrm{d}m}{r}$) exactly equals $-c_{\mathrm{E}}^2$.

- **State:** Phase Equilibrium. Because there is no internal structural pressure, the lattice does not break. Instead, propagating transverse waves simply exhaust their kinematic capacity via continuous visco-elastic decay ($E_{\text{obs}} = E_{\text{emit}} e^{-\Gamma_{\text{D}} x / c_{\text{E}}}$), degrading into longitudinal phonons to form the isotropic 2.725 K Cosmic Microwave Background (CMB) bed. The physical FCC lattice seamlessly survives this optical saturation, tiling outward to form the total Cosmic Reservoir ($R_{\text{Res}} \approx 10^{35}$ m).

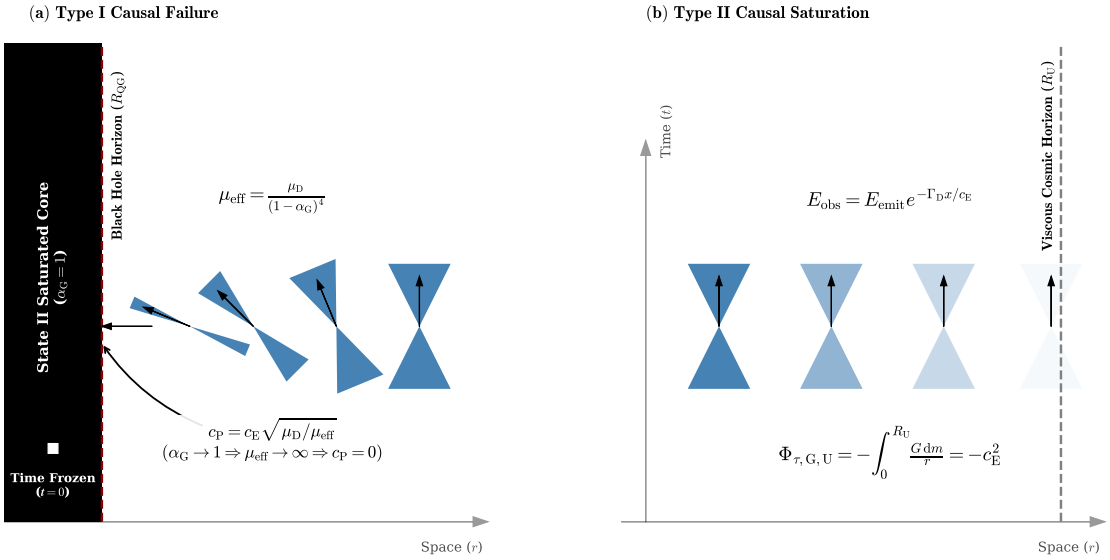

Figure 26.1: **The Causal Hierarchy (Mechanical vs. Energetic Horizons). (a) Type I Causal Failure (The Black Hole):** Represents the crystallographic phase lock of the local vacuum. As density reaches the convergence limit (ρ_{QG}), the active FCC lattice undergoes a phase transition to the fully packed SC Substrate, eliminating the interstitial voids necessary for vibration. This geometric lock causes the local effective inertia to diverge ($\mu_{\text{eff}} \to \infty$), making transverse wave propagation mechanically impossible ($c_{\text{P}} = 0$). The light cones squeeze completely shut, irrevocably halting all causal trajectories against the phase-locked core. **(b) Type II Causal Saturation (The Viscous Cosmic Horizon):** Represents the thermodynamic energy exhaustion of the wave. The background medium remains structurally intact (FCC), and the macroscopic light cones remain geometrically uniform. However, cumulative visco-elastic damping (Γ_{D}) continuously forces the wave into simultaneous vertical compression and longitudinal elongation. This macroscopic friction drives a strict exponential thermodynamic decay of the signal (E_{obs}), fully exhausting the photon's invariant transverse energy budget (c_{E}^2) exactly at R_{U}.

26.4.3 Type III: Kinematic Causal Failure (The Structural Cutoff)

- **Mechanism:** Kinematic Saturation (The Quantum Energy Limit).
- **Physics:** In solid-state mechanics, a transverse wave cannot propagate if its wavelength compresses beyond the physical diameter of the fundamental structural grain. Setting the minimum spatial wavelength to the active FCC Node Diameter ($\lambda_{\text{min}} = 2r_{\text{D}}$) defines the

absolute Quantum Energy Limit (E_{Q}) for a single propagating photon:

$$E_{\mathrm{Q}} = \frac{hc_{\mathrm{E}}}{2r_{\mathrm{D}}} \approx 13.331 \text{ J} \approx 8.3205 \times 10^{10} \text{ GeV} \tag{26.6}$$

- **State (The Kinematic Stall):** If a localized event attempts to inject a photon exceeding this limit ($\lambda < 2r_{\mathrm{D}}$), the spatial gradient required for linear propagation is destroyed ($v \to 0$). The entire phase twist is forced into a single node. At this boundary, the geometric strain hits the absolute localized Node Yield Tension (τ_{D}), and the vacuum ceases to act as a linear spring, becoming highly anharmonic.
- **Resolution (Non-Linear Scattering):** This stalled 13.331 J is vastly below the $\sim 10^{18}$ J required to physically shatter the node into a State II black hole, and it lacks the dense nuclear anvil required to coil into stable chiral matter (e^-, e^+). Therefore, rather than undergoing a structural phase transition, the lattice violently rejects the anomaly. Acting as a perfect non-linear rigid reflector, the τ_{D} boundary forces the stored energy to physically broaden to escape the kinematic stall. The wave is mechanically ripped apart by the surrounding FCC axes, undergoing spontaneous parametric down-conversion as the energy scatters into a cascade of lower-energy photons ($\lambda > 2r_{\mathrm{D}}$) capable of stable spatial propagation. This mechanism structurally forbids the infinite energies and "ultraviolet catastrophes" of standard quantum field theory.

Summary: The Unified Phase Map of the Universe

The macroscopic scale of the observable universe ($\approx 10^{26}$ m) is not a random evolutionary epoch; it is the strict geometric boundary where the energy of propagating light perfectly balances the visco-elastic damping of the lattice, forming the Viscous Cosmic Horizon.

However, optical exhaustion is not the true end of causality. The absolute thermodynamic expiration of the lattice occurs at the Kinematic Capacity Limit ($L_{\max} \approx 10^{28}$ m), where the localized accumulation of State II Saturated Core's surface mass reaches global topological percolation ($M_{\mathrm{trg}} \approx 10^{78}$ kg). Because this absolute chronological expiration occurs vastly earlier than a signal could ever reach the physical Deflation boundary ($R_{\mathrm{rup}} \approx 10^{34}$ m), the universe contains a massive, permanent Domain of Opaque Causality—fracturing the macroscopic reservoir into approximately 16.7 quintillion ($N_{\mathrm{dom}} \approx 1.6706 \times 10^{19}$) strictly isolated causal spheres.

The total Cosmic Reservoir reaches its massive structural span ($R_{\mathrm{Res}} \approx 10^{35}$ m) not through ongoing kinematic expansion, but as the strict volumetric requirement of the fully decompressed State I FCC lattice. Just as the observable active vacuum is strictly bounded by the Kinematic Lattice Index ($N_{\mathrm{D}} = R_{\mathrm{U}}/2r_{\mathrm{D}} \approx 10^{52}$), the absolute totality of the cosmos is governed by the Absolute Substrate Index:

$$N_{\mathrm{S}} = \frac{R_{\mathrm{Res}}}{\ell_{\mathrm{S}}} = \frac{5.8383 \times 10^{34} \text{ m}}{1.6163 \times 10^{-35} \text{ m}} \approx 3.6121 \times 10^{69} \tag{26.7}$$

The grand macroscopic boundaries (10^{26} m, 10^{28} m, and 10^{35} m) and the microscopic quantum depths (10^{-26} m and 10^{-35} m) are not governed by disparate regimes. As mapped in Figure 26.2, they are dictated by the exact same invariant continuum law of mechanical capacity and visco-elastic load.

Ultimately, these static spatial boundaries serve strictly as the geometric scaffolding for a dynamic temporal cycle (≈ 2.3715 trillion years), revealing the universe not as a terminal expansion, but as a deterministic, closed, perpetual macro-oscillator.

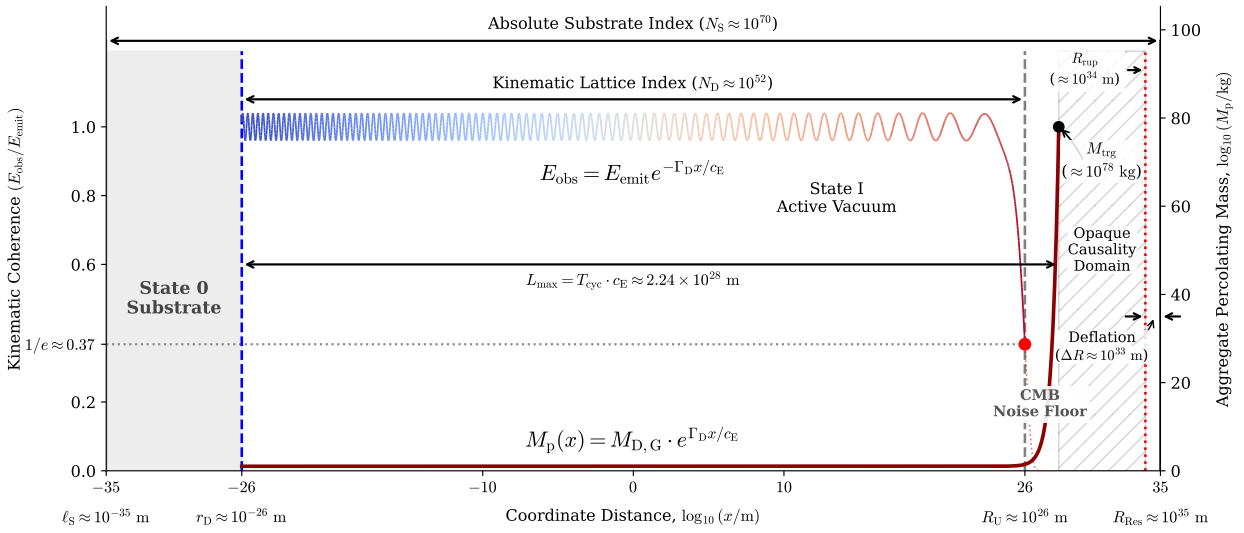

Figure 26.2: **The Unified Phase Map of the Macroscopic Oscillator.** This diagram maps the absolute causal boundaries of Tension Field Theory across 70 orders of magnitude. **Left (The Wall):** The timeless, rigid Simple Cubic geometry of the State 0 Substrate strictly bounds the active universe at $\ell_S \approx 10^{-35}$ m. **Center (The Arena):** Within the vast physical expanse of the State I Active Vacuum, the observable kinematic envelope spans 52 orders of magnitude ($N_D \approx 10^{52}$). A transverse wave (blue) degrades due to visco-elastic damping ($e^{-\Gamma_D x/c_E}$), falling to the $1/e$ threshold exactly at the Viscous Cosmic Horizon ($R_U \approx 10^{26}$ m) where it thermalizes into the CMB. **Right (The Expiration):** Entirely decoupled from optical decay, the Global Phase Avalanche (red curve) tracks the exponential accumulation of macroscopic defect mass (M_p). The thermodynamic clock triggers a vertical asymptote (Critical Divergence), hitting the global percolation threshold (M_{trg}) exactly at the absolute kinematic expiration limit ($L_{max} \approx 10^{28}$ m). **Far Right (The Opaque Domain):** Because the thermodynamic clock expires at $L_{max} \approx 10^{28}$ m, the remaining State I Active Vacuum extending out to the spatial boundary is structurally real but permanently causally inaccessible. This establishes the Domain of Opaque Causality. The mechanical ΔR Deflation gap represents the massive spatial contraction the native reservoir ($R_{Res} \approx 10^{35}$ m) undergoes prior to failure. Upon reaching the critical ruptured geometry ($R_{rup} \approx 10^{34}$ m), the Big Rupture triggers Catastrophic Decompression, violently snapping the boundary back across this gap to restore the native volume. *Note: The kinematic and substrate indices (N_D and N_S) are displayed at their nearest logarithmic orders of magnitude ($\approx 10^{52}$ and $\approx 10^{70}$) to align with the macroscopic base-10 coordinate scale. Their exact derived values are* 8.4995×10^{51} *and* 3.6121×10^{69}*, respectively.*

END OF PART III

Consolidated Equations

This appendix consolidates the complete mathematical derivations and governing equations of Tension Field Theory (TFT), providing a unified reference across the microscopic, macroscopic, and cosmological scales.

Part I: Foundations of the Dual-Phase Vacuum

Gravitational Constant *(G)*	$G_i = \mathcal{F}_i \cdot \left(\frac{c_{\text{E}}^2 A_{\text{S}}}{J_i} \right)$	-	Appendix G
Gravitational *Tension*	$\tau_{\text{M}} = \frac{G \cdot M \cdot \mu_{\text{D}}}{R}$	12.3	Field Mechanics
Gravitational *Acceleration*	$g = -\left(\frac{1}{\mu_{\text{D}}} \right) \frac{\text{d}\tau_{\text{M}}}{\text{d}R} = -\frac{G \cdot M}{R^2}$	12.3	Field Mechanics
Total Acceleration *Law (Unscreened)*	$g_{\text{obs}}(R) = \Pi(R) g_b(R) + \sqrt{a_{\text{gal}} \Pi(R) g_b(R)}$	-	Appendix L
Radial Projection *Operator (Π)*	$\Pi(r) = 1 \pm \delta \left(\frac{R_{\text{d}}}{r} \right)^n$	-	Appendix M
Master Acceleration *Equation*	$g_{\text{obs}}(R) = \Pi(R) g_b(R) + \Xi(R) \sqrt{a_{\text{gal}} \Pi(R) g_b(R)}$	-	Appendix L

Parameter	Mathematical Expression	Section	Derivation Ref.
Condensate Relative *Response (χ_{g})*	$\chi_{\mathrm{g}}(R) = \sqrt{\frac{a_{\mathrm{gal}}}{g_{b,\Pi}(R)}}$	-	Appendix L
Baryonic Tully–Fisher *Relation*	$v_\infty^4 = G a_{\mathrm{gal}} M_b$	-	Appendix L
Unified Screening *Function ($\Xi(R)$)*	$\Xi(R) = \left[1 + \left(\frac{g_{b,\Pi}(R)}{g_*}\right)^{n_1}\right]^{-1} \left[1 + \left(\frac{R}{R_{\mathrm{c}}}\right)^{n_2}\right]^{-1}$	-	Appendix L
Gravitational *Wave Speed*	$c_{\mathrm{GW}} = \sqrt{\frac{\mathcal{T}_{\mathrm{TT}}^{(0)}}{M_{\mathrm{TT}}^{(0)}}} = c_{\mathrm{E}}$	-	Appendix N
Structural Gravitational *Strain (α_G)*	$\alpha_{\mathrm{G}} = \frac{GM}{r c_{\mathrm{E}}^2}$	13.2	Field Mechanics
Density-Based *Strain Coupling*	$\alpha_{\mathrm{G}} = \frac{\rho_{\mathrm{M}}}{\rho_{\mathrm{QG}}}$	-	Appendix S
Quantum Gravitational *Unification*	$\alpha_{\mathrm{G}} = \frac{G m_{\mathrm{p}}^2}{\hbar c_{\mathrm{E}}}$	13.2	Geometric Proof
Gravitational Saturation *Radius*	$R_{\mathrm{sat}} = \frac{c_{\mathrm{E}}}{\sqrt{\kappa \cdot \rho \cdot G}}$	-	Appendix S
TFT Field Equation *Strain Formulation*	$\|G_{\mu\nu}\| = \frac{1}{\ell_{\mathrm{S}}^2} - \frac{1}{R^2} = \frac{\kappa \cdot G}{c_{\mathrm{E}}^2}(\rho_{\mathrm{S}} - \rho_{\mathrm{L}})$	13.4.1	Lattice Mechanics
TFT Field Equation *Tension Formulation*	$\|G_{\mu\nu}\| = \frac{\kappa \cdot G}{c_{\mathrm{E}}^4}(\tau_{\mathrm{S}} - \tau_{\mathrm{L}})$	13.4.2	Stress Balance
TFT Field Equation *Tensor Formulation*	$G_{\mu\nu}^{(\tau)} = \frac{\kappa G}{c_{\mathrm{E}}^4} \Delta T_{\mu\nu}^{(\tau)}$	-	App. Q
Vacuum Refractive *Index*	$n_\tau(r) = \frac{1}{(1-\alpha_{\mathrm{G}})^2} \approx 1 + 2\alpha_{\mathrm{G}}$	-	Appendix R
Surface Time *Dilation*	$T_{\mathrm{surface}} = \frac{T_{\mathrm{vac}}}{1-\alpha_{\mathrm{G}}}$	13.5.2	Clock Mechanics
Variable Speed *of Light*	$c_{\mathrm{P}}(r) = \frac{c_{\mathrm{E}}}{n(r)} \approx c_{\mathrm{E}}(1 - 2\alpha_{\mathrm{G}})$	-	Appendix R
Total Flight Time *(Shapiro Delay)*	$\Delta t \approx \frac{1}{c_{\mathrm{E}}} \int (1 + 2\alpha_{\mathrm{G}})\, \mathrm{d}l$	-	Appendix R
Total Deflection *Angle*	$\theta_{\mathrm{total}} = \frac{4GM}{b c_{\mathrm{E}}^2} = 4\alpha_{\mathrm{G}}(b)$	-	Appendix R
Work-Conjugate *Coordinate Constraint*	$u_i = \mathcal{C}_i y_i$	-	Appendix J

Parameter	Mathematical Expression	Section	Derivation Ref.
Volumetric *Referred Inertia*	$\rho_{\text{eff}} = \frac{\rho_{\text{eff}}^{(0)}}{\mathcal{C}^2}$	-	Appendix J
Bond-Resolved *Propagation Speed*	$c_{\text{P}}^{(i\to j)} = c_{\text{E}}\left[(1-\alpha_{\text{G}})^2 - \frac{(\delta\alpha_{\text{G}})^2}{4}\right]$	-	Appendix J

Part II (Continued): Weak-Field Orbital Dynamics (Perihelion Precession)

Parameter	Mathematical Expression	Section	Derivation Ref.
Radial Strain *Potential*	$\Phi_\tau(r) = -\frac{GM}{r}$	-	App. K
Tangential *Loading Factor*	$q_{\text{orb}} = \frac{v_\perp^2}{c_{\text{E}}^2}$	-	App. K
Specific Orbital *Strain Coupling*	$\Phi_{\text{orb}} = \Phi_\tau\left(\frac{v_\perp^2}{c_{\text{E}}^2}\right)$	-	App. K
Reduced Orbital *Strain Potential*	$\Phi_{\text{orb}}^{(\text{red})} = -\frac{GM\ell_{\text{orb}}^2}{c_{\text{E}}^2 r^3}$	-	App. K
Bound-Orbit *Acceleration Correction*	$g_{\text{orb}} = 3g_{\text{b}}\frac{v_\perp^2}{c_{\text{E}}^2}$	-	App. K
TFT Post-Newtonian *Orbital Equation*	$\frac{\mathrm{d}^2u}{\mathrm{d}\varphi^2} + u = \frac{GM}{\ell_{\text{orb}}^2} + \frac{3GM}{c_{\text{E}}^2}u^2$	-	App. K
Perihelion *Advance*	$\Delta\varphi = \frac{6\pi GM}{a(1-e^2)c_{\text{E}}^2}$	-	App. K
Total Bound-Orbit *Acceleration*	$g_{\text{bound}} = g_{\text{env}} + g_{\text{orb}}$	-	App. K

Part II (Continued): Microphysics of Black Holes and Gravitational Saturation

Parameter	Mathematical Expression	Section	Derivation Ref.
Soft Floor *Ignition Mass*	$M_{\mathrm{D,G}} = \frac{c_{\mathrm{E}}^2 \cdot r_{\mathrm{D}}}{G} \approx 10.033 \text{ kg}$	-	Appendix S
Vacuum Stability *Margin*	$\frac{E_{\mathrm{struc}}}{E_{\mathrm{vib}}} \approx \frac{\rho_{\mathrm{G}}}{\rho_{\mathrm{D}}} \approx 10^{17}$	-	Appendix S
Isoenergetic *Continuity*	$E_{\mathrm{QG}} = E_{\mathrm{S}} = E_{\mathrm{P}} = \sqrt{\frac{\hbar c_{\mathrm{E}}^5}{G}}$	-	Appendix S
Effective Causal *Inertia*	$\mu_{\mathrm{eff}} = \frac{\mu_{\mathrm{D}}}{(1-\alpha_{\mathrm{G}})^4}$	14.8	Lattice Mechanics
Causal Propagation *Speed*	$c_{\mathrm{P}} = c_{\mathrm{E}}\sqrt{\frac{\mu_{\mathrm{D}}}{\mu_{\mathrm{eff}}}}$	14.8	Kinematics
Lattice Energy *Dissipation*	$\frac{\mathrm{d}E}{\mathrm{d}t} = -\Gamma_{\mathrm{D}} \cdot E$	-	Appendix AQ
Visco-Elastic *Damping Shift*	$c_{\mathrm{E}} \cdot z = \Gamma_{\mathrm{D}} \cdot r$	-	Appendix AQ
Vacuum Damping Rate *Hubble Identity*	$\Gamma_{\mathrm{D}} \equiv H_0 \approx 2.36 \times 10^{-18} \text{ s}^{-1}$	-	Appendix AQ
Universal Closure *Mass (M_{Sat})*	$M_{\mathrm{Sat}} = \frac{c_{\mathrm{E}}^3}{G\Gamma_{\mathrm{D}}}$	15.2	Kinematic Limits
Cosmic Reservoir *Radius (R_{Res})*	$R_{\mathrm{Res}} = R_{\mathrm{U}} \cdot (10^{26})^{1/3} \sim 10^{35} \text{ m}$	15.3.1	Volumetric Scaling
Interior Growth Law *Node Rate*	$\frac{\mathrm{d}N}{\mathrm{d}t} = \frac{\eta_{\mathrm{N}} P_{\mathrm{in}} - L_{\mathrm{out}}}{E_{\mathrm{S}}}$	15.4.1	Phase Transition
Horizon Surface *Tension*	$\tau_{\mathrm{QG}} = \left(\frac{c_{\mathrm{E}}^2}{4\pi G R_{\mathrm{QG}}}\right) g_{\mathrm{QG}}$	-	Appendix S
Event Horizon *Surface Gravity*	$g_{\mathrm{QG}} = \frac{c_{\mathrm{E}}^4}{GM}$	15.5	Macroscopic Limit
Quantum Saturation *Density (ρ_{Q})*	$\rho_{\mathrm{Q}} = \frac{\hbar}{c_{\mathrm{E}} r^4}$	-	Appendix S
Gravitational Yield *Density (ρ_{G})*	$\rho_{\mathrm{G}} = \frac{c_{\mathrm{E}}^2}{G r^2}$	-	Appendix S

Parameter	Mathematical Expression	Section	Derivation Ref.
Convergence Phase *Density (ρ_{QG})*	$\rho_{\mathrm{QG}} = \sqrt{\rho_{\mathrm{Q}} \cdot \rho_{\mathrm{G}}}$	-	Appendix S
Master Phase Radius *Equation*	$r(\rho) = \ell_{\mathrm{S}} \cdot \left(1.5 \frac{\rho_{\mathrm{S}}}{\rho}\right)^{1/4}$	-	Appendix S

Part II (Continued): Black Hole Thermodynamics & Information (Phase Boundaries)

Parameter	Mathematical Expression	Section	Derivation Ref.
Holographic Limit *Translation Metric*	$S_{\mathrm{holo}} = \frac{2\pi^2 k_{\mathrm{B}}}{N_{\mathrm{M}}}$	-	Appendix T
Geometric Capacity *Boundary Limit*	$S_{\mathrm{geo}} = k_{\mathrm{B}} \frac{4\pi R_{\mathrm{QG}}^2}{r_{\mathrm{D}}^2}$	-	Appendix T
Kinematic Occupancy *Defect Count*	$S_{\mathrm{kin}} = \frac{R_{\mathrm{QG}}}{r_{\mathrm{D}}}$	-	Appendix T
Kinematic Fill Ratio *Mass Dilution*	$\Phi_{\mathrm{kin}} = \frac{1}{4\pi} \left(\frac{r_{\mathrm{D}}}{R_{\mathrm{QG}}}\right)$	-	Appendix T
Convergence Information *Absolute Capacity*	$N_{\mathrm{QG}} = \frac{8\pi^2 R_{\mathrm{QG}}^2}{\ell_{\mathrm{S}}^2}$	-	Appendix T
Information Fill Ratio *Strain Dilution*	$\Phi_{\mathrm{info}} = \frac{1}{4\pi} \left(\frac{\ell_{\mathrm{S}}}{R_{\mathrm{QG}}}\right)^4$	-	Appendix T
Topological Invariant *Absolute Unitarity*	$N_{\mathrm{QG}} \cdot N_{\mathrm{M}} = 16\pi^3$	-	Appendix T

Part II (Continued): Gravitational Radiation and Tensor Mechanics

Parameter	Mathematical Expression	Section	Derivation Ref.
Normalized Tensor *Wave Equation*	$\frac{1}{c_{\mathrm{E}}^2}\ddot{\mathsf{H}}_{ij}^{(\mathrm{GW})} - \nabla^2 \mathsf{H}_{ij}^{(\mathrm{GW})} = \frac{8\pi G}{c_{\mathrm{E}}^4} T_{ij}^{(\mathrm{TT})}$	-	Appendix N
Spectral GW *Stiffness*	$K_{\mathrm{GW}}^{(\mathrm{eff})}(f) = \frac{\pi c_{\mathrm{E}}^2 f^2}{4G}$	-	Appendix N
Micro-to-Collective *Response Ratio (ζ_{GW})*	$\zeta_{\mathrm{GW}}(f) = \frac{1}{\sqrt{2}} \left(\frac{r_{\mathrm{D}}}{\ell_{\mathrm{S}}}\right)^2 \left(\frac{f r_{\mathrm{D}}}{c_{\mathrm{E}}}\right)^2$	-	Appendix N
Far-Zone Quadrupole *Strain*	$h_{ij}^{(\mathrm{TT})}(\mathbf{x}, t) = \frac{2G}{c_{\mathrm{E}}^4 R} \Lambda_{ij,kl}(\mathbf{n}) \ddot{Q}_{kl}\left(t_{\mathrm{R}}\right)$	-	Appendix N
Total Quadrupole *Luminosity*	$P_{\mathrm{GW}} = \frac{G}{5c_{\mathrm{E}}^5} \left\langle \dddot{Q}_{ij} \dddot{Q}_{ij} \right\rangle$	-	Appendix N
Circular-Binary *Chirp Relation*	$\dot{f} = \frac{96}{5}\pi^{8/3} \frac{(G\mathcal{M})^{5/3}}{c_{\mathrm{E}}^5} f^{11/3}$	-	Appendix N

Part II (Continued): Live Phase-Boundary Dynamics & Binary Kinematics

Parameter	Mathematical Expression	Section	Derivation Ref.
Spherical Boundary *Growth Rate*	$\dot{R}_{\mathrm{QG}} = \frac{G}{c_{\mathrm{E}}^2} \dot{M}$	-	App. U
Live-Boundary *Spin Relation*	$\mathcal{J}_{\mathrm{BH}} = I_{\mathrm{surf}} \frac{v_{\mathrm{tor}}}{R_{\mathrm{QG}}}$	-	App. U
Dimensionless *Spin Parameter*	$a_* = \left(\frac{I_{\mathrm{surf}}}{M R_{\mathrm{QG}}^2}\right) \frac{v_{\mathrm{tor}}}{c_{\mathrm{E}}}$	-	App. U
Binary Separation *Orbital Velocity*	$v_{\mathrm{rel}} = c_{\mathrm{E}} \sqrt{\frac{R_1 + R_2}{d}}$	-	App. U
Merger Bridge *Saturation Condition*	$\alpha_{\mathrm{bridge}} = \alpha_{\mathrm{G},1} + \alpha_{\mathrm{G},2} + \alpha_{\mathrm{dyn}} \geq 1$	-	App. U

Parameter	Mathematical Expression	Section	Derivation Ref.
Boundary Mass *Conservation*	$\frac{\partial \Sigma_\partial}{\partial t} + \nabla_A \left(\Sigma_\partial v_\parallel^A \right) + \frac{2\Sigma_\partial v_n}{R} = \dot{\Sigma}_{\partial,\mathrm{in}} + \dot{\Sigma}_{\partial,\mathrm{vac}} - \dot{\Sigma}_{\partial,\mathrm{shed}}$	-	App. U
Remnant Mass *(Stress Shedding)*	$M_f = M_1 + M_2 - \frac{E_{\mathrm{shed}}}{c_{\mathrm{E}}^2}$	-	App. U
Remnant *Angular Momentum*	$\mathcal{J}_f = \mathcal{J}_1^{(\mathrm{spin})} + \mathcal{J}_2^{(\mathrm{spin})} + \mathcal{J}_{\mathrm{orb}}^{(\mathrm{bin})} - \mathcal{J}_{\mathrm{shed}}$	-	App. U
Linearized Boundary *Ringdown Equation*	$\frac{\partial^2 \delta R}{\partial t^2} + \Gamma_{\mathrm{QG}} \frac{\partial \delta R}{\partial t} + \omega_{\mathrm{QG}}^2 \delta R = 0$	-	App. U
Kinematic Capacity *Constraint*	$V_{\mathrm{CM}}^2 + v_n^2 + v_\parallel^2 + v_{\mathrm{tor}}^2 \lesssim c_{\mathrm{E}}^2$	-	App. U
Exterior Torsional *Field Equation*	$\frac{\mathrm{d}}{\mathrm{d}r} \left[\tau_{\mathrm{tor}}(r) r^4 \frac{\mathrm{d}\omega_{\mathrm{drag}}}{\mathrm{d}r} \right] = 0$	-	App. V
Effective Rotating *Optical Line Element*	$ds_{\tau,\mathrm{rot}}^2 = -c_{\mathrm{E}}^2 (1-\alpha_{\mathrm{G}})^2 dt^2 + \frac{dr^2 + r^2 d\theta^2 + r^2 \sin^2\theta (d\phi - \omega_{\mathrm{drag}} dt)^2}{(1-\alpha_{\mathrm{G}})^2}$	-	App. V
Spin-Orbit Strain *Effective Potential*	$\Phi_{\mathrm{spin}} = -\ell_{\mathrm{orb}} \omega_{\mathrm{drag}}(r)$	-	App. V
Boundary Relaxation *Selection Law*	$\frac{\mathrm{d}\mathcal{E}_{\mathrm{stored}}}{\mathrm{d}t} = -\mathcal{P}_{\mathrm{shed}} \leq 0$	-	App. V

Part II (Continued): Rotating Black Hole Exteriors (Kerr Correspondence)

Parameter	Mathematical Expression	Section	Derivation Ref.
Torsional Stiffness *Constitutive Closure*	$\tau_{\mathrm{tor}}(\alpha_{\mathrm{G}}) = \tau_{D,\mathrm{bulk}} = \frac{c_{\mathrm{E}}^4}{G r_D^2}$	-	App. W
Angular Drag Field *Lense–Thirring Match*	$\omega_{\mathrm{drag}}(r) = \frac{2G\mathcal{J}_{\mathrm{BH}}}{c_{\mathrm{E}}^2 r^3}$	-	App. W
No-Hair Quadrupole *TFT Closure*	$Q_{\mathrm{TFT}} = -\frac{\mathcal{J}_{\mathrm{BH}}^2}{M c_{\mathrm{E}}^2} = -a_*^2 M R_{\mathrm{QG}}^2$	-	App. W

Parameter	Mathematical Expression	Section	Derivation Ref.
Rotating Strain Field *Quadrupole-Corrected*	$\alpha_{\mathrm{G}}(r,\theta) = \frac{R_{\mathrm{QG}}}{r} - a_*^2\left(\frac{R_{\mathrm{QG}}}{r}\right)^3 P_2(\cos\theta)$	-	App. W
Phase Boundary *Spin-Deformed Saturation*	$r_{\mathrm{sat}}(\theta,a_*) = R_{\mathrm{QG}}\left[1 - a_*^2 P_2(\cos\theta)\right]$	-	App. W
Torsional Capacity *Co-Motion Surface*	$r_{\mathrm{cap}}(\theta,a_*) = R_{\mathrm{QG}}\left[1+\sqrt{2\lvert a_*\rvert\sin\theta}\right]$	-	App. W
Photon Ring *Equatorial Orbit Condition*	$\omega'_{\mathrm{drag}}(r) + s_{\mathrm{br}}\left[\frac{c'_P(r)}{r} - \frac{c_P(r)}{r^2}\right] = 0$	-	App. W
Shadow Edge *Impact Scale*	$B_{\gamma,s_{\mathrm{br}}}(a_*) = \frac{c_{\mathrm{E}}}{\left\lvert\omega_{\mathrm{drag}} + s_{\mathrm{br}}\frac{c_P}{r_{\gamma,s_{\mathrm{br}}}}\right\rvert}$	-	App. W
ISCO Map *Marginal Stability*	$\mathcal{R}_m = 0, \quad \frac{\partial\mathcal{R}_m}{\partial x} = 0, \quad \frac{\partial^2\mathcal{R}_m}{\partial x^2} = 0$	-	App. W
Ringdown Spectrum *Complex Eigenfrequency*	$\varpi_{\ell m} = \frac{c_{\mathrm{E}}^3}{GM}\left[\widehat{\omega}_{\ell m} - i\widehat{\Gamma}^{(\mathrm{rd})}_{\ell m}\right]$	-	App. W
Massive-Particle *Radial Potential ($\mathcal{R}_m$)*	$\mathcal{R}_m(x;\varepsilon,j_z) = \frac{[\varepsilon - j_z\widehat{\omega}(x)]^2}{\widehat{c}_P^2(x)} - j_z^2x^2 - 1$	-	App. W
Nonrotating Photon *Ring Radius*	$r_{\gamma,0} = 3R_{\mathrm{QG}}$	-	App. W
Nonrotating Shadow *Impact Scale*	$B_{\gamma,0} = \frac{27}{4}R_{\mathrm{QG}}$	-	App. W
Nonrotating ISCO *Radius*	$r_{\mathrm{ISCO},0} = 6R_{\mathrm{QG}}$	-	App. W

Part II (Continued): The Quantum Structure of the Vacuum & Vertical Topology

Parameter	Mathematical Expression	Section	Derivation Ref.
Physical Wavefunction *Order Parameter*	$\Psi = \sqrt{\rho}\cdot\exp\left(\frac{iS}{\hbar}\right)$	-	Appendix X

Parameter	Mathematical Expression	Section	Derivation Ref.
Viscous Non-Linear *Wave Equation*	$i\hbar\frac{\partial\Psi}{\partial t} = \left[-\frac{\hbar^2}{2m}\nabla^2 + V\right]\Psi - \left[i(\hbar\Gamma)\ln(\|\Psi\|^2)\right]\Psi$	16.1.2	Fluid Mechanics
Lattice Quantum *Potential*	$Q = -\frac{\hbar^2}{2m}\left(\frac{\nabla^2\sqrt{\rho}}{\sqrt{\rho}}\right)$	16.1.3	Fluid Mechanics
Condensate Force Law *Euler Formulation*	$F = -\nabla V - \nabla Q - F_{\text{friction}}$	16.1.3	Fluid Mechanics
Electron Rotational *Mass Limit*	$M_{\text{spin}} = \frac{\hbar}{2\cdot c_{\text{E}}\cdot r_{\text{D}}} \approx 2.229 \times 10^{-17}$ kg	16.2.5	Mechanical Proof
Localized Viscous *Boundary Friction*	$\Gamma(x) = \sigma \cdot c_{\text{P}} \cdot n_K(x)$	16.3.2	Node Topology
Generalized Linear *Uncertainty*	$\Delta x \cdot \Delta p \geq h \cdot (1 - \alpha_{\text{G}}) \cdot e^{-\Gamma t}$	16.4.3	Generalized Law
Generalized Angular *Uncertainty*	$\Delta\theta \cdot \Delta L \geq \frac{\hbar}{2}$	16.4.3	Generalized Law
Generalized *Commutator*	$[x, p] = i\hbar \cdot (1 - \alpha_{\text{G}}) \cdot e^{-\Gamma t}$	16.4.4	Generalized Law
Node Cell Hamiltonian *Energy*	$E_{\text{total}} = \frac{1}{2}\tau_{\text{D}}(\Delta x)^2 + \frac{1}{2}\mu_{\text{eff}}v^2$	-	Appendix Z
Active Tunneling *Transmission Law*	$T_{\text{active}} = \frac{\exp(-2DL)}{1+\left(\frac{Z_{\text{wall}}}{Z_{\text{drive}}}\right)^2\cdot\left[\sin^2(kL+\varphi_0)+\left(\frac{\omega-\omega_0}{\omega_0}\right)^2\right]}$	-	Appendix AA
Gravitational Strain *of a Photon*	$\alpha_{\text{G}} = 2\pi\left(\frac{\ell_{\text{S}}}{\lambda}\right)^2$	-	Appendix AB
Graviton Energy *Strain Shadow*	$E_{\text{g}} = \frac{h^2 G}{c_{\text{E}}^2\lambda^3}$	-	Appendix AB
Speed of Substrate *Transmission*	$c_{\text{S}} = \sqrt{\frac{\tau_{\text{S}}}{\mu_{\text{S}}}}$	17.4	Hard Floor Physics
Topological Budget *Identity*	$\alpha_{\text{Q}} = 1 - \alpha_{\text{G}}$	-	Appendix AC
Operative Local *Tension (τ_{local})*	$\tau_{\text{local}} = \frac{hc_{\text{E}}}{r_{\text{D}}^3}$	-	Appendix Z
Quantum Displacement *Limit (Δx)*	$\Delta x = r_{\text{D}}\sqrt{\frac{2r_{\text{D}}}{\lambda}}$	-	Appendix Z
Phase Crosstalk *Budget Limit*	$\Delta\varphi \leq \eta_\varphi\left(\frac{c_{\text{E}}}{r^3}\right)A_{\text{overlap}}T$	-	Appendix AD

Parameter	Mathematical Expression	Section	Derivation Ref.
Macroscopic Tunneling *(T_{device})*	$T_{\text{device}} \approx \frac{1}{1+\left(\frac{Z_{\text{wall}}}{Z_{\text{drive}}}\right)^2(\Delta\varphi^2+\Delta f^2)}$	-	Appendix AA
Topological Winding *Condition*	$\oint \nabla\varphi \cdot \mathrm{d}\ell = 2\pi n$	-	Appendix X

Part II (Continued): Grand Unification of the Fundamental Forces

Parameter	Mathematical Expression	Section	Derivation Ref.
Raw Structural *Mass Moment*	$J_i = \rho_i r_i^4$	-	Appendix G
Strong Force *1D Confinement*	$T_{\mathrm{s}} = 2\pi\rho_{\mathrm{eff}} c_{\mathrm{E}}^2 r_{\mathrm{N}}^2$	-	Appendix AH
Electromagnetism *Fine-Structure*	$\alpha = \frac{K_{\mathrm{L}}}{\hbar c_{\mathrm{E}}}$	-	App. AE & AF
Macroscopic *Coulomb Constant*	$k_{\mathrm{e}} = 10^{-7} \cdot c_{\mathrm{E}}^2$	-	Appendix AG
Elementary *Charge*	$e = \sqrt{\frac{K_{\mathrm{L}}}{k_{\mathrm{e}}}}$	-	Appendix AG
Weak Force *3D Torsional Slip*	$G_{\mathrm{F}} = (2\pi\rho(r_{\mathrm{w}}) c_{\mathrm{E}}^2 r_{\mathrm{w}}^3)^{-2}$	-	Appendix AH
Gravity *Radial Tension*	$\alpha_{\mathrm{G}} = \frac{\kappa c_{\mathrm{E}}^2}{\rho_{\mathrm{eff}} G R^2}$	-	Appendix AH
Unified EM *Torsional Projection*	$\alpha = \frac{K_{\mathrm{L}}}{c_{\mathrm{E}}^2 J_{\mathrm{N}}}$	-	Appendix AH
Unified Weak *Torsional Projection*	$E_{\mathrm{weak}} = \frac{2\pi J_i c_{\mathrm{E}}^2}{r_{\mathrm{w}}}$	-	Appendix AH
Unified Strong *Torsional Projection*	$\sigma_{\mathrm{s}} = \frac{2\pi c_{\mathrm{E}}^2 J_i}{r_{\mathrm{N}}^2}$	-	Appendix AH
Unified Gravity *Torsional Projection*	$\alpha_{\mathrm{G}} = \frac{\kappa J_i G}{c_{\mathrm{E}}^2 r^2}$	-	Appendix AH

Part II (Continued): The Mechanical Foundations of the Hydrogen Atom

Parameter	Mathematical Expression	Section	Derivation Ref.
Proton Mechanical *Radius*	$r_{\mathrm{N}} \approx 0.88 \times 10^{-15}$ m	19.1	Anchor Topology
Effective Nuclear *Confinement*	$F_{\mathrm{strong}} = \rho_{\mathrm{eff}} \cdot c_{\mathrm{E}}^2 \cdot 2\pi r_{\mathrm{N}}^2 \approx 1.6$ GeV/fm	-	Appendix AH
Nucleon Structural *Mass Moment*	$J_{\mathrm{N}} = \rho_{\mathrm{N}} r_{\mathrm{N}}^4 \approx 3.51 \times 10^{-43}$ kg $\cdot$ m	-	Appendix G
Lattice *Fine-Structure*	$\alpha = \frac{K_{\mathrm{L}}}{c_{\mathrm{E}}^2 J_{\mathrm{N}}} \approx \frac{1}{137}$	-	Appendix AE
TFT Hydrogenic *Shell Law*	$r_n = \frac{n^2 \hbar}{m_{\mathrm{e}} \alpha c_{\mathrm{E}}}$	-	Appendix AJ
TFT Hydrogenic *Energy Spectrum*	$E_n = -\frac{m_{\mathrm{e}} \alpha^2 c_{\mathrm{E}}^2}{2n^2}$	-	Appendix AJ
Angular Standing *Mode Limit*	$l \leq n - 1$	-	Appendix AK
TFT Fine-Structure *Splitting*	$E_{n,l,j_{\mathrm{tot}}}^{\mathrm{TFT}} = -\frac{m_{\mathrm{e}} \alpha^2 c_{\mathrm{E}}^2}{2n^2} - \frac{m_{\mathrm{e}} \alpha^4 c_{\mathrm{E}}^2}{8n^4} + \zeta_{\mathrm{SO}} \frac{m_{\mathrm{e}} \alpha^4 c_{\mathrm{E}}^2}{2n^6 \left[j_{\mathrm{tot}}(j_{\mathrm{tot}}+1) - l(l+1) - \frac{3}{4} \right]}$	-	Appendix AL
Bipolar Lattice *Strain Force*	$F_{\mathrm{lattice}} = \frac{K_{\mathrm{L}}(\chi_1)(\chi_2)}{r^2}$	-	Appendix AG
Photonic Extrusion *Energy*	$E_\gamma = \int \delta\tau \, \mathrm{d}V \approx \tau_{\mathrm{bulk}} \cdot A_{\mathrm{chan}} \cdot \Delta r$	-	Appendix AD
Nucleon Resonance *Threshold*	$E_{\mathrm{N}} = \frac{h c_{\mathrm{E}}}{r_{\mathrm{N}}} \approx 1.41$ GeV	19.6	Energy Limits

Part III: Cosmic Architecture, Kinematics, and Thermodynamics

Parameter	Mathematical Expression	Section	Derivation Ref.
Phonon Hysteresis *CMB Deficit*	$\oint F \cdot \mathrm{d}x > 0$	24.5	Solid-State Mechanics
Lattice Thermal *Diffusion*	$T \propto t^{-1/2}$	-	Appendix AN
Visco-Elastic *Damping Equation*	$1 + z = e^{\frac{\Gamma_{\mathrm{D}} x}{c_{\mathrm{E}}}}$	-	Appendix AQ
Logarithmic *Coordinate Distance*	$d = \frac{c_{\mathrm{E}}}{H_0} \ln(1+z)$	-	Appendix AS
Non-Linear *Luminosity Distance*	$d_{\mathrm{L}} = \frac{c_{\mathrm{E}}}{H_0}(1+z)\ln(1+z)$	-	Appendix AS
Lattice Impedance *Acceleration*	$a_{\mathrm{D}} = c_{\mathrm{E}} \cdot \Gamma_{\mathrm{D}} \approx 7.0964 \times 10^{-10}$ m/s^2	-	Appendix L
Galactic Acceleration *Scale (a_{gal})*	$a_{\mathrm{gal}} \equiv \frac{a_{\mathrm{D}}}{2\pi} \approx 1.1294 \times 10^{-10}$ m/s^2	-	Appendix L
Macroscopic *MOND Equivalent*	$a_0 = \frac{a_{\mathrm{D}}}{2\pi}$	26.5	Geometric Projection
TFT Absolute *Optical Horizon*	$R_{\mathrm{U}} = \frac{c_{\mathrm{E}}}{H_0} \approx 4104.5$ Mpc	26.3.2	Viscous Boundary
True Euclidean *Acoustic Ruler*	$r_{s(\mathrm{TFT})} = R_{\mathrm{U}} \cdot \theta_* \approx 42.73$ Mpc	26.3.2	Geometric Triang.
Topological *Invariant Cycles*	$N = f \cdot \Delta t$	-	Appendix AR
Observed SN *Time Dilation*	$\Delta t_{\mathrm{obs}} = \frac{N}{f_{\mathrm{obs}}} = \Delta t_{\mathrm{emit}}(1+z)$	-	Appendix AR
Thermodynamic *Dimming (Energy)*	$E_{\mathrm{obs}} = \frac{E_{\mathrm{emit}}}{1+z}$	-	Appendix AR
Kinematic *Power Drop*	$P_{\mathrm{obs}} = \frac{P_{\mathrm{emit}}}{(1+z)^2}$	-	Appendix AR
Effective Gravitational *Impedance*	$\mu_{\mathrm{eff}} = \frac{\mu_{\mathrm{D}}}{(1-\alpha_{\mathrm{G}})^4}$	25.4	Part II Unity
Cosmic Critical *Mass (Observed)*	$M_{\mathrm{U}} = \frac{c_{\mathrm{E}}^3}{G\Gamma_{\mathrm{D}}}$	27.1	Kinematic Limits

Parameter	Mathematical Expression	Section	Derivation Ref.
TFT Kinematic *State Equation*	$\Gamma_{\mathrm{D}}^2 = \frac{4\pi G}{3}\rho_{\mathrm{c}}$	27.2	Geometric Projection
Total Cosmic *Reservoir Mass*	$M_{\mathrm{Res}} = M_{\mathrm{U}} \times 9.7957 \times 10^{25} \approx 1.6707 \times 10^{79}$ kg	27.3	Volumetric Scaling
Octahedral *Void Limit*	$\beta_{\mathrm{oct}} = \frac{\pi(\sqrt{2}-1)^3}{3\sqrt{2}} \approx 0.0526$	-	Appendix AT
Baryonic Mass *Capacity*	$\beta_{\mathrm{b}} \leq \beta_{\mathrm{oct}} \approx 0.0526$	-	Appendix AT
Phase-Volume *Reference Tensor*	$\left\langle T_{\mu\nu}^{(0)} \right\rangle = \beta_{\mathrm{geo}} T_{\mu\nu}^{(\mathrm{D},0)} + \beta_{\mathrm{IC}} T_{\mu\nu}^{(\mathrm{IC},0)}$	-	App. Q
Exact Capacity *Ledger*	$T_{\mu\nu}^{(0)} = T_{\mu\nu}^{(\mathrm{rem})} + \Delta T_{\mu\nu}^{(\tau)}$	-	App. Q
Uniform Structural *Capacity Closure*	$T_{\hat{0}\hat{0}}^{(\mathrm{D},0)} = T_{\hat{0}\hat{0}}^{(\mathrm{IC},0)} = \tau_{\mathrm{G}}$	-	App. Q
TFT Effective *Cosmological Constant*	$\Omega_{\Lambda,\mathrm{eff}}^{(\mathrm{TFT})} = \beta_{\mathrm{geo}} - \beta_{\mathrm{b}}$	-	App. Q
TFT Effective *Dark Matter Fraction*	$\Omega_{\mathrm{DM}}^{(\mathrm{TFT},0)} = \beta_{\mathrm{IC}}$	-	App. Q
Late-Time Equation *of State Diagnostic*	$w_{\mathrm{tot}} \simeq -(\beta_{\mathrm{geo}} - \beta_{\mathrm{b}}) \simeq -0.69048$	-	App. Q
Scale-Invariant Continuum *Equation*	$E_{\max} = h\Gamma_{\mathrm{D}} N_{\mathrm{D}}$	28.1	Strain Unification
Global Cosmic Energy *(E_{Res})*	$E_{\mathrm{Res}} = M_{\mathrm{Res}} c_{\mathrm{E}}^2 \approx 10^{96}$ J	28.2.1	Volumetric Scaling
Local Yield Tension *(τ_G)*	$\tau_{\mathrm{G}} = \rho_{\mathrm{G}} c_{\mathrm{E}}^2 = \tau_{\mathrm{D,bulk}} \approx 10^{96}$ J/m^3	28.2.2	Phase Saturation
Global-Local Energy *Equivalence*	$\frac{E_{\mathrm{Res}}}{1\ \mathrm{m}^3} \approx \tau_{\mathrm{G}}$	28.2	Scale Identity
Global Phase Avalanche *Equation*	$M_{\mathrm{p}}(t) = M_{\mathrm{D,G}} \cdot e^{\Gamma_{\mathrm{D}} t}$	-	App. AT
Global Rupture *Trigger Mass (M_{trg})*	$M_{\mathrm{trg}} = 0.0516 \cdot M_{\mathrm{Res}} \approx 8.6208 \times 10^{77}$ kg	-	App. AT
Total Oscillation *Time (T_{cyc})*	$T_{\mathrm{cyc}} = 177.15 \cdot \Gamma_{\mathrm{D}}^{-1} \approx$ 2.3715 Trillion yrs	-	App. AT

Parameter	Mathematical Expression	Section	Derivation Ref.
Current Aggregate *State II Mass (M_{cur})*	$M_{\text{cur}} = M_{\text{obs}} \cdot (9.7957 \times 10^{25}) \approx 9.7957 \times 10^{75}$ kg	-	App. AT
Current Cosmic *Epoch (t_{cur})*	$t_{\text{cur}} = 172.67 \cdot \Gamma_{\text{D}}^{-1} \approx 2.3116$ Trillion yrs	-	App. AT
Remaining Cosmic *Lifespan (Δt)*	$\Delta t = \frac{1}{\Gamma_{\text{D}}} \ln\left(\frac{M_{\text{trg}}}{M_{\text{cur}}}\right) \approx 59.94$ Billion yrs	-	App. AT
Cosmological Damping *Specific Work Extract*	$W_{\text{total}} = a_{\text{D}} \cdot R_{\text{U}} = c_{\text{E}}^2$	-	Appendix H
Non-Linear Redshift *Expansion*	$z \approx \Gamma_{\text{D}} t + \frac{(\Gamma_{\text{D}} t)^2}{2}$	-	Appendix AQ

Table of Notation and Constants

This appendix details the fundamental constants, geometric boundaries, and mathematical notation utilized throughout Tension Field Theory (TFT).

I. Geometric Boundaries and Dimensional Limits

Symbol	Mechanical Definition	TFT Mathematical Relation	Numerical Value
ℓ_S	Substrate Lattice Spacing (Hard Floor 1D Limit)	$\sqrt{\hbar G/c_E^3}$	$\approx 1.6163 \times 10^{-35}$ m
r_D	FCC Soft Floor Node Radius	$hc_E/2E_D$	$\approx 7.4504 \times 10^{-27}$ m
r_N	Nucleon Mechanical Radius (Torsional Anchor)	Derived geometric limit	$\approx 0.88 \times 10^{-15}$ m
R_{QG}	Event Horizon Radius (Gravitational Saturation)	GM/c_E^2	Variable
R_U	Geometric Cosmic Horizon (Viscous Limit)	c_E/Γ_D	$\approx 1.2665 \times 10^{26}$ m
R_{Res}	Total Cosmic Reservoir Radius	$R_U \cdot (\rho_S/\rho_{QG})^{1/3}$	$\approx 5.8383 \times 10^{34}$ m
r_{QG}	Convergence Radius (Microscopic Phase Trigger)	$\ell_S \cdot \left(1.5\frac{\rho_S}{\rho_{QG}}\right)^{1/4}$	$\approx 5.6248 \times 10^{-29}$ m
r_G	Gravitational Yield Radius (Fracture Scale)	$\ell_S \cdot \left(1.5\frac{\rho_S}{\rho_G}\right)^{1/4}$	$\approx 3.8439 \times 10^{-31}$ m
r_w	Weak Interaction Vertex Radius	Derived geometric focus	$\approx 5.0 \times 10^{-18}$ m
a_{TFT}	Fundamental Hydrogenic Radius	$\frac{\hbar}{m_e \alpha c_E}$	$\approx 5.29 \times 10^{-11}$ m
A_{chan}	Micro-emission Channel Area	$\frac{\lvert\Delta E\rvert}{\tau_{bulk}\Delta r}$	Variable (m^2)
$A_{overlap}$	Shared Strain Bottleneck	Field overlap boundary	Variable (m^2)
N_D	Kinematic Lattice Index	$R_U/2r_D$	$\approx 8.4995 \times 10^{51}$

Symbol	Mechanical Definition	TFT Mathematical Relation	Numerical Value
N_{S}	Absolute Substrate Index	$R_{\mathrm{Res}}/\ell_{\mathrm{S}}$	$\approx 3.6121 \times 10^{69}$
V_{eff}	Effective Hydrodynamic Volume	Kinematic boundary	Variable (m^3)
N_{QG}	Convergence Information Limit (Absolute Boundary Capacity)	$\frac{8\pi^2 R_{\mathrm{QG}}^2}{\ell_{\mathrm{S}}^2}$	Dimensionless
N_{M}	True Coherent Information Record (Active Strain Bits)	$2\pi \left(\frac{m_{\mathrm{S}}}{M}\right)^2$	Dimensionless
S_{geo}	Geometric Capacity (Max FCC Boundary Slots)	$k_{\mathrm{B}} \frac{4\pi R_{\mathrm{QG}}^2}{r_{\mathrm{D}}^2}$	Variable (J/K)
S_{kin}	Kinematic Occupancy (Actual Defect Count)	$\frac{R_{\mathrm{QG}}}{r_{\mathrm{D}}}$	Dimensionless
Φ_{kin}	Kinematic Fill Ratio (Mass Dilution)	$\frac{1}{4\pi}\left(\frac{r_{\mathrm{D}}}{R_{\mathrm{QG}}}\right)$	Dimensionless
Φ_{info}	Information Fill Ratio (Strain Dilution)	$\frac{1}{4\pi}\left(\frac{\ell_{\mathrm{S}}}{R_{\mathrm{QG}}}\right)^4$	Dimensionless
d_{nn}	FCC Nearest-Neighbor Separation	$2r_{\mathrm{D}}$	$\approx 1.4901 \times 10^{-26}$ m
V_{p}	FCC Primitive-Cell Volume	$4\sqrt{2}r_{\mathrm{D}}^3$	$\approx 2.339 \times 10^{-78}$ m^3
$A_{\mathrm{ct}}^{(\mathrm{modal})}$	Effective Modal Contact Area	$2\pi\ell_{\mathrm{S}}^2$	$\approx 1.641 \times 10^{-69}$ m^2

II. Vacuum Mechanics, Density, and Inertia

Symbol	Mechanical Definition	TFT Mathematical Relation	Numerical Value
ρ_{S}	Substrate Density (Absolute Lattice Capacity)	Mass / Volume at ℓ_{S}	$\approx 5.1550 \times 10^{96}$ kg/m^3
ρ_{QG}	Convergence Density (Void Exhaustion Limit)	Derived phase trigger	$\approx 5.2625 \times 10^{70}$ kg/m^3
ρ_{D}	Operational Node Density (Soft Floor Baseline)	Derived mass / volume	$\approx 1.7124 \times 10^{62}$ kg/m^3
ρ_{c}	Cosmic Critical Density	$\frac{3\Gamma_{\mathrm{D}}^2}{4\pi G}$	$\approx 2.0042 \times 10^{-26}$ kg/m^3
ρ_{M}	Macroscopic Baryonic Density	Local mass distribution	Variable (kg/m^3)
Σ_{surf}	Areal Mass Density (Black Hole Boundary)	$\left(\frac{\rho_{\mathrm{QG}} \cdot r_{\mathrm{D}}^2}{4\pi}\right) \frac{1}{R_{\mathrm{QG}}}$	Variable (kg/m^2)
ρ_{IC}	Interstitial Condensate Density	$\mu_{\mathrm{D}} \cdot \iota_{\mathrm{V}}$	$\approx 1.8074 \times 10^{53}$ kg/m^3
ι_{V}	Dimensional Projection Constant (2D to 3D mapping)	$\rho_{\mathrm{IC}}/\mu_{\mathrm{D}}$	$\equiv 1$ m^{-1}
β_{geo}	Vacuum Geometric Packing Fraction (Dark Energy)	$\frac{\pi}{\sqrt{18}}$	≈ 0.74048
β_{IC}	Interstitial Condensate Fraction (Dark Matter)	$1 - \beta_{\mathrm{geo}}$	≈ 0.25952
β_{oct}	Octahedral Void Limit (Baryonic Mass Limit)	$\frac{\pi(\sqrt{2}-1)^3}{3\sqrt{2}}$	≈ 0.05260
μ_{D}	Baseline Lattice Interface Inertia	$\frac{c_{\mathrm{E}}^2}{G \cdot r_{\mathrm{D}}}$	$\approx 1.8074 \times 10^{53}$ kg/m^2
μ_{eff}	Effective Causal Inertia	$\frac{\mu_{\mathrm{D}}}{(1-\alpha_{\mathrm{G}})^4}$	Variable (kg/m^2)
F_{S}	Ultimate Substrate Yield Force (Planck Force)	$\frac{c_{\mathrm{E}}^4}{G}$	$\approx 1.2102 \times 10^{44}$ N
τ_{S}	Max Substrate Tension (Hard Floor Yield Limit)	$\frac{F_{\mathrm{S}}}{\ell_{\mathrm{S}}^2}$	$\approx 4.6330 \times 10^{113}$ Pa
τ_{D}	Lattice Shear Stiffness (Soft Floor Tension)	$\frac{c_{\mathrm{E}}^4}{G \cdot r_{\mathrm{D}}^2}$	$\approx 2.1803 \times 10^{96}$ Pa

Symbol	Mechanical Definition	TFT Mathematical Relation	Numerical Value
τ_{M}	Macroscopic Gravitational Tension	$\frac{G \cdot M \cdot \mu_{\mathrm{D}}}{R}$	Variable (Pa)
τ_{G}	Local Yield Tension	$\rho_{\mathrm{G}} c_{\mathrm{E}}^2$	$\approx 2.1803 \times 10^{96}$ J/m^3
K_{shear}	Substrate Shear Modulus	$\rho_{\mathrm{c}} \cdot c_{\mathrm{E}}^2$	Derived limit (Pa)
$\mathcal{C}$	Two-Endpoint Residual Capacity Factor	$(1 - \alpha_{\mathrm{G}})^2$	Dimensionless
$\rho_{\mathrm{sh}}^{(\mathrm{micro},0)}$	Microscopic Scaffold Inertia Normalization	$\beta_{\mathrm{geo}} \rho_{\mathrm{D}}$	$\approx 1.268 \times 10^{62}$ kg/m^3
$K_{\mathrm{sh}}^{(\mathrm{micro},0)}$	Microscopic Tangent Shear Coefficient	$\beta_{\mathrm{geo}} \rho_{\mathrm{D}} c_{\mathrm{E}}^2$	$\approx 1.14 \times 10^{79}$ Pa
$\mathcal{T}_{\mathrm{TT}}^{(0)}$	Collective Tensor-Gradient Coefficient	$\frac{c_{\mathrm{E}}^4}{8\pi G}$	$\approx 4.814 \times 10^{42}$ N
$M_{\mathrm{TT}}^{(0)}$	Collective Line Inertia	$\frac{c_{\mathrm{E}}^2}{8\pi G}$	$\approx 5.356 \times 10^{25}$ kg/m
$\iota_{\mathrm{V}}^{(\mathrm{def})}$	Localized Defect Impedance Projection	$1/\ell_{\mathrm{imp}}^{(\mathrm{def})}$	Variable (m^{-1})
$\rho_{\mathrm{IC}}^{(\mathrm{imp})}$	Mode-Resolved Condensate Impedance Density	$\mu_{\mathrm{D}} \iota_{\mathrm{V}}^{(\mathrm{def})}$	Variable (kg/m^3)
ρ_{Q}	Quantum Saturation Density (Kinematic Limit)	$\frac{\hbar}{c_{\mathrm{E}} r_{\mathrm{D}}^4}$	$\approx 1.1416 \times 10^{62}$ kg/m^3
ρ_{G}	Gravitational Yield Density (Lattice Yield)	$\frac{c_{\mathrm{E}}^2}{G r_{\mathrm{D}}^2}$	$\approx 2.4259 \times 10^{79}$ kg/m^3
τ_{QG}	Macroscopic Boundary Tension	$\frac{c_{\mathrm{E}}^4}{4\pi G R_{\mathrm{QG}}^2}$	Scale-dependent (Pa)
τ_{local}	Operative Local Tension (Photon Stiffness)	$\frac{h c_{\mathrm{E}}}{r_{\mathrm{D}}^3}$	$\approx 4.8035 \times 10^{53}$ N/m
Z_{wall}	Static Mechanical Impedance (Barrier)	Resistance metric	Variable (kg/(m^2·s))
Z_{drive}	Active Drive Impedance (Tunneling)	Applied frequency drive	Variable (kg/(m^2·s))
$n_K(x)$	Topological Knot Density	Local structural defects	Variable (m^{-3})
Ψ	Physical Wavefunction (Macroscopic Order)	$\sqrt{\rho} \cdot e^{i\varphi}$	Complex Phase

III. Kinematics, Energy, and Coupling Constants

Symbol	Mechanical Definition	TFT Mathematical Relation	Numerical Value
t_{S}	Substrate Time Interval (Quantization Limit)	$\sqrt{\frac{\hbar G}{c_{\mathrm{E}}^5}}$	$\approx 5.391 \times 10^{-44}$ s
E_{S}	Substrate Phase Transition Energy (Yield Limit)	$\sqrt{\frac{\hbar c_{\mathrm{E}}^5}{G}}$	$\approx 1.956 \times 10^{9}$ J
T_{S}	Substrate Transition Temperature (Thermal Yield)	$\sqrt{\frac{\hbar c_{\mathrm{E}}^5}{G k_{\mathrm{B}}^2}}$	$\approx 1.416 \times 10^{32}$ K
c_{E}	Invariant Energy Constant (Absolute Shear Limit)	$\sqrt{\frac{\tau_{\mathrm{D}}}{\mu_{\mathrm{D}}}}$	299,792,458 m/s
c_{P}	Dynamic Wave Propagation Speed	$c_{\mathrm{E}}\sqrt{\frac{\mu_{\mathrm{D}}}{\mu_{\mathrm{eff}}}}$	$\leq c_{\mathrm{E}}$
c_{S}	Substrate Longitudinal Speed (Entanglement)	$\sqrt{\frac{\tau_{\mathrm{S}}}{\mu_{\mathrm{S}}}}$	$\to \infty$
t_{p}	Proper Time (Internal Clock of Localized Defect)	$n\left(\frac{h}{E_0}\right)$	Variable (s)
$\Delta\varphi$	Lattice Phase Differential	Phase topology	Radians
J_i	Structural Mass Moment	$\rho_i r_i^4$	Topology-weighted ($J_i = \mathcal{F}_i \hat{J}$)
$\hat{J}$	Topology-Normalized Scale-Invariant Mass Moment	$\frac{J_i}{\mathcal{F}_i}$	Universal constant
J_{D}	Fundamental Node Structural Mass Moment	$\rho_{\mathrm{D}} r_{\mathrm{D}}^4$	Derived constant
J_{N}	Nucleon Structural Mass Moment	$\rho_{\mathrm{N}} r_{\mathrm{N}}^4$	$\approx 3.51 \times 10^{-43}$ kg·m
h	Quantum of Action (Lattice Rotational Momentum)	$2\pi \cdot \hat{J} \cdot c_{\mathrm{E}}$	$\approx 6.626 \times 10^{-34}$ J · s
$\hbar$	Reduced Quantum of Action	$\frac{h}{2\pi}$	$\approx 1.054 \times 10^{-34}$ J·s
G	Gravitational Coupling Efficiency	$\mathcal{F}_i \cdot \left(\frac{c_{\mathrm{E}}^2 A_{\mathrm{S}}}{J_i}\right)$	$\approx 6.674 \times 10^{-11}$ $\mathrm{m}^3/(\mathrm{kg}\cdot\mathrm{s}^2)$
κ	TFT Gravitational Coupling Constant	Field equation limit	Variable mapping

Symbol	Mechanical Definition	TFT Mathematical Relation	Numerical Value
$\mathcal{F}_i$	Master Geometric Scaling Factor	Dimensional projection	Dimensionless
K_{L}	Absolute Lattice Shear Coupling ($k_{\mathrm{e}}e^2$)	Derived geometric limit	$\approx 2.307\times10^{-28}$ N·m^2
α	Fine-Structure Constant (Transverse Survival Ratio)	$\frac{K_{\mathrm{L}}}{\hbar c_{\mathrm{E}}}$	$\approx 1/137.036$
α_{G}	Structural Gravitational Strain	$\frac{GM}{rc_{\mathrm{E}}^2}$	Dimensionless
$n_\tau(\mathbf{x})$	Strain-Induced Vacuum Refractive Index	$\frac{c_{\mathrm{E}}}{c_{\mathrm{P}}} = \frac{1}{(1-\alpha_{\mathrm{G}})^2}$ (Spherical: $\approx 1 + \frac{2GM}{rc_{\mathrm{E}}^2}$)	Dimensionless; variable
α_{Q}	Topological Quantum Coupling Budget	$1 - \alpha_{\mathrm{G}}$	Dimensionless
σ	Local Scattering Cross-Section (Interaction Area)	*Derived geometric target*	Variable (m^2)
K_{D}	Fundamental Impedance Constant	$\rho_{\mathrm{IC}} \cdot 4\pi r_{\mathrm{D}}^2$	≈ 126.08 kg/m
f_{D}	Baseline Structural Frequency	$\frac{c_{\mathrm{E}}}{2r_{\mathrm{D}}}$	Derived constant (Hz)
η_φ	Geometric Coupling Efficiency	Empirical calibration	Dimensionless (< 1)
G_{F}	Weak Force 3D Gear Slip (Fermi Limit)	$(\tau V)^{-2}$	$\approx 1.6 \times 10^{-5}$ GeV^{-2}
T_{s}	Strong Force 1D Bond Pull (QCD Tension)	τA_{chan}	≈ 1.6 GeV/fm
k_{e}	Electrostatic Constant (SI Normalized)	$10^{-7} \cdot c_{\mathrm{E}}^2$	$\approx 8.987 \times 10^9$ N · m^2/C^2
e	Elementary Charge Conversion Factor	$\sqrt{K_{\mathrm{L}}/k_{\mathrm{e}}}$	$\approx 1.602 \times 10^{-19}$ C
a_{gal}	Galactic Acceleration Scale	$\frac{a_{\mathrm{D}}}{2\pi}$	$\approx 1.129\times10^{-10}$ m/s^2
$\chi_{\mathrm{g}}(R)$	Condensate Relative Response	$\sqrt{a_{\mathrm{gal}}/g_{b,\Pi}}$	Dimensionless
$\mathsf{H}_{ij}^{(\mathrm{GW})}$	Collective Transverse-Traceless Tensor	Directional-tension redistribution	Dimensionless
$h_{ij}^{(\mathrm{TT})}$	Observable Transverse-Traceless Strain	$2\mathsf{H}_{ij}^{(\mathrm{GW})}$	Dimensionless
$K_{\mathrm{GW}}^{(\mathrm{eff})}$	Spectral Gravitational-Wave Stiffness	$\frac{\pi c_{\mathrm{E}}^2 f^2}{4G}$	Variable (Pa)

Symbol	Mechanical Definition	TFT Mathematical Relation	Numerical Value
$\zeta_{\mathrm{GW}}(f)$	Microscopic-to-Collective Response Ratio	$\frac{K_{\mathrm{GW}}^{(\mathrm{eff})}}{K_{\mathrm{sh}}^{(\mathrm{micro},0)}}$	Variable

IV. Mass Limits, Chronology, and Observables

Symbol	Mechanical Definition	TFT Mathematical Relation	Numerical Value
$E_{\max}$	Absolute Max Coherent Energy (Nyquist Limit)	$\frac{hc_{\mathrm{E}}}{2r_{\mathrm{D}}}$	$\approx 8.3203 \times 10^{10}$ GeV
m_{S}	Universal Substrate Mass Potential (SC Node Limit)	$\sqrt{\frac{\hbar c_{\mathrm{E}}}{G}}$	$\approx 2.1764 \times 10^{-8}$ kg
$M_{\mathrm{D,G}}$	Soft Floor Ignition Mass (Micro-BH Nucleation)	$\frac{c_{\mathrm{E}}^2 \cdot r_{\mathrm{D}}}{G}$	≈ 10.033 kg
M_{U}	Universal Saturation Mass (Observable Cosmic Mass)	$\frac{c_{\mathrm{E}}^3}{G\Gamma_{\mathrm{D}}}$	$\approx 1.7056 \times 10^{53}$ kg
M_{Res}	Total Cosmic Reservoir Mass	$M_{\mathrm{U}} \cdot \left(\frac{\rho_{\mathrm{S}}}{\rho_{\mathrm{QG}}}\right)$	$\approx 1.6707 \times 10^{79}$ kg
$M_{\mathrm{net}}(t)$	Aggregate State II Mass	$M_{\mathrm{D,G}} \cdot e^{\Gamma_{\mathrm{D}} t}$	Variable (kg)
M_{trg}	Global Rupture Trigger Mass (Percolation Threshold)	$0.0516 \cdot M_{\mathrm{Res}}$	$\approx 8.6208 \times 10^{77}$ kg
M_{cur}	Current Aggregate State II Mass	$M_{\mathrm{obs}} \cdot \left(\frac{\rho_{\mathrm{S}}}{\rho_{\mathrm{QG}}}\right)$	$\approx 9.7957 \times 10^{75}$ kg
Γ_{D}	Viscoelastic Vacuum Relaxation Rate (FCC–Condensate Relaxation Rate)	$\frac{c_{\mathrm{E}}}{R_{\mathrm{U}}}$; $\Gamma_{\mathrm{D}}^{(\mathrm{cal})} = H_0^{(\mathrm{obs})}$	$\approx 2.3671 \times 10^{-18}$ s^{-1}
Γ	Localized Quantum Damping Rate (Measurement / Wave Arrest)	$\sigma c_{\mathrm{P}} n_K(x)$	Variable (s^{-1})
Γ_{eff}	Effective Viscoelastic Relaxation Rate	$\Gamma_{\mathrm{D}} + \Gamma(x)$	Variable (s^{-1})
a_{D}	Lattice Impedance Acceleration (Dark Matter Effect)	$c_{\mathrm{E}} \cdot \Gamma_{\mathrm{D}}$	$\approx 7.0964 \times 10^{-10}$ m/s^2

Symbol	Mechanical Definition	TFT Mathematical Relation	Numerical Value
g_{b}	Baryonic Newtonian Acceleration	$\frac{GM}{r^2}$	Variable ($\mathrm{m/s^2}$)
T_{cyc}	Total Oscillation Time (Macroscopic Lifespan)	$\frac{1}{\Gamma_{\mathrm{D}}} \ln\left(\frac{M_{\mathrm{trg}}}{M_{\mathrm{D,G}}}\right)$	≈ 2.3715 Trillion yrs
t_{cur}	Current Cosmic Epoch (Elapsed Time)	$\frac{1}{\Gamma_{\mathrm{D}}} \ln\left(\frac{M_{\mathrm{cur}}}{M_{\mathrm{D,G}}}\right)$	≈ 2.3116 Trillion yrs
Δt	Remaining Cosmic Lifespan (Expiration Timer)	$T_{\mathrm{cyc}} - t_{\mathrm{cur}}$	≈ 59.938 Billion yrs
$\Pi(r)$	Radial Projection Factor	Distance modulation	Dimensionless
$\Xi(R)$	Structural Shielding Operator	Acoustic boundary	Dimensionless
$g_{\mathrm{QG,max}}$	Maximum Finite Gravity Limit	$\frac{c_{\mathrm{E}}^2}{r_{\mathrm{D}}}$	$\approx 1.2063 \times 10^{43}$ $\mathrm{m/s^2}$
T_{nuc}	Nucleation Temperature (Hydrogen Limit)	Topological stability limit	$\approx 3.0 \times 10^3$ K

V. Rotating Black Hole & Live Boundary Dynamics

Symbol	Mechanical Definition	TFT Mathematical Relation	Numerical Value
$\mathcal{J}_{\rm BH}$	Total Axial Angular Momentum	$I_{\rm surf}\frac{v_{\rm tor}}{R_{\rm QG}}$	Variable (kg·m^2/s)
a_*	Dimensionless Spin Parameter	$\frac{c_{\rm E}\mathcal{J}_{\rm BH}}{GM^2}$	≤ 1
$I_{\rm surf}$	Effective Surface Moment of Inertia	$\int_\partial r_\perp^2\,{\rm d}M_\partial$	Variable (kg·m^2)
$v_{\rm tor}$	Effective Torsional Boundary Speed	$a_* c_{\rm E}\left(\frac{MR_{\rm QG}^2}{I_{\rm surf}}\right)$	$\leq c_{\rm E}$
$\omega_{\rm drag}$	Torsional Soft-Floor Dragging Rate	$\frac{2G\mathcal{J}_{\rm BH}}{c_{\rm E}^2 r^3}$ (Weak Field)	Variable (rad/s)
$v_\phi^{(\rm SF)}$	Tangential Soft-Floor Shear Speed	$r\sin\theta\,\omega_{\rm drag}(r)$	Variable (m/s)
$\tau_{\rm tor}$	3D Torsional Stiffness Density	$\tau_{D,\rm bulk}=\frac{c_{\rm E}^4}{Gr_{\rm D}^2}$	$\approx 2.18\times10^{96}$ Pa
$r_\perp$	Cylindrical Distance from Spin Axis	$r\sin\theta$	Variable (m)
$r_{\rm sat}$	Spin-Deformed Phase Boundary	$R_{\rm QG}\left[1-a_*^2P_2(\cos\theta)\right]$	Variable (m)
$r_{\rm cap}$	Torsional Capacity Surface	$\left\lvert v_\phi^{(\rm SF)}\right\rvert = c_P(r)$	Variable (m)
$Q_{\rm TFT}$	Spin-Induced Mass Quadrupole	$-\frac{\mathcal{J}_{\rm BH}^2}{Mc_{\rm E}^2}$	Variable (kg·m^2)
$R_{\rm obs}$	Observational Surface Map	Derived optical/orbital bounds	Variable (m)
d	Binary Center-to-Center Separation	Geometric distance	Variable (m)
$v_{\rm rel}$	Binary Relative Orbital Velocity	$c_{\rm E}\sqrt{\frac{R_1+R_2}{d}}$	$\leq c_{\rm E}$
$\alpha_{\rm bridge}$	Bridge Saturation Condition (Merger)	$\alpha_{\rm G,1}+\alpha_{\rm G,2}+\alpha_{\rm dyn}$	≥ 1 (at merger)
Σ_∂	Live Boundary Surface Mass Density	$\frac{{\rm d}M_\partial}{{\rm d}A}$	Variable (kg/m^2)
$\mathcal{E}_{\rm stored}$	Stored Boundary/Exterior Strain Energy	$\mathcal{E}_{\rm radial}+\mathcal{E}_{\rm tor}+\mathcal{E}_\partial$	Variable (J)
$\mathcal{P}_{\rm shed}$	Stress Shedding Power (Gravitational Waves)	$-\frac{{\rm d}\mathcal{E}_{\rm stored}}{{\rm d}t}$	Variable (W)

Symbol	Mechanical Definition	TFT Mathematical Relation	Numerical Value
$\omega_{\ell m}$	Ringdown Normal Mode Frequency	Derived eigenvalue	Variable (rad/s)
$\Gamma_{\ell m}^{(\mathrm{rd})}$	Ringdown Normal Mode Damping Rate	Derived eigenvalue	Variable (s^{-1})
$r_{\gamma,s_{\mathrm{br}}}$	Photon Ring Radius (Prograde/Retrograde)	Circular null geodesic root	Variable (m)
$B_{\gamma,s_{\mathrm{br}}}$	Shadow Impact Scale	$\frac{c_{\mathrm{E}}}{\left\lvert\omega_{\mathrm{drag}}+s_{\mathrm{br}}\frac{c_P}{r_\gamma}\right\rvert}$	Variable (m)
$r_{\mathrm{ISCO},s_{\mathrm{br}}}$	Innermost Stable Circular Orbit Radius	Massive-particle marginal stability	Variable (m)
Q_{ij}	Symmetric Trace-Free Mass Quadrupole	$I_{ij}-\frac{1}{3}\delta_{ij}I_{kk}$	Variable ($\mathrm{kg}\cdot\mathrm{m}^2$)
$\mathcal{M}$	Binary Chirp Mass	$\mu^{3/5}M^{2/5}$	Variable (kg)
P_{GW}	Total Quadrupole Luminosity	$\frac{G}{5c_{\mathrm{E}}^5}\left\langle \dddot{Q}_{ij}\dddot{Q}_{ij}\right\rangle$	Variable (W)

Glossary of TFT Terminology

This appendix provides formal definitions for the specialized terminology and mechanical concepts unique to Tension Field Theory (TFT).

Absolute Lattice Shear Coupling (K_{L}): The exact mechanical efficiency of the lattice capturing the local action budget ($\hbar c_{\mathrm{E}}$) on the 2D surface of a Soft Floor node. In macroscopic terms, it is the dimensional conversion factor bridging absolute vacuum topology to human electrostatic units ($k_{\mathrm{e}} e^2$).

Acoustic Transparency: The deterministic mechanical mechanism of quantum tunneling. It occurs when a standing wave bridge phase-locks with a geometric barrier, neutralizing the wall's mechanical impedance and allowing a topological knot to slide through.

Active Vacuum (State I / Soft Floor): The dynamically spaced Face–Centered Cubic (FCC) lattice that operates as the observable universe. It possesses the necessary geometric tolerance (interstitial voids) to allow for mechanical vibration, wave propagation, and hydrodynamic impedance.

Bipolar Strain Field: The locked, high-tension structural web between a Torsional Anchor (nucleus) and a Resonant Standing Wave Boundary (electron shell). Its macroscopic geometric projection is the mechanical reality of electrostatic charge.

Capacity Surface (r_{cap}): The mechanical co-motion surface around a rotating TFT black hole where the torsional drift speed of the Soft Floor equals the local propagation capacity. It operates as the functional equivalent of the Kerr ergosphere, but is defined by local wave kinematics rather than metric geometry.

Catastrophic Decompression (The Big Rupture): The strictly mechanical genesis event of the observable universe. It is the martensitic phase transition where a hyper-compressed, saturated State II Black Hole core violently yields, snapping outward to restore the interstitial voids of the Face–Centered Cubic (FCC) active vacuum.

Center-of-Mass Motion (Boundary Translation): One of the four velocity channels of a live TFT black hole. It describes the macroscopic displacement of the entire saturated SC phase domain through the external Soft Floor, distinct from phase-front growth or surface torsion.

Chiral Nucleation: The mechanical origin of Baryon Asymmetry. Because the universe decompressed from a spinning saturated core, the resulting vacuum possesses a slight torsional

twist. Matter formed with this helical grain (lower nucleation energy), while antimatter formed against it (higher nucleation energy), naturally producing a matter-dominant cosmos.

Completed Coordinate Map ($u_i = \mathcal{C}_i y_i$): The work-conjugate constitutive constraint derived from the active-capacity balance. It dictates that the completed displacement (u_i) accepted by the active FCC contact state is strictly a fraction of the latent node-condensate reconfiguration (y_i) presented to the endpoint, determined by the local gravitational residual capacity ($\mathcal{C}_i$).

Contact-Point Relative Displacement ($\Delta\mathbf{u}^{\mathrm{c}}_{ij}$): The objective local deformation measure for the nearest-neighbor FCC contact energy. It includes nodal translations, nodal microrotations, and internal phase differences to ensure the contact law remains rigorously frame-indifferent under rigid translation and uniform rotation.

Convergence Information Limit (N_{QG}): The absolute geometric capacity for information encoded onto the fully saturated SC core boundary. It represents the theoretical maximum number of longitudinal strain bits the boundary can support, not the actual mass footprint.

Cosmic Critical Mass (M_{U}): The absolute mass limit of the observable universe ($\approx 10^{53}$ kg). It is mechanically identical to the saturation mass of a Type I Black Hole (M_{Sat}), proving the observable cosmos operates exactly at the structural boundary limit of causal saturation.

Cosmic Impedance (a_{D}): The fundamental hydrodynamic resistance of the active vacuum lattice ($a_{\mathrm{D}} = c_{\mathrm{E}} \cdot \Gamma_{\mathrm{D}}$). It mechanically generates flat galactic rotation curves (the "Dark Matter" effect) via inductive reactance against baryonic inertia.

Directional-Tension Redistribution: The mechanical origin of gravitational radiation in TFT. It is not an ordinary affine Cauchy strain of the FCC scaffold, but a propagating, self-equilibrated transverse-traceless variation in the directional transfer capacity of the active Soft Floor.

Dynamic Covariant Conservation: The on-shell requirement that the total completed effective action (encompassing the nodal scaffold, interstitial condensate, and baryonic defects) must satisfy $\nabla^{(\tau)}_{\mu} T^{\mu\nu}_{\mathrm{TFT}} = 0$, ensuring the coupled dual-phase vacuum remains compatible with the emergent gravitational Bianchi identity.

Euclidean Acoustic Resolution: The recalculation of the primordial Baryon Acoustic Oscillations (BAO) using a static, visco-elastic Euclidean metric rather than a frictionless, expanding metric. It yields a true acoustic standard ruler of exactly 42.75 Mpc, mechanically resolving the Hubble Tension.

Exact Capacity Ledger ($T^{(0)}_{\mu\nu} = T^{(\mathrm{rem})}_{\mu\nu} + \Delta T^{(\tau)}_{\mu\nu}$): The precise mechanical accounting of the State-I tensor budget. It separates the unperturbed structural reference tensor ($T^{(0)}_{\mu\nu}$) into the remaining available transfer capacity ($T^{(\mathrm{rem})}_{\mu\nu}$) and the converted structural capacity ($\Delta T^{(\tau)}_{\mu\nu}$) that sources the effective gravitational strain field.

Face–Centered Cubic (FCC) Lattice: The specific crystallographic packing geometry of the

State I Active Vacuum. It is the only stable geometric configuration that provides the precise ratio of solid structure to void space required to support transverse electromagnetic waves.

FCC Node Radius (r_{D}): The fundamental physical radius of an active Soft Floor node ($\approx 7.45 \times 10^{-27}$ m). It is the specific dimensional threshold where the microscopic continuity of the Substrate transitions into the macroscopic granularity of the Active Vacuum.

Global Phase Avalanche: The aggregate thermodynamic process by which the active Face–Centered Cubic (FCC) vacuum is exponentially consumed and converted into the frozen Simple Cubic (SC) Substrate by the global network of Black Holes, functioning as the fundamental timekeeper of the macroscopic universe.

Global Rupture Trigger (M_{trg}): The absolute mass threshold representing exactly 5.16% of the total Cosmic Reservoir (M_{Res}). It is the critical aggregate mass at which the network of frozen State II defects achieves site percolation, physically shattering the active vacuum and initiating Catastrophic Decompression.

Goalpost Topology: The structural framework of quantum entanglement. Separated particles on the Soft Floor remain instantaneously connected via perpendicular Tension Columns anchored to a shared, rigid Residual Phase-Tether on the Hard Floor.

Gravitational Saturation Radius (R_{sat}): The exact geometric boundary where local mass density reaches the convergence limit (ρ_{QG}), consuming 100% of the available Soft Floor tension ($\alpha_{\mathrm{G}} = 1$) and forcing an FCC to SC phase transition (a Black Hole).

Graviton (Strain Shadow): Not an independent exchange particle, but the highly localized longitudinal strain field (a physical cursor) dragged across the perfectly rigid Hard Floor by a primary transverse wave propagating on the Soft Floor above.

Geometric Capacity (S_{geo}): The absolute maximum structural slots available on the macroscopic Event Horizon to contain physical baryonic defect states. Because the boundary is one node thick (r_{D}), this capacity scales strictly quadratically with the surface area (R^2).

Hard Floor (State 0 / Latent Substrate): The absolute, invariant background frame of reality. It is a perfectly rigid, time-frozen Simple Cubic (SC) crystal operating at the fundamental pixel limit ($\ell_{\mathrm{S}} \approx 10^{-35}$ m), possessing zero interstitial voids and zero entropy.

Hydrodynamic Impedance: The strict mechanical origin of inertial mass. It is the physical resistance generated when a localized topological knot (a particle) is forced to displace the fluid-like Interstitial Condensate while translating across the lattice.

Incrementally Incompressible Coherent Branch: The reduced dynamical mode of the active vacuum in which the interstitial condensate is strictly entrained with the FCC scaffold ($\mathbf{v}_{\mathrm{rel}} = \mathbf{0}$) and volumetric fluctuations are constrained ($\nabla \cdot \mathbf{u} = 0$), leaving only two finite-frequency transverse translational polarizations in the acoustic spectrum.

Interstitial Condensate (β_{IC}): The fluid-like capacity occupying the $\approx 26\%$ interstitial void space of the FCC active vacuum. It provides the hydrodynamic resistance that generates microscopic inertial mass and the macroscopic inductive reactance observationally attributed to Dark Matter.

ISCO Map ($r_{\mathrm{ISCO}}(a_*)$): The Innermost Stable Circular Orbit mapped as a massive-particle observational surface in TFT. It is mechanically derived from the marginal stability limit of the rotating Soft Floor Hamiltonian rather than imported from Kerr geometry.

Isotropic Volumetric Relaxation: The mechanical phenomenon responsible for the $(1+z)^{-4}$ Tolman surface brightness dimming. As a photon wave packet performs work against vacuum's visco-elastic damping, it must symmetrically relax across all four degrees of freedom (longitudinal, kinematic, and two transverse) to maintain its topological integrity.

Kepler Conjecture Limit (β_{geo}): The absolute mathematical maximum packing fraction of perfect spheres (≈ 0.74048). In TFT, this geometric limit dictates the maximum structural solid-node energy capacity of the active vacuum, observationally identified as Dark Energy.

Kinematic Budget (c_{E}^2): The invariant energy cost of the vacuum structure. It represents the absolute maximum elastic shear speed limit of the contiguous lattice, operating as the fundamental baseline for all wave propagation and energy conversion.

Kinematic Occupancy (S_{kin}): The actual thermodynamic reality of a Black Hole: the discrete number of phase-segregated topological defects physically occupying the boundary layer. It scales strictly linearly with the radius (R^1), mathematically guaranteeing that growing Black Holes become structurally less crowded.

Kinematic State Equation ($\Gamma_{\mathrm{D}}^2 = \frac{4\pi G}{3}\rho_{\mathrm{c}}$): The TFT mechanical replacement for the Friedmann equation. It derives the relationship between the cosmic critical density and the expansion rate strictly from the solid-state geometry of the saturated strain limit, without invoking a stretching geometric metric."

Lattice Annealing Time (τ_{nuc}): The mechanical reinterpretation of the 380,000-year recombination epoch (In TFT, 386,000 years. See Appendix AN). It is not a kinematic age, but the strict thermal relaxation constant of the newly ruptured FCC vacuum cooling to the 3000 K stability limit via standard 3D volumetric heat diffusion.

Lense–Thirring Correspondence Normalization: The weak-field matching condition that fixes the absolute amplitude of the torsional Soft-Floor exterior field. It ensures that the exterior angular-drag field generated by the rotating FCC/SC boundary exactly reproduces the standard $2G\mathcal{J}_{\mathrm{BH}}/c_{\mathrm{E}}^2 r^3$ frame-dragging limit at large distances.

Live Phase Boundary: The interpretation of the black-hole event horizon as an active, dynamic FCC/SC transition surface. It carries the physical degrees of freedom for phase-front growth, tangential mass redistribution, torsional spin loading, and stress-shedding ringdown.

Mode-Resolved Impedance Density ($\rho_{\mathrm{IC}}^{(\mathrm{imp})}$): The equivalent hydrodynamic added-inertia density associated with a localized relative-condensate-flow coordinate. It replaces the historical empirical assumption of a universal intrinsic condensate density by formally linking the inertial coefficient to a specific geometric defect boundary-value problem.

Node Interface Inertia (μ_{D}): The 2D surface skin where contiguous FCC lattice nodes physically touch. It is the geometric lever that governs the propagation of untethered transverse shear waves (photons) without permanently displacing the node's core.

No-Hair Quadrupole Closure (Q_{TFT}): The dissipative boundary-selection principle requiring that a relaxed, rotating FCC/SC phase boundary must erase arbitrary surface memory. The boundary sheds stress until its external mass quadrupole matches the required Kerr-correspondence limit ($Q_{\mathrm{TFT}} = -a_*^2 M R_{\mathrm{QG}}^2$).

Octahedral Void Limit (β_{oct}): The strict geometric boundary ($\approx 5.26\%$) determining the maximum baryonic mass capacity of the universe. It dictates that macroscopic, isotropic mass can only securely condense within the perfectly spherical octahedral voids of the FCC lattice before triggering structural failure.

Phonon Echo (The CMB): The mechanical reinterpretation of the Cosmic Microwave Background. It is not the primordial flash of the Big Bang, but the isotropic, longitudinal thermodynamic waste heat generated by the continuous visco-elastic decay of transverse optical waves (photons) into the lattice.

Photonic Extrusion: The deterministic geometric process in which a sudden volumetric contraction of an atomic Bipolar Strain Field (an orbital drop) forces the hyper-rigid lattice to squeeze out a discrete, braided package of neutralized structural tension (a photon).

Primitive-Cell Kinetic Bookkeeping: The rigorous accounting rule for the FCC Soft Floor microphysics. The six undirected nearest-neighbor bonds contribute generalized stiffness to the primitive-cell potential, but the generalized scaffold inertia associated with the retained node coordinates is assigned only once through the primitive-cell mass matrix ($\mathbf{M}_{\mathrm{cell}}^{(0)}$).

Quantum Damping Rate (Γ): The localized viscoelastic relaxation rate associated with nonconservative energy transfer from a coherently evolving quantum mode into unresolved FCC–Condensate degrees of freedom at a measurement or localization boundary. In TFT, this rate governs the progressive loss of coherent modal support that is proposed to drive Wave Arrest and the transition to a localized measurement outcome.

Residual Phase-Tether: A continuous line of microscopic longitudinal strain connecting entangled particles directly along the fully saturated, rigid Substrate, permitting instantaneous phase-locking ($c_{\mathrm{S}} \to \infty$) without violating the active vacuum speed limit.

Restorative Gravity: The mechanical response of the highly elastic vacuum lattice actively attempting to minimize topological defects (mass) and return to the flat equilibrium of the underlying Substrate, manifesting as a radial tension gradient.

Saturated Bridge Formation: The TFT mechanical definition of a binary black hole merger. It occurs when the heavily strained Soft Floor between two inspiraling phase boundaries reaches local saturation ($\alpha_{\rm G} \geq 1$) and locks into the SC phase, merging the two transition surfaces into a single continuous boundary.

Shadow Impact Scale (B_γ): The observable optical edge of a rotating TFT black hole. It is defined by the critical impact parameter of massless rays asymptotically approaching the circular photon orbit within the dragged, quadrupole-corrected Soft Floor.

Spin-Deformed Saturation Boundary ($r_{\rm sat}$): The physical, non-spherical shape of the rotating FCC/SC phase transition. To leading order, torsional loading forces the boundary into an oblate geometry, expanding the equator and contracting the poles relative to the static saturation radius ($R_{\rm QG}$).

Stress Shedding: The physical mechanism of gravitational wave emission during black hole merger. It is the process by which a newly formed, highly distorted common FCC/SC phase boundary rapidly exports excess shear, compression, and torsional strain into the surrounding Soft Floor to achieve a relaxed state.

Simple Cubic (SC) Lattice: The zero-void, fully packed crystallographic geometry of the Latent Substrate and Black Hole cores. Because its packing factor is 1.0, it is hyper-rigid and cannot support internal mechanical vibration or the flow of time.

Soft Floor Ignition Mass ($M_{\rm D,G}$): The absolute minimum localized macroscopic mass (≈ 10.625 kg) required to completely fracture a single fundamental Soft Floor cell ($r_{\rm D}$) and sustain a macroscopic phase boundary (a micro-black hole).

Spacetime Gravitational Floor (SGF): The overarching, dual-phase visco-elastic continuum that mechanically replaces the continuous, empty mathematical manifold of General Relativity.

State II Phase (Frozen Defect): A localized, hyper-dense macroscopic region of the lattice that has undergone a geometric phase collapse from the active FCC configuration (State I) into the rigid, void-less SC configuration (State 0), observationally known as a Black Hole.

Strain-Induced Vacuum Refractive Index (n_τ): The dimensionless optical index of the active vacuum produced by local gravitational strain. It is defined as the ratio between the invariant lattice kinematic budget $c_{\rm E}$ and the local propagation speed $c_{\rm P}$:

$$n_\tau = \frac{c_{\rm E}}{c_{\rm P}} = \frac{1}{(1-\alpha_{\rm G})^2}. \tag{26.8}$$

In a general strain field it is written as $n_\tau(\mathbf{x})$. For a static, spherically symmetric gravitational source it reduces to $n_\tau(r)$. In the weak-field limit, $n_\tau(r) \approx 1 + 2\alpha_{\rm G}$, which provides the TFT optical mechanism for Shapiro delay and gravitational lensing.

Structural Gravitational Coupling ($\alpha_{\rm G}$): A dimensionless ratio representing the mechanical

strain of the Soft Floor, determining exactly how strongly a local mass couples to the active lattice ($\alpha_{\mathrm{G}} = \frac{GM}{rc_{\mathrm{E}}^2}$).

Structural Mass Moment (J_i): Defined as $J_i = \rho_i r_i^4$. It represents the raw, topology-weighted density-radius moment of a specific phase state i.

Structural Reservoir (R_{Res}): The absolute macroscopic limit of the contiguous FCC lattice ($\approx 10^{35}$ m), vastly larger than the observable universe. It represents the total theoretical volume of vacuum required to be consumed to form a cosmic-scale saturated core.

Spanning Cluster: The contiguous, highly tortuous fractal web of connected State II defect cores (Black Holes) that forms at the global percolation threshold (5.16%). Its formation physically spans the deflated cosmic reservoir, shattering the active vacuum and triggering Catastrophic Decompression.

Tension Column: The physical longitudinal topological connection extending from a dynamic, pulsating surface node on the active Soft Floor down to its static, permanent address on the Hard Floor Substrate.

Thermodynamic Impedance Signature: The visco-elastic reinterpretation of CMB anisotropies (± 30 μK). They are thermal deficits (shadows) cast upon the local phonon noise floor by ancient density rings, because optical waves must pay an elevated damping penalty to traverse those fossilized high-strain structures.

Topology-Normalized Scale-Invariant Mass Moment ($\hat{J}$): Defined as $\hat{J} = J_i/\mathcal{F}_i$. It is the absolute, conserved cross-topology invariant of the TFT phase architecture, from which macroscopic observables like Planck's constant and the gravitational constant are universally derived.

Topological Percolation Limit (β_{rupture}): The mathematical threshold (≈ 0.0516) at which isolated topological defects mechanically connect across the interwoven sub-lattice to form a contiguous, macroscopic fault line. In TFT, it dictates the structural expiration timer of the active vacuum.

Topological Phase Defect: A self-sustaining, twisted, or knotted phase boundary within the contiguous active vacuum resulting from the Big Rupture. These permanent structural impurities are the mechanical reality of fundamental baryonic matter.

Topological Winding Number: The mechanical origin of fractional quantum spin. It dictates that a tethered Fermion phase-knot must physically rotate 720° (4π radians) to fully untangle its surrounding lattice bonds, manifesting macroscopically as spin–1/2.

Topological Invariant ($16\pi^3$): The absolute dimensionless constant (≈ 496.06) proving the indestructible nature of information. It dictates that the product of a physical system's true coherent information (N_{M}) and its maximal boundary capacity (N_{QG}) is strictly conserved across all phase states, rigorously preserving Quantum Unitarity.

Torsional Boundary Motion: The mechanical carrier of axial angular momentum in a rotating TFT black hole. Because the SC core is internally phase-locked and cannot undergo fluid rotation, black hole spin is stored exclusively as torsional shear across the live phase boundary and the adjacent Soft Floor.

Transverse-Traceless Source Normalization ($\kappa_{\mathrm{TT}} = 8\pi$): The absolute scalar conversion factor fixing the relationship between the localized mechanical momentum-flux tensor and the collective gravitational-wave tensor. It is derived entirely from static spherical tension-flux conservation and the two-endpoint temporal response, without any prior calibration against binary merger events.

True Information Record (N_{M}): The actual dimensionless topological strain footprint that a coherent, localized mass imposes upon the underlying static Simple Cubic (SC) Substrate. Unlike physical entropy, it scales inversely to macroscopic mass.

Universal Substrate Mass Potential (m_{S}): The latent energy capacity of a single fundamental SC Substrate node ($\approx 2.176 \times 10^{-8}$ kg). It functions as the absolute base unit for TFT information scaling, mechanically identical to the standard Planck Mass but representing structural capacity rather than inertial resistance.

Viscous Cosmic Horizon (R_{U}): The absolute causal and optical boundary of the observable universe ($R_{\mathrm{U}} = c_{\mathrm{E}}/\Gamma_{\mathrm{D}}$). It is the distance at which the accumulated visco-elastic damping of the lattice entirely dissipates the kinetic energy of an optical wave, acting as a mechanical limit rather than an expanding geometric horizon.

Visco-Elastic Damping Equation: The mechanical replacement for metric expansion. It proves that observed cosmic redshift $(1 + z)$ is a logarithmic compounding of boundary friction ($e^{\Gamma_{\mathrm{D}} x / c_{\mathrm{E}}}$), where the $+z^2/2$ Taylor expansion perfectly mirrors the mathematical illusion of Dark Energy acceleration.

Viscous Non-Linear Wave Equation (VNLW): The deterministic, mechanical formulation of the Schrödinger equation governing lattice condensate dynamics. It explicitly includes a visco-elastic friction term ($\hbar\Gamma$) to model localized wave arrest.

Viscoelastic Vacuum Relaxation Rate (Γ_{D}); FCC–Condensate Relaxation Rate: The macroscopic fractional coherent-energy relaxation rate associated with the weak out-of-phase viscoelastic response of the FCC–Condensate vacuum to a propagating transverse photon mode. The corresponding stress–strain phase lag provides the nonconservative work channel through which energy is transferred from the coherent photon carrier into non-coherent FCC–Condensate reservoir degrees of freedom. In the weak-loss regime, $\Gamma_{\mathrm{D}} \simeq \omega \tan \Delta\varphi$. When coherent modal action E/ω is preserved, the same rate governs coherent frequency relaxation and therefore the accumulated propagation redshift. Its present numerical magnitude is empirically calibrated from the observed low-redshift Hubble slope; a first-principles microscopic determination remains open.

Appendix A

The Mechanical Definition of the Substrate Unit System

A.1 Introduction: Empirical Calibration vs. Parameter-Free Derivation

Before defining the structural limits of the Latent Substrate (the Hard Floor), we must explicitly establish the methodological boundaries of Tension Field Theory (TFT). TFT does not derive the fundamental constants of nature (h, G, and c_{E}) from a parameter-free void.

Instead, TFT mechanically reinterprets the known empirical Planck-scale combinations as the absolute mechanical yield limits of a discrete, visco-elastic continuum. By mapping the standard quantum and gravitational constants to the constitutive properties of a solid-state lattice, we establish the Substrate Unit System.

Consequently, the subsequent derivations in this framework do not claim to generate h and G from nothing. Rather, they demonstrate how the scale-invariant geometric architecture of the Soft Floor physically projects these absolute substrate baseline limits into the macroscopic observables.

A.2 The Gravitational Saturation Postulate

We postulate that the vacuum substrate is a discrete material structure with a finite yield strength. This limit is defined by the Gravitational Saturation Coupling ($\alpha_{\mathrm{G}} = 1$), where the deformation energy of a quantum node equals the structural binding energy of the lattice.

Using the TFT gravitational structural coupling (strain) definition established in Section 10.3:

$$\alpha_{\mathrm{G}} = \frac{GM_{\mathrm{eff}}}{rc_{\mathrm{E}}^2} \tag{A.1}$$

(Where c_{E} is the invariant stiffness potential—the structural constant relating tension to energy).

A.3 Definition of the Substrate Lattice Spacing (ℓ_{S})

We define the fundamental unit of length as the discrete node spacing where a minimal quantum energy packet induces maximal lattice strain ($\alpha_{\mathrm{G}} = 1$).

Substituting the reduced quantum mass equivalence $M_{\mathrm{Q}} = \frac{\hbar}{c_{\mathrm{E}} r}$ into the coupling equation:

$$1 = \left(\frac{G}{r c_{\mathrm{E}}^2}\right)\left(\frac{\hbar}{c_{\mathrm{E}} r}\right) = \frac{G\hbar}{c_{\mathrm{E}}^3 r^2} \tag{A.2}$$

Solving for r and replacing r with ℓ_{S} yields:

$$\ell_{\mathrm{S}} = \sqrt{\frac{\hbar G}{c_{\mathrm{E}}^3}} \tag{A.3}$$

- **Physical definition:** ℓ_{S} is the fundamental node spacing of the Simple Cubic (SC) substrate grid.

A.4 Definition of the Substrate Force (F_{S})

We define the absolute tension of the lattice by expressing force as the energy gradient (E/r) at the saturation limit.

The energy of a quantum node at the saturation scale ℓ_{S} is:

$$E_{\mathrm{sat}} = \frac{\hbar c_{\mathrm{E}}}{\ell_{\mathrm{S}}} \tag{A.4}$$

The force is the gradient of this energy across ℓ_{S}:

$$F_{\mathrm{S}} = \frac{E_{\mathrm{sat}}}{\ell_{\mathrm{S}}} = \frac{\hbar c_{\mathrm{E}}}{\ell_{\mathrm{S}}^2} \tag{A.5}$$

Substitute $\ell_{\mathrm{S}}^2 = \frac{\hbar G}{c_{\mathrm{E}}^3}$:

$$F_{\mathrm{S}} = \frac{c_{\mathrm{E}}^4}{G} \tag{A.6}$$

- **Physical definition:** F_{S} is the ultimate yield tension of the substrate (the maximum force the vacuum can support before structural failure).

A.5 Definition of the Latent Constants ($m_{\mathrm{S}}, \rho_{\mathrm{S}}, t_{\mathrm{S}}$)

Because the Substrate is a spatially contiguous, topologically locked phase, it possesses neither intrinsic inertial density ($\mu \to 0$) nor flowing time. We therefore define its fundamental units strictly as latent structural potentials.

A.5.1 Substrate Mass Potential (m_{S})

Just as μ_{D} is the structural constant of the Soft Floor medium, m_{S} is the structural constant of a single Substrate node. It represents the latent energy capacity of a single cell.

$$m_{\mathrm{S}} = \frac{E_{\mathrm{sat}}}{c_{\mathrm{E}}^2} = \frac{\hbar}{c_{\mathrm{E}} \ell_{\mathrm{S}}} \tag{A.7}$$

Substituting ℓ_{S}:

$$m_{\mathrm{S}} = \sqrt{\frac{\hbar c_{\mathrm{E}}}{G}} \tag{A.8}$$

- **Physical definition:** m_{S} is a latent mass potential (structural capacity), not an inertial mass; the raw substrate has $\mu_{\mathrm{S}} \to 0$.

A.5.2 Substrate Density (ρ_S)

The volumetric packing density of the discrete SC Substrate:

$$\rho_S = \frac{m_S}{\ell_S^3} \tag{A.9}$$

Substituting m_S and ℓ_S:

$$\rho_S = \frac{c_E^5}{\hbar G^2} \tag{A.10}$$

- **Physical definition:** This is the structural packing density of the lattice ($\approx 5.1549 \times 10^{96}$ kg/m^3), measuring latent potential concentration rather than inertial resistance.

A.5.3 Substrate Time Interval (t_S)

The dimensional scaling factor required to define action ($\hbar$) within the Substrate geometry:

$$t_S = \frac{\ell_S}{c_E} = \sqrt{\frac{\hbar G}{c_E^5}} \tag{A.11}$$

- **Physical definition:** Stiffness-time equivalence. In the zero inertia ($\mu_S \to 0$) substrate frame, transit time is zero; t_S represents the absolute observer's quantization limit.

A.5.4 Substrate Phase Transition Energy (E_S) & Temperature (T_S)

The dimensional scaling factor defining the maximum kinetic energy a lattice node can sustain before structural failure. In Tension Field Theory, this energy limit is defined strictly from classical mechanics, representing the maximum structural tension (F_S) acting over the fundamental dimension of a single node (ℓ_S).

$$E_S = F_S \cdot \ell_S = \left(\frac{c_E^4}{G}\right)\sqrt{\frac{\hbar G}{c_E^3}} = \sqrt{\frac{\hbar c_E^5}{G}} \tag{A.12}$$

- **Value:** $\approx 1.9561 \times 10^9$ J

Because temperature is strictly a measure of mechanical kinetic energy, the Boltzmann constant (k_B) is merely an anthropogenic conversion factor. To convert this absolute mechanical yield energy into standard thermodynamic temperature, we apply the Boltzmann conversion:

$$T_S = \frac{E_S}{k_B} = \sqrt{\frac{\hbar c_E^5}{G k_B^2}} \tag{A.13}$$

- **Physical Definition:** The thermal equivalent of absolute structural tension. During Catastrophic Decompression, this represents the maximum kinetic phonon vibration (heat) released into the nascent Face-Centered Cubic lattice.
- **Value:** $\approx 1.4168 \times 10^{32}$ K

A.6 Unification Table: Substrate Units vs. Planck Units

The following table shows that the mechanical limits defined by TFT saturation ($\alpha_G = 1$) perfectly reproduce the standard Planck units.

Table A.1: Mechanical Unification of Substrate Limits and Planck Units

Quantity	**Symbol**	**TFT Mechanical Reinterpretation**	**Value (SI)**	**Planck Unit Ident**
Substrate Lattice Spacing	ℓ_S	$\sqrt{\frac{\hbar G}{c_E^3}}$	1.6163×10^{-35} m	ℓ_P
Substrate Force	F_S	$\frac{c_E^4}{G}$	1.2103×10^{44} N	F_P
Substrate Mass	m_S	$\sqrt{\frac{\hbar c_E}{G}}$	2.1764×10^{-8} kg	m_P
Substrate Time	t_S	$\sqrt{\frac{\hbar G}{c_E^5}}$	5.3912×10^{-44} s	t_P
Substrate Density	ρ_S	$\frac{c_E^5}{\hbar G^2}$	5.1549×10^{96} kg/m^3	ρ_P
Substrate Transition Temp.	T_S	$\sqrt{\frac{\hbar c_E^5}{G k_B^2}}$	1.4168×10^{32} K	T_P

A.7 Conclusion

The identity between the Substrate units and Planck units implies that the Planck scale is not merely a mathematical boundary; it is the physical specification of the Tension substrate:

- ℓ_S is the Lattice Spacing (Fundamental Grain).
- F_S is the Ultimate Bond Strength.
- m_S and ρ_S are the latent potentials of the grid structure.

Standard physics treats these as limiting numbers; TFT identifies them as material properties of the vacuum floor.

Appendix B

Conservation of Action and the Master Geometric Law

Subject: Conditional derivation of the scaling law

$$\rho(r) \propto r^{-4} \tag{B.1}$$

and the associated geometric form factor within the TFT framework.

B.1 Scale Invariance and the Conservation of Action

In Tension Field Theory, the characteristic densities and length scales of the vacuum are not treated as unrelated phenomenological parameters. Rather, they are treated as geometrically related manifestations of a contiguous elastic substrate.

Under this assumption, the transition from the Latent Substrate, State 0, to the Active Vacuum, State I, must preserve the fundamental mechanical action of the field under the appropriate topological projection.

We therefore take the Action of Existence, denoted h, to be conserved across topological phase reconfiguration. The purpose of this appendix is to derive the corresponding scaling law for density under two assumptions:

$$h = \text{invariant} \tag{B.2}$$

and

$$c_{\mathrm{E}} = \text{invariant}. \tag{B.3}$$

Topology-dependent geometric compression is encoded by the form factor

$$\mathcal{F}_i. \tag{B.4}$$

This appendix does not independently derive the numerical value of h. Rather, it derives the density-scaling constraint required if the action scale is preserved across the stratified TFT architecture.

B.2 Kinematic Definition of Action

For a localized mechanical excitation of the lattice, action is defined in the standard kinematic form as

$$\text{Action} = E \cdot t, \tag{B.5}$$

where E is the energy associated with one localized vibrational or rotational cycle, and t is the corresponding cycle time.

B.3 Geometric Scaling of Energy and Time

To determine how action scales with the geometric size of a localized node, we express both E and t in terms of the characteristic radius r.

The energy of a localized node is written as

$$E = mc_{\mathrm{E}}^2, \tag{B.6}$$

with

$$m = \rho V. \tag{B.7}$$

For a three-dimensional localized state, the volume scales as

$$V \propto r^3. \tag{B.8}$$

Therefore,

$$E \propto \rho r^3 c_{\mathrm{E}}^2. \tag{B.9}$$

The characteristic time for one cycle is taken to be the traversal time across the node radius at speed c_{E}:

$$t = \frac{r}{c_{\mathrm{E}}}. \tag{B.10}$$

Substituting these expressions into the definition of action gives

$$\text{Action} \equiv h \propto \left(\rho r^3 c_{\mathrm{E}}^2\right)\left(\frac{r}{c_{\mathrm{E}}}\right). \tag{B.11}$$

Thus,

$$h \propto \rho r^4 c_{\mathrm{E}}. \tag{B.12}$$

If h and c_{E} are both invariant, then the density-radius structure must preserve a common mass-moment scale after topology-dependent projection is accounted for.

This motivates the raw structural mass moment:

$$J_i \equiv \rho_i r_i^4. \tag{B.13}$$

The quantity J_i captures the density-radius content of a phase state before topology-normalization is applied.

B.4 Geometric Form Factor

The form factor $\mathcal{F}_i$ represents the geometric compression associated with confining a propagating linear mode into a localized bound state.

For the spherical Soft Floor node, the propagating mode is modeled as sweeping a cylindrical volume:

$$V_{\mathrm{cyl}} = \pi r^2(2r) = 2\pi r^3. \tag{B.14}$$

The localized node occupies a spherical volume:

$$V_{\text{node}} = \frac{4}{3}\pi r^3. \tag{B.15}$$

The resulting compression ratio is

$$\mathcal{F}_{\text{D}} = \frac{V_{\text{cyl}}}{V_{\text{node}}} = \frac{2\pi r^3}{\frac{4}{3}\pi r^3}. \tag{B.16}$$

Therefore,

$$\mathcal{F}_{\text{D}} = 1.5. \tag{B.17}$$

Accordingly, TFT assigns

$$\mathcal{F}_{\text{D}} = 1.5 \tag{B.18}$$

to spherical Soft Floor nodes.

For the rectilinear Substrate state, no spherical localization factor is applied:

$$\mathcal{F}_{\text{S}} = 1.0. \tag{B.19}$$

For the nucleon core, TFT treats the relevant coupling geometry as effectively vortical or cylindrical rather than spherical-node compression. Therefore,

$$\mathcal{F}_{\text{N}} = 1.0. \tag{B.20}$$

These assignments are topology-specific projection factors within TFT. They are not universal geometric constants for arbitrary matter distributions.

B.5 Topology-Normalized Conservation Law

The raw structural mass moment is

$$J_i \equiv \rho_i r_i^4. \tag{B.21}$$

However, J_i alone is not required to be numerically identical across all phase topologies. Different topological configurations carry different projection factors.

The conserved quantity is therefore the topology-normalized combination:

$$\frac{J_i}{\mathcal{F}_i}. \tag{B.22}$$

For the rectilinear Substrate state,

$$\mathcal{F}_{\text{S}} = 1.0, \tag{B.23}$$

so the substrate-normalized invariant becomes

$$\frac{J_{\text{S}}}{\mathcal{F}_{\text{S}}} = J_{\text{S}} = \rho_{\text{S}} \ell_{\text{S}}^4. \tag{B.24}$$

Therefore, topological phase reconfiguration preserves

$$\frac{J_i}{\mathcal{F}_i} = \rho_{\text{S}} \ell_{\text{S}}^4. \tag{B.25}$$

Using

$$J_i = \rho_i r_i^4, \tag{B.26}$$

the conserved projection law becomes

$$\rho_{\text{S}} \ell_{\text{S}}^4 = \frac{\rho_i r_i^4}{\mathcal{F}_i}. \tag{B.27}$$

This is the topology-normalized conservation law underlying the Master Geometric Law.

B.6 Master Geometric Scaling Relation

Starting from

$$\rho_{\mathrm{S}}\ell_{\mathrm{S}}^4 = \frac{\rho_i r_i^4}{\mathcal{F}_i}, \tag{B.28}$$

we solve for the localized density:

$$\rho_i r_i^4 = \mathcal{F}_i \rho_{\mathrm{S}} \ell_{\mathrm{S}}^4. \tag{B.29}$$

Therefore,

$$\rho_i(r_i) = \mathcal{F}_i \rho_{\mathrm{S}} \left(\frac{\ell_{\mathrm{S}}}{r_i}\right)^4. \tag{B.30}$$

This expression is the Master Geometric Law of TFT.

It states that, for contiguous topological phase states, density decreases as

$$r^{-4}, \tag{B.31}$$

modified by the relevant topology-dependent projection factor

$$\mathcal{F}_i. \tag{B.32}$$

Within the TFT construction, this law determines the projected density of a contiguous localized phase state as a function of scale and topology.

B.7 Boundary Equation

The Master Geometric Law may be inverted to determine the characteristic boundary scale associated with a given internal density.

Starting from

$$\rho_i(r_i) = \mathcal{F}_i \rho_{\mathrm{S}} \left(\frac{\ell_{\mathrm{S}}}{r_i}\right)^4, \tag{B.33}$$

we obtain

$$r_i = \ell_{\mathrm{S}} \left(\frac{\mathcal{F}_i \rho_{\mathrm{S}}}{\rho_i}\right)^{1/4}. \tag{B.34}$$

This relation is used in subsequent appendices as the boundary equation for localized contiguous phase states.

B.8 Domain of Applicability

The scaling law derived here applies only to contiguous topological phase states of the TFT vacuum architecture, such as the Substrate cell, the spherical Soft Floor node, and the continuous nucleon core.

The densities ρ_i appearing in the Master Geometric Law are phase-local structural densities associated with the characteristic radius r_i of the corresponding contiguous state. They are not primitive-cell or macroscopic homogenized densities. In particular, evaluation of the law at the Soft-Floor node scale determines the intrinsic nodal-phase density ρ_{D}; the volume-averaged FCC scaffold inertia density is obtained separately by primitive-cell homogenization in Appendix D.

It is not assumed to extend directly to composite macroscopic bodies. The quoted bulk densities of planets, stars, ordinary condensed matter, or composite baryonic systems are coarse-grained averages of many internal structures embedded within the active vacuum.

The Master Geometric Law should therefore be interpreted as a microscopic phase-projection rule, not as a general-purpose density law for arbitrary matter distributions.

B.9 Conclusion

Within the TFT framework, the relation

$$\rho_i(r_i) = \mathcal{F}_i \rho_{\mathrm{S}} \left(\frac{\ell_{\mathrm{S}}}{r_i} \right)^4 \tag{B.35}$$

provides the scale-projection rule required to preserve the topology-normalized invariant

$$\frac{J_i}{\mathcal{F}_i} = \rho_{\mathrm{S}} \ell_{\mathrm{S}}^4. \tag{B.36}$$

The raw structural mass moment is

$$J_i = \rho_i r_i^4. \tag{B.37}$$

Therefore, J_i is topology-weighted rather than strictly identical across all phase states.

As the characteristic radius increases across topological phases, the density decreases as

$$r^{-4}, \tag{B.38}$$

modified by the relevant geometric projection factor

$$\mathcal{F}_i. \tag{B.39}$$

In this sense, the Master Geometric Law functions as the conditional scaling constraint that preserves action across the stratified architecture of the field.

Appendix C

Mechanical Derivation of the FCC Lattice Constants

Subject: The Mechanical Constitution of the Soft Floor and the Dual Nature of the Constants.

C.1 The Soft Floor Node Density (ρ_{D}) — The Potential Reservoir

With the Master Geometric Law ($\rho(r) = \mathcal{F}_i \cdot \rho_{\mathrm{S}} \left(\frac{\ell_{\mathrm{S}}}{r}\right)^4$) and the Spherical Form Factor ($\mathcal{F}_{\mathrm{D}} = 1.5$) strictly defined in Appendix B, we can directly derive the volumetric stiffness density of the Soft Floor node by evaluating the law at the Soft Floor Coherence Scale (r_{D}).

- **Definition:** ρ_{D} represents the Operational Density of the vacuum node that stores the potential energy for quantum action.
- **Calculation:** Using $r_{\mathrm{D}} \approx 7.4504 \times 10^{-27}$ m:

$$\rho_{\mathrm{D}} = 1.5 \cdot \rho_{\mathrm{S}} \cdot \left(\frac{\ell_{\mathrm{S}}}{r_{\mathrm{D}}}\right)^4 \approx 1.7124 \times 10^{62} \text{ kg/m}^3 \tag{C.1}$$

(Note: This density is the mechanical source of the quantum action h, as mapped in the Fractal Architecture of Appendix G).

C.2 The Soft Floor Structural Mass Moment (J_{D}) — The Master Coupling Gear

As established in Appendix B, the absolute conserved mechanical quantity that governs topological phase transitions is the topology-normalized Scale-Invariant Mass Moment ($\hat{J} \equiv J_i/\mathcal{F}_i$), where $J_i = \rho_i r_i^4$ is the raw structural mass moment. Having derived both the scale (r_{D}) and the operational density (ρ_{D}) of the Soft Floor, we can define its specific raw structural mass moment.

- **Definition:** J_{D} is the irreducible raw structural mass moment of a single Soft Floor spherical node. It is the central mechanical gear that, when topology-normalized by its spherical form factor ($\mathcal{F}_{\mathrm{D}} = 1.5$), projects the Substrate's latent potential into the observable action (h) and gravitational coupling (G) of the active vacuum.
- **Calculation:**

$$J_{\mathrm{D}} = \rho_{\mathrm{D}} \cdot r_{\mathrm{D}}^4 \tag{C.2}$$

$$J_{\mathrm{D}} \approx (1.7124 \times 10^{62}) \cdot (7.4504 \times 10^{-27})^4 \approx 5.2764 \times 10^{-43}\ \mathrm{kg \cdot m} \tag{C.3}$$

(Note: The strict mathematical proof demonstrating how J_{D} and its associated geometric form factor mechanically generate the exact empirical values of h and G is detailed in Appendix G).

C.3 Vacuum Tension (τ_{D}) — The Dual-Faced Stiffness

The vacuum exhibits two distinct moduli depending on the mode of propagation: Shear (Transverse) and Bulk (Longitudinal).

C.3.1 Surface Stiffness (Shear Modulus)

The propagation of light is governed by the surface interface of the node. We define τ_{D} as the fundamental surface tension constant:

$$\tau_{\mathrm{D}} = \frac{c_{\mathrm{E}}^4}{G \cdot r_{\mathrm{D}}} \approx 1.6244 \times 10^{70}\ \mathrm{N/m} \tag{C.4}$$

- **Role:** When the vacuum transmits a transverse wave (Light), τ_{D} acts strictly as the shear modulus. This elastic snap-back of the lattice skin drives the propagation speed c_{E}.

C.3.2 Volume Stiffness (Bulk Modulus)

The background stress that supports the universe against structural failure and mediates static gravity is volumetric. We define the volumetric Gravitational Yield Tension ($\tau_{\mathrm{D,bulk}}$) of the FCC lattice:

$$\tau_{\mathrm{D,bulk}} = \frac{\tau_{\mathrm{D}}}{r_{\mathrm{D}}} = \frac{c_{\mathrm{E}}^4}{G \cdot r_{\mathrm{D}}^2} \approx 2.1803 \times 10^{96}\ \mathrm{N/m^2} \tag{C.5}$$

- **Role:** It is the ultimate structural yield strength of the active vacuum Soft Floor lattice.

C.4 Vacuum Inertia (μ_{D}) and Mass Discretization

Inertia is the resistance to change. We postulate that the vacuum possesses an intrinsic node interface inertia (μ_{D}), defined by the contiguous 2D surface density of the Soft Floor nodes.

$$\mu_{\mathrm{D}} = \frac{c_{\mathrm{E}}^2}{G \cdot r_{\mathrm{D}}} \approx 1.8074 \times 10^{53}\ \mathrm{kg/m^2} \tag{C.6}$$

This single constant governs both Light and Mass depending on the dimension of interaction.

C.4.1 The Surface Interaction (Speed of Light)

Light is a transverse shear wave surfing the 2D interface of the contiguous nodes. It encounters μ_{D} directly as an areal surface load:

$$c_{\mathrm{E}} = \sqrt{\frac{\tau_{\mathrm{D}}}{\mu_{\mathrm{D}}}} \tag{C.7}$$

(Verification: $\sqrt{1.6244 \times 10^{70} / 1.8074 \times 10^{53}} \approx 2.9979 \times 10^8$ m/s).

C.4.2 The Volumetric Projection (Holographic Impedance)

Matter is modeled in TFT as a volumetric displacement of the interstitial phase. A particle vibrating in the lattice displaces the interstitial condensate through an effective 3D volume. Therefore, although transverse waves couple to the 2D surface inertia of the active vacuum (μ_{D}), localized mass defects require an effective 3D impedance density.

Because the active-vacuum inertia μ_{D} is defined as a surface inertia with units ($\mathrm{kg/m^2}$), while inertial mass generation requires a volumetric impedance with units ($\mathrm{kg/m^3}$), TFT introduces a projection scale ι_{V} to define the effective interstitial density:

$$\rho_{\mathrm{IC}} = \mu_{\mathrm{D}} \cdot \iota_{\mathrm{V}}. \tag{C.8}$$

In the present formulation, $\iota_{\mathrm{V}} \equiv 1\ \mathrm{m^{-1}}$ is not derived from microscopic symmetry; it is a macroscopic SI calibration convention used to anchor the 2D-to-3D impedance projection. Consequently, the active-vacuum node radius r_{D} obtained in Appendix H should be interpreted as an empirically calibrated scale, not as a parameter-free derivation.

The physical meaning of this projection is that transverse waves couple to the 2D surface inertia μ_{D}, whereas localized mass defects displace the 3D interstitial phase and therefore couple to the effective density ρ_{IC}. A future dimensionless formulation must replace ι_{V} with a microscopic phase-ratio, thermodynamic projection factor, or explicit field-coupling derivation. Under the present macroscopic SI calibration convention, the effective interstitial density becomes:

$$\rho_{\mathrm{IC}} \approx 1.8074 \times 10^{53}\ \mathrm{kg/m^3}. \tag{C.9}$$

Mechanism: Inertial mass m is the hydrodynamic impedance generated when a localized topological defect displaces this projected interstitial density:

$$m = \rho_{\mathrm{IC}} \cdot V_{\mathrm{eff}} \cdot \sin(\Delta\varphi). \tag{C.10}$$

Conclusion: Light propagates transversely and couples to the 2D surface inertia μ_{D}. Mass displaces the interstitial phase volumetrically and couples to the effective 3D density ρ_{IC}. These are not separate substances, but two dimensional projections of the same active-vacuum impedance structure.

C.4.3 The Quantum Mass (M_{D}) — The Node Gear

While μ_{D} defines the 2D surface load of the vacuum interface, we must define the absolute localized 3D mass (M_{D}) of a single Soft Floor node.

Derivation 1: The Geometric Origin (Volume)
Because the Soft Floor node is a physical structure, its quantum mass is simply the Active Vacuum Density (ρ_{D}) multiplied by its fundamental 3D spherical volume:

$$M_{\mathrm{D}} = \rho_{\mathrm{D}} \cdot \left(\frac{4}{3}\pi r_{\mathrm{D}}^3\right) \approx 2.9665 \times 10^{-16}\ \mathrm{kg} \tag{C.11}$$

Derivation 2: The Kinematic Origin (Quantum of Action)
As established by the fractal geometry in Appendix E, the fundamental unreduced action (h) of

the vacuum is generated by the geometric volumetric lever ($\frac{4}{3}\pi \cdot \rho_{\mathrm{D}} \cdot r_{\mathrm{D}}^4$) operating at the kinematic speed limit (c_{E}):

$$h = \left[\frac{4}{3}\pi \cdot \rho_{\mathrm{D}} \cdot r_{\mathrm{D}}^3\right] \cdot c_{\mathrm{E}} \cdot r_{\mathrm{D}} = M_{\mathrm{D}} \cdot c_{\mathrm{E}} \cdot r_{\mathrm{D}} \tag{C.12}$$

This confirms that the physical spherical mass (M_{D}) is the exact inertial generator of the unreduced wave action (h):

$$M_{\mathrm{D}} = \frac{h}{c_{\mathrm{E}} \cdot r_{\mathrm{D}}} \tag{C.13}$$

Because standard quantum mechanics defines localized particle states using the reduced Planck constant ($\hbar = h/2\pi$), we can immediately translate this kinematic relationship to the localized mass. Substituting $h = 2\pi\hbar$ into the wave equation yields:

$$M_{\mathrm{D}} = \frac{2\pi\hbar}{c_{\mathrm{E}} \cdot r_{\mathrm{D}}} \tag{C.14}$$

Conclusion: The unreduced wave action (h) and the localized particle action ($\hbar$) are kinematic duals that isolate the exact same physical spherical mass. The emergence of the 2π multiplier in the $\hbar$ equation strictly preserves the rotational topology of the localized node, ensuring the physical geometry of the vacuum remains entirely spherical.

C.4.4 The Fundamental Impedance Constant (K_{D})

K_{D} is the linear mass gradient of the vacuum node. It defines the direct mathematical conversion between a particle's spatial vibration amplitude (r_{amp}) and its resulting hydrodynamic mass (m).
Calculation:

$$K_{\mathrm{D}} = \rho_{\mathrm{IC}} \cdot (4\pi r_{\mathrm{D}}^2) \tag{C.15}$$

$$K_{\mathrm{D}} \approx (1.8074 \times 10^{53}) \cdot (6.9754 \times 10^{-52}) \approx 126.07 \text{ kg/m} \tag{C.16}$$

Role: For every 1 m of volumetric expansion (amplitude) a particle forces onto the vacuum condensate, the vacuum exerts 126.07 kg of inertial resistance ($m = K_{\mathrm{D}} \cdot r_{\mathrm{amp}}$).

C.5 Summary of Soft Floor Constants

The "D" constants define the constitution and absolute mechanical boundaries of the observable vacuum.

Table C.1: Summary of the Soft Floor Vacuum Constants

Property	**Symbol**	**Value (SI)**	**TFT Mechanical Definition**
Operational Density	ρ_{D}	$\approx 1.7124 \times 10^{62}$ kg/m^3	Baseline mechanical mass-density of the active FCC node (source of h).
Structural Mass Moment	J_{D}	$\approx 5.2764 \times 10^{-43}$ kg $\cdot$ m	The absolute structural mass moment of the node (mediates h and G).
Shear Tension	τ_{D}	$\approx 1.6244 \times 10^{70}$ N/m	Lattice Surface Tension (Source of light speed).
Gravitational Yield Tension	$\tau_{\mathrm{D,bulk}}$	$\approx 2.1803 \times 10^{96}$ N/m^2	Lattice Gravitational Yield Strength.
Node Interface Inertia	μ_{D}	$\approx 1.8074 \times 10^{53}$ kg/m^2	Emergent Inertial Density for FCC lattice.
Interstitial Condensate	ρ_{IC}	$\approx 1.8074 \times 10^{53}$ kg/m^3	Interstitial Condensate Density (Holographic Impedance).
Quantum Mass	M_{D}	$\approx 2.9665 \times 10^{-16}$ kg	3D localized spherical inertia of a single quantum node.
Fundamental Impedance	K_{D}	≈ 126.07 kg/m	Absolute Hydrodynamic Coupling Constant.

Appendix D

Contact Microphysics and Homogenization of the Active FCC Vacuum Scaffold

D.1 Scope, Status of Results, and Constitutive Limits

This appendix develops the baseline contact mechanics and long-wavelength homogenization of the active FCC Soft Floor. It establishes the gravity-independent FCC scaffold carrier on which the later gravitational, condensate, localized-defect, and photon-transport constitutive sectors act.

The analysis is restricted to small perturbations about a fixed active-phase equilibrium. The retained contact coefficients are tangent coefficients of that state and are not assumed to remain valid through the nonlinear FCC-to-SC phase transition. The interstitial-condensate pressure constraint and localized defect-induced relative-flow response are developed separately in Appendix E.

The gravity-specific endpoint-transfer map, gravitationally referred inertia, and loaded propagation law are developed in Appendix J, using the baseline FCC scaffold stiffness and primitive-cell inertia normalization derived here as the unstrained constitutive reference.

The mechanical sequence developed in this appendix proceeds from FCC contact geometry through objective bond kinematics, the parity-even contact action, primitive-cell assembly, and the long-wavelength acoustic tensor.

The full finite-wave-number Bloch spectrum is not completed here. The FCC stiffness assembly is defined formally, while the explicit dynamical matrix, its eigenvalue branches throughout the first Brillouin zone, and the corresponding global lattice-stability proof remain open microscopic calculations. A selected positive reduced transverse photon branch, including its dispersion-suppressed finite-wave-number closure and observational screening, is developed separately in Appendix AP. That reduced branch does not constitute a derivation of the complete FCC dynamic matrix or its full multi-branch spectrum.

The status of the principal results is summarized below.

The active Soft Floor is treated as a dual mechanical structure. The solid FCC scaffold supplies the baseline microscopic contact rigidity and primitive-cell inertia normalization. In the conservative coherent branch, the interstitial condensate is carried with the scaffold without relative flow and supplies the pressure constraint developed in Appendix E. Entrainment fixes the relative kinematics of the two phases but does not, at the present constitutive order, establish an independently additive condensate contribution to the primitive-cell inertia normalization. The Hard Floor supplies the phase-locked structural address of the active node and is not introduced here as

Result	Status in this appendix
$d_{\mathrm{nn}} = 2r_{\mathrm{D}}$	FCC geometric identity
$V_{\mathrm{p}} = 4\sqrt{2}r_{\mathrm{D}}^3$	primitive-cell geometric identity
baseline transverse chain dispersion	derived from the scaffold surface stiffness–inertia action
objective contact measures	derived from frame-indifferent contact kinematics
parity-even quadratic contact action	leading local nearest-neighbor bond model
primitive-cell kinetic bookkeeping	generalized scaffold inertia assigned once per primitive cell
FCC Bloch stiffness assembly	defined formally from the six undirected bonds
FCC cubic elastic constants	derived in the affine $k \to 0$ limit
$\kappa_{\mathrm{n}} = \kappa_{\mathrm{t}}$	condition for exact long-wavelength isotropy
$A_{\mathrm{ct}}^{(\mathrm{modal})}$	constitutive surface-to-cell normalization
$\rho_{\mathrm{sh}}^{(\mathrm{micro},0)}$ and $K_{\mathrm{sh}}^{(\mathrm{micro},0)}$	microscopic scaffold coefficients derived from primitive-cell normalization
selected dispersion-suppressed transverse photon branch	developed separately in Appendix AP
full finite-k spectrum and global stability	formally posed but not completed

an independent finite-frequency oscillator.

The present appendix therefore establishes the reference FCC scaffold contact action and its long-wavelength continuum limit. The gravitational endpoint-transfer, condensate, localized-defect, and reduced photon-transport sectors act on this baseline while preserving the objective contact kinematics, primitive-cell bookkeeping, and stability requirements developed below.

D.2 Baseline Nearest-Neighbor Transverse FCC Contact Action

Consider a representative nearest-neighbor sequence in the active FCC Soft Floor. The nearest-neighbor separation is

$$d_{\mathrm{nn}} = 2r_{\mathrm{D}}. \tag{D.1}$$

Let $u_n(t)$ denote the transverse displacement of the n-th active FCC node along one selected polarization orthogonal to the bond direction. For the contact between neighboring nodes n and $n+1$, the transverse strain is

$$\varepsilon_{n,n+1}^{\perp} = \frac{u_{n+1} - u_n}{d_{\mathrm{nn}}}. \tag{D.2}$$

The baseline surface shear tension is τ_{D}. The corresponding transverse contact energy per unit participating interface area is

$$\mathcal{U}_{n,n+1}^{\perp} = \frac{\tau_{\mathrm{D}}}{2d_{\mathrm{nn}}^2}\left(u_{n+1} - u_n\right)^2. \tag{D.3}$$

The two-node potential Hessian is

$$\mathbf{H}_U^{(n,n+1)} = \frac{\tau_{\mathrm{D}}}{d_{\mathrm{nn}}^2} \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix}. \tag{D.4}$$

This Hessian is positive semidefinite, with the uniform-translation mode as its null direction. The baseline scaffold surface inertia is μ_{D}, so the directional Lagrangian per unit participating interface area is

$$\mathcal{L}_\perp^{(0)} = \sum_n \left[\frac{1}{2}\mu_{\mathrm{D}} \dot{u}_n^2 - \frac{\tau_{\mathrm{D}}}{2d_{\mathrm{nn}}^2} \left(u_{n+1} - u_n\right)^2 \right]. \tag{D.5}$$

Variation with respect to u_n gives

$$\mu_{\mathrm{D}} \ddot{u}_n = \frac{\tau_{\mathrm{D}}}{d_{\mathrm{nn}}^2} \left(u_{n+1} - 2u_n + u_{n-1}\right). \tag{D.6}$$

For a plane-wave mode,

$$u_n(t) = u_0 \exp\left[i\left(knd_{\mathrm{nn}} - \omega t\right)\right], \tag{D.7}$$

the nearest-neighbor difference is

$$u_{n+1} - 2u_n + u_{n-1} = -4u_n \sin^2\left(\frac{kd_{\mathrm{nn}}}{2}\right). \tag{D.8}$$

The baseline directional dispersion relation is therefore

$$\omega^2(k) = \frac{4\tau_{\mathrm{D}}}{\mu_{\mathrm{D}} d_{\mathrm{nn}}^2} \sin^2\left(\frac{kd_{\mathrm{nn}}}{2}\right). \tag{D.9}$$

Using the baseline surface stiffness–inertia identity

$$c_{\mathrm{E}}^2 = \frac{\tau_{\mathrm{D}}}{\mu_{\mathrm{D}}}, \tag{D.10}$$

the dispersion becomes

$$\omega^2(k) = \frac{4c_{\mathrm{E}}^2}{d_{\mathrm{nn}}^2} \sin^2\left(\frac{kd_{\mathrm{nn}}}{2}\right). \tag{D.11}$$

In the local continuum limit,

$$kd_{\mathrm{nn}} \ll 1, \tag{D.12}$$

so

$$\omega^2 = c_{\mathrm{E}}^2 k^2 + \mathcal{O}\left(k^4 d_{\mathrm{nn}}^2\right). \tag{D.13}$$

Hence the long-wavelength phase velocity is

$$c_T^{(0)} = \lim_{k\to 0} \frac{\omega}{k} = c_{\mathrm{E}}. \tag{D.14}$$

On the positive-frequency monotonic branch,

$$0 \le kd_{\mathrm{nn}} \le \pi, \tag{D.15}$$

the dispersion and group velocity are

$$\omega(k) = \frac{2c_{\mathrm{E}}}{d_{\mathrm{nn}}} \sin\left(\frac{kd_{\mathrm{nn}}}{2}\right), \tag{D.16}$$

and

$$v_g = \frac{\mathrm{d}\omega}{\mathrm{d}k} = c_{\mathrm{E}} \cos\left(\frac{k d_{\mathrm{nn}}}{2}\right), \tag{D.17}$$

so

$$\lim_{k\to 0} v_g = c_{\mathrm{E}}. \tag{D.18}$$

This one-dimensional sequence is a directional reduction used to establish the baseline transverse normalization. In the full FCC assembly, six undirected nearest-neighbor bonds contribute stiffness to the primitive-cell potential, while the generalized scaffold inertial coefficients associated with the retained node coordinates are assigned once through the primitive-cell mass matrix. The coherent condensate constraint is introduced separately in Appendix E; condensate entrainment is not counted here as an independently additive bond or primitive-cell inertia. The directional derivation must therefore not be interpreted as assigning an independent complete nodal mass to every bond.

The nearest-neighbor branch derived here is the baseline normalization branch and is not identified with the completed physical photon eigenbranch. The selected positive dispersion-suppressed transverse photon branch, its higher-gradient closure, and its observational screening are developed in Appendix AP.

D.3 Objective Nearest-Neighbor FCC Contact Kinematics

The directional action above captures one transverse nearest-neighbor sequence. To assemble the active Soft Floor as a three-dimensional FCC lattice, the contact law must be written in an objective form. A contact energy depending only on the relative displacement of two node centers is not sufficient, because a rigid-body rotation produces relative center motion even when the physical contact surfaces undergo no elastic deformation. The bond kinematics must therefore include nodal translations, nodal microrotations, and internal phase differences.

Consider two nearest-neighbor FCC nodes labeled i and j. Their reference center-to-center vector is

$$\mathbf{d}_{ij} = d_{\mathrm{nn}} \hat{\mathbf{n}}_{ij}, \tag{D.19}$$

where

$$d_{\mathrm{nn}} = 2r_{\mathrm{D}}, \qquad |\hat{\mathbf{n}}_{ij}| = 1. \tag{D.20}$$

The normal projector associated with the contact is

$$\mathbf{P}_{\mathrm{n}}^{(ij)} = \hat{\mathbf{n}}_{ij} \hat{\mathbf{n}}_{ij}^{\mathsf{T}}, \tag{D.21}$$

and the transverse projector is

$$\mathbf{P}_{\perp}^{(ij)} = \mathbf{I} - \hat{\mathbf{n}}_{ij} \hat{\mathbf{n}}_{ij}^{\mathsf{T}}. \tag{D.22}$$

Let $\mathbf{u}_i, \mathbf{u}_j$ be the infinitesimal translations of the two node centers. Let $\boldsymbol{\vartheta}_i, \boldsymbol{\vartheta}_j$ be their infinitesimal microrotations. These are mechanical rotations of the local contact frames. They are not identical to the internal scalar phase variable. The internal phases are denoted φ_i, φ_j.

Thus the contact theory uses three types of local variables:

- $\mathbf{u}$ for center translation,
- $\boldsymbol{\vartheta}$ for mechanical microrotation,
- φ for internal topological phase.

They are kept distinct at the present constitutive order.

The reference contact point lies at $+r_{\mathrm{D}}\hat{\mathbf{n}}_{ij}$ relative to the center of node i, and at $-r_{\mathrm{D}}\hat{\mathbf{n}}_{ij}$ relative to the center of node j. The displacement of the contact point carried by node i is

$$\mathbf{u}_i^{\mathrm{c}} = \mathbf{u}_i + r_{\mathrm{D}}\boldsymbol{\vartheta}_i \times \hat{\mathbf{n}}_{ij}. \tag{D.23}$$

The displacement of the corresponding contact point carried by node j is

$$\mathbf{u}_j^{\mathrm{c}} = \mathbf{u}_j - r_{\mathrm{D}}\boldsymbol{\vartheta}_j \times \hat{\mathbf{n}}_{ij}. \tag{D.24}$$

The relative displacement of the two material contact points is therefore $\Delta\mathbf{u}_{ij}^{\mathrm{c}} = \mathbf{u}_j^{\mathrm{c}} - \mathbf{u}_i^{\mathrm{c}}$. Substitution gives

$$\Delta\mathbf{u}_{ij}^{\mathrm{c}} = \mathbf{u}_j - \mathbf{u}_i - r_{\mathrm{D}}(\boldsymbol{\vartheta}_i + \boldsymbol{\vartheta}_j) \times \hat{\mathbf{n}}_{ij}. \tag{D.25}$$

This is the objective contact-point displacement. It is the correct local deformation measure entering the nearest-neighbor contact energy.

The normal contact deformation is

$$\delta_{\mathrm{n}}^{(ij)} = \hat{\mathbf{n}}_{ij} \cdot \Delta\mathbf{u}_{ij}^{\mathrm{c}}. \tag{D.26}$$

The rotational term is transverse to $\hat{\mathbf{n}}_{ij}$, and therefore

$$\delta_{\mathrm{n}}^{(ij)} = \hat{\mathbf{n}}_{ij} \cdot (\mathbf{u}_j - \mathbf{u}_i). \tag{D.27}$$

The objective tangential slip is

$$\boldsymbol{\delta}_{\mathrm{t}}^{(ij)} = \mathbf{P}_{\perp}^{(ij)} \Delta\mathbf{u}_{ij}^{\mathrm{c}}. \tag{D.28}$$

Explicitly,

$$\boldsymbol{\delta}_{\mathrm{t}}^{(ij)} = \mathbf{P}_{\perp}^{(ij)} \left[\mathbf{u}_j - \mathbf{u}_i - r_{\mathrm{D}}(\boldsymbol{\vartheta}_i + \boldsymbol{\vartheta}_j) \times \hat{\mathbf{n}}_{ij}\right]. \tag{D.29}$$

This is the relative displacement of the physical contact surfaces in the tangent plane. It differs from the simpler expression $\mathbf{P}_{\perp}^{(ij)}(\mathbf{u}_j - \mathbf{u}_i)$, which would incorrectly assign elastic slip to a rigidly rotating pair of nodes.

Define the relative microrotation by $\Delta\boldsymbol{\vartheta}_{ij} = \boldsymbol{\vartheta}_j - \boldsymbol{\vartheta}_i$. Its transverse part gives the local rolling or bending measure,

$$\boldsymbol{\delta}_{\mathrm{b}}^{(ij)} = \mathbf{P}_{\perp}^{(ij)} \Delta\boldsymbol{\vartheta}_{ij}. \tag{D.30}$$

Its axial part gives the relative twist about the contact direction,

$$\delta_{\mathrm{tw}}^{(ij)} = \hat{\mathbf{n}}_{ij} \cdot \Delta\boldsymbol{\vartheta}_{ij}. \tag{D.31}$$

The internal phase difference across the bond is

$$\Delta\varphi_{ij} = \varphi_j - \varphi_i. \tag{D.32}$$

Only $\Delta\varphi_{ij}$, not φ_i or φ_j separately, may enter the contact energy. The bond action is therefore invariant under a uniform internal phase displacement,

$$\varphi_i \to \varphi_i + \varphi_0, \qquad \varphi_j \to \varphi_j + \varphi_0. \tag{D.33}$$

This is the local contact expression of the phase-shift freedom of the Soft Floor.

The objectivity of the construction can be checked directly. Consider a rigid-body motion composed of a uniform translation $\mathbf{a}$ and an infinitesimal rotation $\boldsymbol{\Omega}$. The nodal center displacements are

$$\mathbf{u}_i = \mathbf{a} + \boldsymbol{\Omega} \times \mathbf{X}_i, \qquad \mathbf{u}_j = \mathbf{a} + \boldsymbol{\Omega} \times \mathbf{X}_j. \tag{D.34}$$

Since $\mathbf{X}_j - \mathbf{X}_i = d_{\mathrm{nn}} \hat{\mathbf{n}}_{ij}$, the relative center displacement is

$$\mathbf{u}_j - \mathbf{u}_i = d_{\mathrm{nn}} \boldsymbol{\Omega} \times \hat{\mathbf{n}}_{ij}. \tag{D.35}$$

For a rigid rotation of the node frames, $\boldsymbol{\vartheta}_i = \boldsymbol{\vartheta}_j = \boldsymbol{\Omega}$. Then

$$\Delta \mathbf{u}_{ij}^{\mathrm{c}} = d_{\mathrm{nn}} \boldsymbol{\Omega} \times \hat{\mathbf{n}}_{ij} - 2 r_{\mathrm{D}} \boldsymbol{\Omega} \times \hat{\mathbf{n}}_{ij}. \tag{D.36}$$

Using $d_{\mathrm{nn}} = 2 r_{\mathrm{D}}$, one obtains $\Delta \mathbf{u}_{ij}^{\mathrm{c}} = \mathbf{0}$.

Consequently,

$$\delta_{\mathrm{n}}^{(ij)} = 0, \qquad \boldsymbol{\delta}_{\mathrm{t}}^{(ij)} = \mathbf{0}. \tag{D.37}$$

Because the two nodes undergo the same microrotation,

$$\boldsymbol{\delta}_{\mathrm{b}}^{(ij)} = \mathbf{0}, \qquad \delta_{\mathrm{tw}}^{(ij)} = 0. \tag{D.38}$$

A uniform phase displacement gives $\Delta \varphi_{ij} = 0$.

Thus all retained contact deformation measures vanish under rigid translation, rigid rotation, and uniform internal phase displacement. The bond law constructed from these measures is frame-indifferent to the linearized order retained here.

The resulting objective nearest-neighbor deformation set is

$$\left\{ \delta_{\mathrm{n}}^{(ij)}, \boldsymbol{\delta}_{\mathrm{t}}^{(ij)}, \boldsymbol{\delta}_{\mathrm{b}}^{(ij)}, \delta_{\mathrm{tw}}^{(ij)}, \Delta \varphi_{ij} \right\}. \tag{D.39}$$

This set is the local kinematic foundation for the parity-even quadratic bond action.

D.4 Parity-Even Quadratic Bond Action

The contact energy is now written as a minimal diagonal quadratic form built from the objective contact measures above, subject to three restrictions:

- rigid-motion invariance,
- reciprocity of an unpolarized nearest-neighbor bond,
- parity evenness of the active vacuum.

Introduce the tangent contact coefficients

$$\kappa_{\mathrm{n}}, \qquad \kappa_{\mathrm{t}}, \qquad \kappa_{\mathrm{b}}, \qquad \kappa_{\mathrm{tw}}, \qquad \kappa_{\varphi}. \tag{D.40}$$

All coefficients are tangent coefficients of the active phase. Their dimensions are chosen so that the contact energy is expressed per unit participating interface area ($[\kappa] = \mathrm{N/m^3}$). The rotational and phase variables enter through the associated arc-length factors $r_{\mathrm{D}} \boldsymbol{\vartheta}$ and $r_{\mathrm{D}} \varphi$.

The parity-even quadratic contact energy is

$$\begin{aligned} \mathcal{U}_{ij}^{(2)} = {} & \frac{1}{2} \kappa_{\mathrm{n}} (\delta_{\mathrm{n}}^{(ij)})^2 + \frac{1}{2} \kappa_{\mathrm{t}} |\boldsymbol{\delta}_{\mathrm{t}}^{(ij)}|^2 + \frac{1}{2} \kappa_{\mathrm{b}} r_{\mathrm{D}}^2 |\boldsymbol{\delta}_{\mathrm{b}}^{(ij)}|^2 \\ & + \frac{1}{2} \kappa_{\mathrm{tw}} r_{\mathrm{D}}^2 (\delta_{\mathrm{tw}}^{(ij)})^2 + \frac{1}{2} \kappa_{\varphi} r_{\mathrm{D}}^2 (\Delta \varphi_{ij})^2. \end{aligned} \tag{D.41}$$

No tangential–bending cross term is included in the baseline active vacuum. The candidate scalar $\boldsymbol{\delta}_{\mathrm{t}}^{(ij)} \cdot \boldsymbol{\delta}_{\mathrm{b}}^{(ij)}$ is parity odd: $\boldsymbol{\delta}_{\mathrm{t}}$ is a polar vector, while $\boldsymbol{\delta}_{\mathrm{b}}$, being derived from microrotation, is axial. Their dot product is a pseudoscalar. It cannot appear in the parity-even constitutive energy of an unpolarized inversion-symmetric vacuum. This is why the baseline contact action strictly excludes a κ_{tb} coefficient.

A chiral extension may contain a term of the form $\chi_{ij}\kappa_{\mathrm{tb}} r_{\mathrm{D}} \boldsymbol{\delta}_{\mathrm{t}}^{(ij)} \cdot \boldsymbol{\delta}_{\mathrm{b}}^{(ij)}$, where χ_{ij} is an explicit pseudoscalar bond chirality. Such a term belongs to a polarized or chiral defect sector. It vanishes after averaging over an unpolarized active vacuum and is not part of the baseline FCC contact action.

The harmonic phase term may be understood as the tangent approximation to a periodic phase-contact potential,

$$\mathcal{U}_{\varphi}^{(ij)} = \kappa_{\varphi} r_{\mathrm{D}}^2 \left[1 - \cos(\Delta\varphi_{ij})\right]. \tag{D.42}$$

For $|\Delta\varphi_{ij}| \ll 1$, this becomes

$$\mathcal{U}_{\varphi}^{(ij)} = \frac{1}{2}\kappa_{\varphi} r_{\mathrm{D}}^2 (\Delta\varphi_{ij})^2 + \mathcal{O}(\Delta\varphi_{ij}^4). \tag{D.43}$$

The local stability conditions of the uncoupled parity-even bond are

$$\kappa_{\mathrm{n}} > 0, \qquad \kappa_{\mathrm{t}} > 0, \qquad \kappa_{\mathrm{b}} > 0, \qquad \kappa_{\mathrm{tw}} > 0, \qquad \kappa_{\varphi} > 0. \tag{D.44}$$

It is useful to define the contact-strain vector

$$\boldsymbol{\xi}_{ij} = \begin{pmatrix} \delta_{\mathrm{n}}^{(ij)} \\ \boldsymbol{\delta}_{\mathrm{t}}^{(ij)} \\ r_{\mathrm{D}} \boldsymbol{\delta}_{\mathrm{b}}^{(ij)} \\ r_{\mathrm{D}} \delta_{\mathrm{tw}}^{(ij)} \\ r_{\mathrm{D}} \Delta\varphi_{ij} \end{pmatrix}. \tag{D.45}$$

With the tangential and bending entries understood as two-component vectors in the contact tangent plane, the bond energy can be written compactly as $\mathcal{U}_{ij}^{(2)} = \frac{1}{2}\boldsymbol{\xi}_{ij}^{\mathsf{T}} \mathbf{H}_{\mathrm{c}} \boldsymbol{\xi}_{ij}$. The baseline parity-even contact tangent matrix is block diagonal:

$$\mathbf{H}_{\mathrm{c}} = \begin{pmatrix} \kappa_{\mathrm{n}} & 0 & 0 & 0 & 0 \\ 0 & \kappa_{\mathrm{t}}\mathbf{I}_2 & 0 & 0 & 0 \\ 0 & 0 & \kappa_{\mathrm{b}}\mathbf{I}_2 & 0 & 0 \\ 0 & 0 & 0 & \kappa_{\mathrm{tw}} & 0 \\ 0 & 0 & 0 & 0 & \kappa_{\varphi} \end{pmatrix}. \tag{D.46}$$

Let the generalized two-node coordinate be

$$\mathbf{q}_{ij} = \begin{pmatrix} \mathbf{u}_i \\ \boldsymbol{\vartheta}_i \\ \varphi_i \\ \mathbf{u}_j \\ \boldsymbol{\vartheta}_j \\ \varphi_j \end{pmatrix}. \tag{D.47}$$

Every component of $\boldsymbol{\xi}_{ij}$ is linear in the generalized coordinates, so $\boldsymbol{\xi}_{ij} = \mathbf{B}_{ij}\mathbf{q}_{ij}$, where $\mathbf{B}_{ij}$ is the objective bond-kinematic operator. The contact energy per unit participating area becomes

$$\mathcal{U}_{ij}^{(2)} = \frac{1}{2}\mathbf{q}_{ij}^{\mathsf{T}}\overline{\mathbf{K}}_{ij}\mathbf{q}_{ij}, \tag{D.48}$$

with

$$\overline{\mathbf{K}}_{ij} = \mathbf{B}_{ij}^{\mathsf{T}}\mathbf{H}_{\mathrm{c}}\mathbf{B}_{ij}. \tag{D.49}$$

The overbar denotes a generalized stiffness block per unit participating interface area. The integrated bond stiffness entering the primitive-cell assembly is obtained only after multiplication by the effective modal area.

The bond is reciprocal under endpoint interchange ($i \leftrightarrow j$). The squared magnitudes in the energy are unchanged, and because the phase energy is even in $\Delta\varphi_{ij}$, the complete bond energy satisfies $\mathcal{U}_{ij}^{(2)} = \mathcal{U}_{ji}^{(2)}$.

For a mode with no normal deformation, no relative microrotation, and no phase difference, the contact energy reduces to

$$\mathcal{U}_{ij}^{(2)} = \frac{1}{2}\kappa_{\mathrm{t}}|\boldsymbol{\delta}_{\mathrm{t}}^{(ij)}|^2. \tag{D.50}$$

For the restricted directional transverse mode, consistency requires $\kappa_{\mathrm{t}} = \tau_{\mathrm{D}}/d_{\mathrm{nn}}^2$. Under the isotropic contact condition ($\kappa_{\mathrm{n}} = \kappa_{\mathrm{t}}$), the common contact coefficient becomes $\kappa_{\mathrm{c}} = \tau_{\mathrm{D}}/d_{\mathrm{nn}}^2$. This recovers the scalar transverse contact law as one polarization of the objective three-dimensional nearest-neighbor action.

D.5 Primitive-Cell Kinetic Bookkeeping

The bond law above is written per unit participating interface area. Let A_{ct} denote the effective modal area used to integrate that surface law. For the a-th undirected nearest-neighbor contact,

$$U_a = A_{\mathrm{ct}}\mathcal{U}_a^{(2)}, \tag{D.51}$$

and the corresponding integrated generalized stiffness block is

$$\mathbf{K}_a = A_{\mathrm{ct}}\overline{\mathbf{K}}_a. \tag{D.52}$$

The modal interpretation and normalization of A_{ct} are established later in this appendix.

The six undirected nearest-neighbor contacts contribute potential energy once per primitive cell. The kinetic inertia, however, must not be assigned independently to each contact as a separate

copy of the primitive-node inertia. Translational mass, microrotational inertia, and phase inertia if present belong to the retained primitive-cell node coordinates and are assigned once through the primitive-cell mass matrix. The lattice bookkeeping is therefore

$$U = \sum_{\mathbf{R}} \sum_{a=1}^{6} U_a(\mathbf{q}_{\mathbf{R}}, \mathbf{q}_{\mathbf{R}+\mathbf{d}_a}) \,, \tag{D.53}$$

whereas

$$T^{(0)} = \frac{1}{2} \sum_{\mathbf{R}} \dot{\mathbf{q}}_{\mathbf{R}}^{\mathsf{T}} \mathbf{M}_{\mathrm{cell}}^{(0)} \dot{\mathbf{q}}_{\mathbf{R}}. \tag{D.54}$$

The primitive-cell generalized coordinate is

$$\mathbf{q}_{\mathbf{R}} = \begin{pmatrix} \mathbf{u}_{\mathbf{R}} \\ \boldsymbol{\vartheta}_{\mathbf{R}} \\ \varphi_{\mathbf{R}} \end{pmatrix}, \tag{D.55}$$

with the understanding that the independent dynamical status of φ is not fixed by the present appendix. The matrix $\mathbf{M}_{\mathrm{cell}}^{(0)}$ is symmetric and positive on the retained kinetic subspace. It contains the generalized FCC scaffold inertia associated with the retained primitive-cell coordinates once; it is not a sum of six independent full-node masses. No independently additive condensate inertia is included in this primitive-cell normalization. The coherent condensate kinematics and pressure constraint are introduced separately in Appendix E.

After Bloch reduction at fixed $\mathbf{k}$, the primitive-cell quadratic action has the form

$$S_{\mathbf{k}}^{(2)} = \int \left[\frac{1}{2} \dot{\mathbf{q}}_0^{\dagger} \mathbf{M}_{\mathrm{cell}}^{(0)} \dot{\mathbf{q}}_0 - \frac{1}{2} \mathbf{q}_0^{\dagger} \mathbf{K}_{\mathrm{FCC}}(\mathbf{k}) \mathbf{q}_0 \right] \mathrm{d}t. \tag{D.56}$$

This displays the required assembly logic: the six bonds contribute integrated stiffness, whereas the primitive cell carries the generalized scaffold inertia once. Any later constitutive coordinate reduction or coupled scaffold–condensate extension must act on the primitive-cell kinetic structure through a consistent coordinate transformation or enlarged kinetic action; it must not be implemented by duplicating or independently rescaling the full node inertia bond by bond.

D.6 Nearest-Neighbor FCC Assembly and Formal Bloch Stiffness

The active Soft Floor is an FCC Bravais lattice with one generalized node per primitive cell. Each node has twelve nearest neighbors. Because opposite directions represent the same undirected contact, the primitive-cell potential energy is assembled from six independently counted nearest-neighbor bonds.

The nearest-neighbor separation is

$$d_{\mathrm{nn}} = 2r_{\mathrm{D}}. \tag{D.57}$$

A convenient set of six undirected nearest-neighbor vectors is

$$\begin{aligned} \mathbf{d}_1 &= \frac{d_{\mathrm{nn}}}{\sqrt{2}}(1,1,0), \quad \mathbf{d}_2 = \frac{d_{\mathrm{nn}}}{\sqrt{2}}(1,-1,0), \\ \mathbf{d}_3 &= \frac{d_{\mathrm{nn}}}{\sqrt{2}}(1,0,1), \quad \mathbf{d}_4 = \frac{d_{\mathrm{nn}}}{\sqrt{2}}(1,0,-1), \\ \mathbf{d}_5 &= \frac{d_{\mathrm{nn}}}{\sqrt{2}}(0,1,1), \quad \mathbf{d}_6 = \frac{d_{\mathrm{nn}}}{\sqrt{2}}(0,1,-1). \end{aligned} \tag{D.58}$$

The corresponding unit vectors are $\hat{\mathbf{n}}_a = \mathbf{d}_a/d_{\mathrm{nn}}$. The negatives of these six directions supply the remaining six directed neighbors.

The conventional cubic FCC cell has edge length

$$a_{\mathrm{FCC}} = 2\sqrt{2}\, r_{\mathrm{D}}, \tag{D.59}$$

and the primitive-cell volume is

$$V_{\mathrm{p}} = \frac{a_{\mathrm{FCC}}^3}{4} = 4\sqrt{2}\, r_{\mathrm{D}}^3. \tag{D.60}$$

For a Bloch mode,

$$\mathbf{q}_{\mathbf{R}}(t) = \mathbf{q}_0 \exp[i(\mathbf{k}\cdot\mathbf{R} - \omega t)], \tag{D.61}$$

so

$$\mathbf{q}_{\mathbf{R}+\mathbf{d}_a} = e^{i\mathbf{k}\cdot\mathbf{d}_a}\mathbf{q}_{\mathbf{R}}. \tag{D.62}$$

For contact a, the objective contact-strain vector is

$$\boldsymbol{\xi}_a = \mathbf{B}_a(\mathbf{k})\mathbf{q}_0, \tag{D.63}$$

where $\mathbf{B}_a(\mathbf{k})$ contains the Bloch phase, normal and tangential projectors, microrotation terms, and internal phase difference.

Because $\mathbf{H}_{\mathrm{c}}$ is the contact tangent matrix per unit participating area, the corresponding generalized stiffness per unit area is

$$\overline{\mathbf{K}}_a(\mathbf{k}) = \mathbf{B}_a^{\dagger}(\mathbf{k})\mathbf{H}_{\mathrm{c}}\mathbf{B}_a(\mathbf{k}). \tag{D.64}$$

The integrated stiffness contribution is

$$\mathbf{K}_a(\mathbf{k}) = A_{\mathrm{ct}}\overline{\mathbf{K}}_a(\mathbf{k}). \tag{D.65}$$

Hence the primitive-cell Bloch stiffness is

$$\mathbf{K}_{\mathrm{FCC}}(\mathbf{k}) = A_{\mathrm{ct}}\sum_{a=1}^{6}\mathbf{B}_a^{\dagger}(\mathbf{k})\mathbf{H}_{\mathrm{c}}\mathbf{B}_a(\mathbf{k}). \tag{D.66}$$

The factor A_{ct} is required for dimensional consistency between the surface contact law and the primitive-cell mass matrix.

This expression defines the nearest-neighbor FCC stiffness assembly. It is not a completed full dynamic-matrix calculation. The explicit matrices $\mathbf{B}_a(\mathbf{k})$, the complete finite-$\mathbf{k}$ spectrum, the rotational and phase branches, and the stability proof over the full first Brillouin zone remain open calculations.

The positive centered-second-difference contribution with coefficient 1/12 used in the reduced photon action of Appendix AP is a higher-gradient constitutive augmentation of the selected transverse branch. It is not derived by the nearest-neighbor stiffness assembly above alone. A complete microscopic derivation must show whether this effective term emerges from the rotational or internal-phase sectors, elimination of auxiliary coordinates, extended contact interactions, or another structure within the full FCC dynamic matrix.

The baseline generalized eigenvalue problem is

$$\det\left[\mathbf{K}_{\mathrm{FCC}}(\mathbf{k}) - \omega^2\mathbf{M}_{\mathrm{cell}}^{(0)}\right] = 0. \tag{D.67}$$

At $\mathbf{k} = \mathbf{0}$, uniform translation gives three translational null directions. A uniform internal phase shift also gives zero bond energy because every $\Delta\varphi_{ij}$ vanishes. A rigid-body rotation is a null

motion of a finite body or an affine continuum field, but it is not represented by a spatially uniform periodic Bloch amplitude: the compatible displacement $\mathbf{u} = \boldsymbol{\Omega} \times \mathbf{x}$ varies linearly with position. It therefore appears in the affine $\mathbf{k} \to \mathbf{0}$ objectivity test, not as an additional uniform $\mathbf{k} = \mathbf{0}$ Bloch eigenvector.

The spectral statement established here is that the translational acoustic sector contains two long-wavelength transverse branches governed by the homogenized scaffold shear tensor derived below. A selected positive dispersion-suppressed realization of these transverse photon components is developed in Appendix AP. No claim is made that the full active-vacuum spectrum contains only two branches or that the selected reduced photon action completes the full FCC eigenvalue problem.

D.7 FCC Long-Wavelength Homogenization and Cubic Elasticity

The leading continuum tensor is obtained from a spatially affine displacement field $\mathbf{u}(\mathbf{x}) = \mathbf{H}\mathbf{x}$, where $\mathbf{H} = \nabla\mathbf{u}$. Decompose $\mathbf{H}$ into symmetric and antisymmetric parts:

$$\mathbf{H} = \boldsymbol{\varepsilon} + \mathbf{W}, \tag{D.68}$$

with $\boldsymbol{\varepsilon} = \frac{1}{2}(\mathbf{H} + \mathbf{H}^{\mathsf{T}})$ and $\mathbf{W} = \frac{1}{2}(\mathbf{H} - \mathbf{H}^{\mathsf{T}})$. The symmetric tensor $\boldsymbol{\varepsilon}$ is the infinitesimal strain. The antisymmetric tensor $\mathbf{W}$ represents local rigid rotation. Let $\boldsymbol{\omega}$ be the axial vector associated with $\mathbf{W}$, so that $\mathbf{W}\hat{\mathbf{n}} = \boldsymbol{\omega} \times \hat{\mathbf{n}}$.

Across contact a, the affine relative center displacement is $\mathbf{u}(\mathbf{x} + \mathbf{d}_a) - \mathbf{u}(\mathbf{x}) = d_{\mathrm{nn}}\mathbf{H}\hat{\mathbf{n}}_a$. For a spatially uniform microrotation $\boldsymbol{\vartheta}$, the objective relative contact-point displacement becomes

$$\Delta\mathbf{u}_a^{\mathrm{c}} = d_{\mathrm{nn}}\left[\boldsymbol{\varepsilon}\hat{\mathbf{n}}_a + (\boldsymbol{\omega} - \boldsymbol{\vartheta}) \times \hat{\mathbf{n}}_a\right]. \tag{D.69}$$

The normal deformation is therefore $\delta_{\mathrm{n}}^{(a)} = d_{\mathrm{nn}}\hat{\mathbf{n}}_a \cdot \boldsymbol{\varepsilon}\hat{\mathbf{n}}_a$. The tangential deformation is

$$\boldsymbol{\delta}_{\mathrm{t}}^{(a)} = d_{\mathrm{nn}}\mathbf{P}_{\perp}^{(a)}\left[\boldsymbol{\varepsilon}\hat{\mathbf{n}}_a + (\boldsymbol{\omega} - \boldsymbol{\vartheta}) \times \hat{\mathbf{n}}_a\right], \tag{D.70}$$

where $\mathbf{P}_{\perp}^{(a)} = \mathbf{I} - \hat{\mathbf{n}}_a\hat{\mathbf{n}}_a^{\mathsf{T}}$.

The six FCC directions satisfy the second-order identity $\sum_{a=1}^{6} n_i^{(a)} n_j^{(a)} = 2\delta_{ij}$. For a symmetric strain tensor, this identity implies that the summed cross term between $\boldsymbol{\varepsilon}\hat{\mathbf{n}}_a$ and $(\boldsymbol{\omega} - \boldsymbol{\vartheta}) \times \hat{\mathbf{n}}_a$ vanishes. The relative-rotation contribution is positive and proportional to $|\boldsymbol{\omega} - \boldsymbol{\vartheta}|^2$.

Minimizing the affine energy with respect to the uniform microrotation gives $\boldsymbol{\vartheta} = \boldsymbol{\omega}$. Thus the microrotation follows the macroscopic rigid rotation. After relaxation,

$$\boldsymbol{\delta}_{\mathrm{t}}^{(a)} = d_{\mathrm{nn}}\mathbf{P}_{\perp}^{(a)}\boldsymbol{\varepsilon}\hat{\mathbf{n}}_a. \tag{D.71}$$

For a homogeneous affine deformation, neighboring cells share the same microrotation and internal phase. Therefore, $\boldsymbol{\delta}_{\mathrm{b}}^{(a)} = \mathbf{0}$, $\delta_{\mathrm{tw}}^{(a)} = 0$, and $\Delta\varphi_a = 0$. The bending, twisting, and phase sectors do not contribute to the leading affine elastic tensor.

Let A_{ct} denote the effective modal area measure multiplying the contact energy per unit interface area. The leading scaffold strain-energy density is

$$W_{\mathrm{FCC}} = \frac{A_{\mathrm{ct}}}{V_{\mathrm{p}}}\sum_{a=1}^{6}\left[\frac{1}{2}\kappa_{\mathrm{n}}(\delta_{\mathrm{n}}^{(a)})^2 + \frac{1}{2}\kappa_{\mathrm{t}}|\boldsymbol{\delta}_{\mathrm{t}}^{(a)}|^2\right]. \tag{D.72}$$

Using the relaxed affine contact kinematics,

$$|\boldsymbol{\delta}_{\mathrm{t}}^{(a)}|^2 = d_{\mathrm{nn}}^2 \left[|\boldsymbol{\varepsilon}\hat{\mathbf{n}}_a|^2 - (\hat{\mathbf{n}}_a \cdot \boldsymbol{\varepsilon}\hat{\mathbf{n}}_a)^2 \right]. \tag{D.73}$$

Therefore,

$$W_{\mathrm{FCC}} = \frac{A_{\mathrm{ct}} d_{\mathrm{nn}}^2}{2V_{\mathrm{p}}} \sum_{a=1}^{6} \left[\kappa_{\mathrm{t}} |\boldsymbol{\varepsilon}\hat{\mathbf{n}}_a|^2 + (\kappa_{\mathrm{n}} - \kappa_{\mathrm{t}})(\hat{\mathbf{n}}_a \cdot \boldsymbol{\varepsilon}\hat{\mathbf{n}}_a)^2 \right]. \tag{D.74}$$

The required FCC directional sums are $\sum_{a=1}^{6} |\boldsymbol{\varepsilon}\hat{\mathbf{n}}_a|^2 = 2\boldsymbol{\varepsilon} : \boldsymbol{\varepsilon}$, and

$$\begin{aligned} \sum_{a=1}^{6} (\hat{\mathbf{n}}_a \cdot \boldsymbol{\varepsilon}\hat{\mathbf{n}}_a)^2 = {} & \varepsilon_{xx}^2 + \varepsilon_{yy}^2 + \varepsilon_{zz}^2 \\ & + \varepsilon_{xx}\varepsilon_{yy} + \varepsilon_{xx}\varepsilon_{zz} + \varepsilon_{yy}\varepsilon_{zz} \\ & + 2(\varepsilon_{xy}^2 + \varepsilon_{xz}^2 + \varepsilon_{yz}^2). \end{aligned} \tag{D.75}$$

Substitution gives

$$\begin{aligned} W_{\mathrm{FCC}} = \frac{A_{\mathrm{ct}} d_{\mathrm{nn}}^2}{2V_{\mathrm{p}}} \Big[& (\kappa_{\mathrm{n}} + \kappa_{\mathrm{t}})(\varepsilon_{xx}^2 + \varepsilon_{yy}^2 + \varepsilon_{zz}^2) \\ & + (\kappa_{\mathrm{n}} - \kappa_{\mathrm{t}})(\varepsilon_{xx}\varepsilon_{yy} + \varepsilon_{xx}\varepsilon_{zz} + \varepsilon_{yy}\varepsilon_{zz}) \\ & + 2(\kappa_{\mathrm{n}} + \kappa_{\mathrm{t}})(\varepsilon_{xy}^2 + \varepsilon_{xz}^2 + \varepsilon_{yz}^2) \Big]. \end{aligned} \tag{D.76}$$

The strain-energy density of a cubic continuum is

$$\begin{aligned} W_{\mathrm{cub}} = {} & \frac{1}{2} C_{11}(\varepsilon_{xx}^2 + \varepsilon_{yy}^2 + \varepsilon_{zz}^2) \\ & + C_{12}(\varepsilon_{xx}\varepsilon_{yy} + \varepsilon_{xx}\varepsilon_{zz} + \varepsilon_{yy}\varepsilon_{zz}) \\ & + 2C_{44}(\varepsilon_{xy}^2 + \varepsilon_{xz}^2 + \varepsilon_{yz}^2). \end{aligned} \tag{D.77}$$

Matching terms gives the leading FCC scaffold constants:

$$C_{11}^{(\mathrm{FCC})} = \frac{A_{\mathrm{ct}} d_{\mathrm{nn}}^2}{V_{\mathrm{p}}} (\kappa_{\mathrm{n}} + \kappa_{\mathrm{t}}), \tag{D.78}$$

$$C_{12}^{(\mathrm{FCC})} = \frac{A_{\mathrm{ct}} d_{\mathrm{nn}}^2}{2V_{\mathrm{p}}} (\kappa_{\mathrm{n}} - \kappa_{\mathrm{t}}), \tag{D.79}$$

$$C_{44}^{(\mathrm{FCC})} = \frac{A_{\mathrm{ct}} d_{\mathrm{nn}}^2}{2V_{\mathrm{p}}} (\kappa_{\mathrm{n}} + \kappa_{\mathrm{t}}). \tag{D.80}$$

These constants define a cubic continuum. FCC geometry alone guarantees the cubic tensor structure, not exact isotropy. Exact isotropy requires a further relation among the tangent contact coefficients.

The leading cubic continuum is mechanically stable when

$$C_{44} > 0, \qquad C_{11} - C_{12} > 0, \qquad C_{11} + 2C_{12} > 0. \tag{D.81}$$

For the present FCC coefficients, these conditions are equivalent to

$$\kappa_{\mathrm{n}} > 0, \qquad \kappa_{\mathrm{n}} + \kappa_{\mathrm{t}} > 0, \qquad \kappa_{\mathrm{n}} + 3\kappa_{\mathrm{t}} > 0. \tag{D.82}$$

The stronger bond-level positivity conditions

$$\kappa_{\mathrm{n}} > 0, \qquad \kappa_{\mathrm{t}} > 0 \tag{D.83}$$

are sufficient for these affine continuum inequalities and are already required by the positive local bond energy.

D.8 Macroscopic Isotropy Condition of the Active FCC Scaffold

For a cubic elastic continuum, the anisotropy factor is

$$\mathcal{A}_{\mathrm{cub}} = \frac{2C_{44}}{C_{11} - C_{12}}. \tag{D.84}$$

Using the FCC constants derived above,

$$\mathcal{A}_{\mathrm{cub}} = \frac{2\left(\kappa_{\mathrm{n}} + \kappa_{\mathrm{t}}\right)}{\kappa_{\mathrm{n}} + 3\kappa_{\mathrm{t}}}. \tag{D.85}$$

Exact isotropy requires $\mathcal{A}_{\mathrm{cub}} = 1$, which gives

$$\kappa_{\mathrm{n}} = \kappa_{\mathrm{t}}. \tag{D.86}$$

Thus FCC geometry guarantees a cubic continuum, while equality of the incremental normal and tangential contact coefficients is the additional constitutive condition required for exact long-wavelength isotropy.

Define

$$\kappa_{\mathrm{c}} \equiv \kappa_{\mathrm{n}} = \kappa_{\mathrm{t}}, \tag{D.87}$$

and define the baseline microscopic scaffold tangent shear coefficient by

$$K_{\mathrm{sh}}^{(\mathrm{micro},0)} \equiv \frac{A_{\mathrm{ct}} d_{\mathrm{nn}}^2}{V_{\mathrm{p}}} \kappa_{\mathrm{c}}. \tag{D.88}$$

Then

$$C_{11}^{(\mathrm{FCC})} = 2K_{\mathrm{sh}}^{(\mathrm{micro},0)}, \qquad C_{12}^{(\mathrm{FCC})} = 0, \qquad C_{44}^{(\mathrm{FCC})} = K_{\mathrm{sh}}^{(\mathrm{micro},0)}. \tag{D.89}$$

The scaffold tensor is

$$C_{ijkl}^{(\mathrm{FCC})} = K_{\mathrm{sh}}^{(\mathrm{micro},0)} \left(\delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk}\right). \tag{D.90}$$

Thus $K_{\mathrm{sh}}^{(\mathrm{micro},0)}$ is the unstrained primitive-cell tangent shear modulus of the FCC scaffold, homogenized over the full primitive-cell volume. It is a constitutive stiffness of the scaffold and is not itself a static or dynamic shear stress.

The scaffold has first Lamé coefficient zero and shear modulus $K_{\mathrm{sh}}^{(\mathrm{micro},0)}$. It still contributes the finite isotropic-compression response

$$K_{\mathrm{bulk}}^{(\mathrm{FCC})} = \frac{2}{3} K_{\mathrm{sh}}^{(\mathrm{micro},0)}. \tag{D.91}$$

What it does not supply is an independent hydrostatic pressure coefficient.

Introduce a finite interstitial-condensate coefficient B_{IC} only as a diagnostic regularization. The corresponding two-phase isotropic tangent tensor is

$$C_{ijkl}^{(B)} = B_{\mathrm{IC}}\delta_{ij}\delta_{kl} + K_{\mathrm{sh}}^{(\mathrm{micro},0)} \left(\delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk}\right), \tag{D.92}$$

with total bulk modulus

$$K_{\mathrm{bulk}}^{(B)} = B_{\mathrm{IC}} + \frac{2}{3} K_{\mathrm{sh}}^{(\mathrm{micro},0)}. \tag{D.93}$$

The coherent active-vacuum interpretation of B_{IC} is developed in Appendix E; it is not treated here as an independently calibrated ordinary scalar-wave modulus.

For propagation direction

$$\hat{\mathbf{s}} = \frac{\mathbf{k}}{|\mathbf{k}|}, \tag{D.94}$$

the acoustic tensor is

$$\Gamma_{ik} = C^{(B)}_{ijkl} s_j s_l = K^{(\mathrm{micro},0)}_{\mathrm{sh}} \delta_{ik} + \left(B_{\mathrm{IC}} + K^{(\mathrm{micro},0)}_{\mathrm{sh}} \right) s_i s_k. \tag{D.95}$$

For a transverse polarization, $\hat{\mathbf{s}} \cdot \mathbf{e}_{\mathrm{T}} = 0$,

$$\Gamma_{ik} e_{\mathrm{T},k} = K^{(\mathrm{micro},0)}_{\mathrm{sh}} e_{\mathrm{T},i}. \tag{D.96}$$

For a longitudinal polarization, $\mathbf{e}_{\mathrm{L}} \parallel \hat{\mathbf{s}}$,

$$\Gamma_{ik} e_{\mathrm{L},k} = \left(B_{\mathrm{IC}} + 2K^{(\mathrm{micro},0)}_{\mathrm{sh}} \right) e_{\mathrm{L},i}. \tag{D.97}$$

Thus the two translational transverse branches are degenerate at leading isotropic order, while the longitudinal diagnostic branch depends on the separate condensate constraint sector.

D.9 Effective Modal Normalization of the FCC Contact Coefficient

The preceding homogenization expresses the baseline microscopic scaffold tangent shear coefficient as

$$K^{(\mathrm{micro},0)}_{\mathrm{sh}} = \frac{A_{\mathrm{ct}} d^2_{\mathrm{nn}}}{V_{\mathrm{p}}} \kappa_{\mathrm{c}}. \tag{D.98}$$

The directional transverse contact law gives

$$\kappa_{\mathrm{c}} = \frac{\tau_{\mathrm{D}}}{d^2_{\mathrm{nn}}}. \tag{D.99}$$

Therefore,

$$K^{(\mathrm{micro},0)}_{\mathrm{sh}} = \frac{A_{\mathrm{ct}}}{V_{\mathrm{p}}} \tau_{\mathrm{D}}. \tag{D.100}$$

The quantity A_{ct} must be interpreted carefully. It is not introduced here as a directly observed geometric patch on a Wigner–Seitz face. It is an effective modal area that converts the surface-inertia and surface-tension representation of the scaffold contact action into the primitive-cell translational normalization.

The Wigner–Seitz cell of an FCC lattice is a rhombic dodecahedron. Its twelve faces correspond to the twelve nearest-neighbor directions. For nearest-neighbor separation d_{nn}, each rhombic face has diagonals d_{nn} and $d_{\mathrm{nn}}/\sqrt{2}$. The full Wigner–Seitz face area is therefore

$$A_{\mathrm{WS}} = \frac{1}{2} d_{\mathrm{nn}} \frac{d_{\mathrm{nn}}}{\sqrt{2}} = \frac{d^2_{\mathrm{nn}}}{2\sqrt{2}}. \tag{D.101}$$

Using $d_{\mathrm{nn}} = 2r_{\mathrm{D}}$, one obtains

$$A_{\mathrm{WS}} = \sqrt{2} r^2_{\mathrm{D}}. \tag{D.102}$$

The ratio of one full Wigner–Seitz face to the primitive-cell volume is

$$\frac{A_{\mathrm{WS}}}{V_{\mathrm{p}}} = \frac{\sqrt{2} r^2_{\mathrm{D}}}{4\sqrt{2} r^3_{\mathrm{D}}} = \frac{1}{4r_{\mathrm{D}}}. \tag{D.103}$$

This is a valid FCC geometric identity. It defines the full nearest-neighbor face area. It does not by itself identify the modal area associated with the reduced transverse scaffold transfer coordinate.

The modal area is fixed by matching the scaffold surface-inertia representation of the reduced transverse transfer coordinate to the primitive-cell nodal inertia normalization. Let M_{D} be the independently defined Soft Floor node inertia scale, and let μ_{D} be the corresponding baseline scaffold surface inertia. The modal area is defined by

$$A_{\mathrm{ct}}^{(\mathrm{modal})} \equiv \frac{M_{\mathrm{D}}}{\mu_{\mathrm{D}}}. \tag{D.104}$$

This is a normalization identity, not a literal statement that each bond carries an independent mass M_{D}. The primitive cell carries the shared nodal translational inertia once. For the reduced transverse scaffold coordinate used in the homogenized coefficient, the effective area A_{ct} is therefore identified with $A_{\mathrm{ct}}^{(\mathrm{modal})}$. This identification is constitutive and modal rather than a claim that the same area has been geometrically resolved as a physical contact patch on each FCC face.

Using the established TFT relations

$$M_{\mathrm{D}} = \frac{2\pi\hbar}{c_{\mathrm{E}} r_{\mathrm{D}}}, \tag{D.105}$$

and

$$\mu_{\mathrm{D}} = \frac{c_{\mathrm{E}}^2}{G r_{\mathrm{D}}}, \tag{D.106}$$

one obtains

$$A_{\mathrm{ct}}^{(\mathrm{modal})} = \frac{2\pi\hbar/(c_{\mathrm{E}} r_{\mathrm{D}})}{c_{\mathrm{E}}^2/(G r_{\mathrm{D}})} = \frac{2\pi\hbar G}{c_{\mathrm{E}}^3}. \tag{D.107}$$

Since the substrate scale satisfies

$$\ell_{\mathrm{S}}^2 = \frac{\hbar G}{c_{\mathrm{E}}^3}, \tag{D.108}$$

the modal area is

$$A_{\mathrm{ct}}^{(\mathrm{modal})} = 2\pi\ell_{\mathrm{S}}^2. \tag{D.109}$$

The corresponding transverse scaffold modal projection is defined by

$$\iota_{\mathrm{tr}}^{(\mathrm{modal})} \equiv \frac{A_{\mathrm{ct}}^{(\mathrm{modal})}}{V_{\mathrm{p}}}. \tag{D.110}$$

Using

$$V_{\mathrm{p}} = 4\sqrt{2} r_{\mathrm{D}}^3, \tag{D.111}$$

and

$$A_{\mathrm{ct}}^{(\mathrm{modal})} = 2\pi\ell_{\mathrm{S}}^2, \tag{D.112}$$

one obtains

$$\iota_{\mathrm{tr}}^{(\mathrm{modal})} = \frac{\pi\ell_{\mathrm{S}}^2}{2\sqrt{2} r_{\mathrm{D}}^3}. \tag{D.113}$$

This projection also satisfies

$$\iota_{\mathrm{tr}}^{(\mathrm{modal})} = \frac{\rho_{\mathrm{sh}}^{(\mathrm{micro},0)}}{\mu_{\mathrm{D}}}, \tag{D.114}$$

where

$$\rho_{\mathrm{sh}}^{(\mathrm{micro},0)} \equiv \frac{M_{\mathrm{D}}}{V_{\mathrm{p}}} \tag{D.115}$$

is the baseline primitive-cell FCC scaffold inertia density.

Indeed, since

$$A_{\mathrm{ct}}^{(\mathrm{modal})} = \frac{M_{\mathrm{D}}}{\mu_{\mathrm{D}}}, \tag{D.116}$$

it follows that

$$\frac{A_{\mathrm{ct}}^{(\mathrm{modal})}}{V_{\mathrm{p}}} = \frac{\rho_{\mathrm{sh}}^{(\mathrm{micro},0)}}{\mu_{\mathrm{D}}}. \tag{D.117}$$

The quantity $\iota_{\mathrm{tr}}^{(\mathrm{modal})}$ is the transverse projection associated with the periodic FCC scaffold transfer mode. It is not the localized defect-flow projection $\iota_{\mathrm{V}}^{(\mathrm{def})}$ introduced in Appendix E. The former belongs to the periodic scaffold contact normalization; the latter belongs to a boundary-value problem for relative condensate flow around a localized defect.

The equivalent circular radius associated with this modal area is

$$r_{\mathrm{ct}}^{(\mathrm{modal})} = \sqrt{\frac{A_{\mathrm{ct}}^{(\mathrm{modal})}}{\pi}} = \sqrt{2}\ell_{\mathrm{S}}. \tag{D.118}$$

This result should be read as follows: $A_{\mathrm{ct}}^{(\mathrm{modal})}$ is the surface-to-cell normalization area of the reduced transverse scaffold transfer coordinate. It should not be read as having been geometrically located as a literal physical patch on every FCC face.

The ratio to the full Wigner–Seitz face may still be useful as a dimensionless comparison:

$$f_{\mathrm{ct}}^{(\mathrm{modal})} = \frac{A_{\mathrm{ct}}^{(\mathrm{modal})}}{A_{\mathrm{WS}}} = \sqrt{2}\pi \left(\frac{\ell_{\mathrm{S}}}{r_{\mathrm{D}}}\right)^2. \tag{D.119}$$

Because $\ell_{\mathrm{S}} \ll r_{\mathrm{D}}$,

$$f_{\mathrm{ct}}^{(\mathrm{modal})} \ll 1. \tag{D.120}$$

This ratio is an effective modal-area ratio. It does not prove that only this fraction of the Wigner–Seitz face is physically active as a literal geometric contact footprint. The full Wigner–Seitz face remains the geometric nearest-neighbor boundary; the modal area is the normalization measure of the reduced transverse scaffold transfer coordinate.

The integrated modal stiffness associated with the reduced transfer coordinate is

$$k_{\mathrm{ct}}^{(\mathrm{modal})} = A_{\mathrm{ct}}^{(\mathrm{modal})}\kappa_{\mathrm{c}}. \tag{D.121}$$

Using

$$\kappa_{\mathrm{c}} = \frac{\tau_{\mathrm{D}}}{d_{\mathrm{nn}}^2}, \tag{D.122}$$

one obtains

$$k_{\mathrm{ct}}^{(\mathrm{modal})} = \frac{\pi}{2}\tau_{\mathrm{D}} \left(\frac{\ell_{\mathrm{S}}}{r_{\mathrm{D}}}\right)^2. \tag{D.123}$$

The discrete directional speed associated with the reduced scaffold contact sequence is

$$c_{\mathrm{T}}^{(0)} = d_{\mathrm{nn}}\sqrt{\frac{k_{\mathrm{ct}}^{(\mathrm{modal})}}{m_{\mathrm{ct}}^{(\mathrm{modal})}}}. \tag{D.124}$$

The corresponding scaffold modal inertia is

$$m_{\mathrm{ct}}^{(\mathrm{modal})} = A_{\mathrm{ct}}^{(\mathrm{modal})}\mu_{\mathrm{D}} = M_{\mathrm{D}}. \tag{D.125}$$

This equality is a modal normalization of the representative scaffold transfer coordinate, not a statement that each of the six primitive-cell bonds contains a separate full node mass.

Using $k_{\mathrm{ct}}^{(\mathrm{modal})}$, $m_{\mathrm{ct}}^{(\mathrm{modal})}$, and κ_{c}, one finds

$$\begin{aligned}\left(c_{\mathrm{T}}^{(0)}\right)^2 &= d_{\mathrm{nn}}^2 \frac{A_{\mathrm{ct}}^{(\mathrm{modal})}\kappa_{\mathrm{c}}}{A_{\mathrm{ct}}^{(\mathrm{modal})}\mu_{\mathrm{D}}} \\ &= \frac{\tau_{\mathrm{D}}}{\mu_{\mathrm{D}}} = c_{\mathrm{E}}^2.\end{aligned} \tag{D.126}$$

Therefore,

$$c_{\mathrm{T}}^{(0)} = c_{\mathrm{E}}. \tag{D.127}$$

The modal area cancels from the unstrained wave-speed normalization. Its role is not to fit c_{E}, but to keep the surface and primitive-cell representations of the scaffold transfer coordinate mutually consistent.

The baseline primitive-cell scaffold inertia density follows directly from the node mass divided by the full primitive-cell volume:

$$\rho_{\mathrm{sh}}^{(\mathrm{micro},0)} \equiv \frac{M_{\mathrm{D}}}{V_{\mathrm{p}}}. \tag{D.128}$$

Using

$$M_{\mathrm{D}} = \rho_{\mathrm{D}} \left(\frac{4}{3}\pi r_{\mathrm{D}}^3\right), \tag{D.129}$$

and

$$V_{\mathrm{p}} = 4\sqrt{2} r_{\mathrm{D}}^3, \tag{D.130}$$

one obtains

$$\rho_{\mathrm{sh}}^{(\mathrm{micro},0)} = \frac{\pi}{3\sqrt{2}}\rho_{\mathrm{D}}. \tag{D.131}$$

The FCC close-packing fraction is

$$\beta_{\mathrm{geo}} = \frac{\pi}{3\sqrt{2}}. \tag{D.132}$$

Thus,

$$\rho_{\mathrm{sh}}^{(\mathrm{micro},0)} = \beta_{\mathrm{geo}}\rho_{\mathrm{D}}. \tag{D.133}$$

Here ρ_{D} is the density assigned to the solid nodal phase itself, whereas $\rho_{\mathrm{sh}}^{(\mathrm{micro},0)}$ is the corresponding nodal mass averaged over the complete FCC primitive-cell volume. The factor β_{geo} therefore enters because only the fraction β_{geo} of the primitive-cell volume is occupied by the solid FCC nodal phase. It is a geometric volume-averaging factor and does not represent a reduction of the intrinsic nodal density ρ_{D}.

The corresponding baseline primitive-cell scaffold tangent shear coefficient is

$$K_{\mathrm{sh}}^{(\mathrm{micro},0)} = \rho_{\mathrm{sh}}^{(\mathrm{micro},0)} c_{\mathrm{E}}^2 = \beta_{\mathrm{geo}}\rho_{\mathrm{D}} c_{\mathrm{E}}^2. \tag{D.134}$$

Equivalently,

$$K_{\mathrm{sh}}^{(\mathrm{micro},0)} = \frac{A_{\mathrm{ct}}^{(\mathrm{modal})}}{V_{\mathrm{p}}}\tau_{\mathrm{D}}. \tag{D.135}$$

The coefficient $K_{\mathrm{sh}}^{(\mathrm{micro},0)}$ is the unstrained primitive-cell tangent shear modulus of the FCC scaffold, homogenized over the full primitive-cell volume. It is a constitutive stiffness and is not

itself a static shear stress, a gravitational-wave stress, a measure of local gravitational loading, a localized defect impedance coefficient, or an effective macroscopic gravitational-wave response coefficient.

The associated inverse-length projection is $\iota_{\mathrm{tr}}^{(\mathrm{modal})}$, not the localized defect projection $\iota_{\mathrm{V}}^{(\mathrm{def})}$. The scaffold coefficient must therefore not be identified either with the defect-flow impedance calibration or with an effective macroscopic gravitational-wave response coefficient. The cross-scale distinction is addressed next.

D.10 Status of the Full FCC Dynamic Spectrum and Remaining Closures

This appendix establishes the baseline contact mechanics and long-wavelength acoustic tensor of the active FCC Soft Floor. The results define the gravity-independent FCC scaffold carrier but do not constitute a complete finite-wave-number microscopic elastodynamic theory.

The first completed result is the baseline nearest-neighbor directional transverse scaffold action,

$$\omega^2(k) = \frac{4c_{\mathrm{E}}^2}{d_{\mathrm{nn}}^2} \sin^2\left(\frac{k d_{\mathrm{nn}}}{2}\right), \tag{D.136}$$

with long-wavelength limit

$$c_{\mathrm{T}}^{(0)} = c_{\mathrm{E}}. \tag{D.137}$$

This branch establishes the nearest-neighbor transverse normalization only. The selected positive dispersion-suppressed photon branch is developed separately in Appendix AP. Its effective higher-gradient coefficient $1/12$ is not derived here from the complete FCC dynamic matrix.

The second completed result is the objective nearest-neighbor contact kinematics. The local contact deformation is determined by the contact-point displacement

$$\Delta\mathbf{u}_{ij}^{\mathrm{c}} = \mathbf{u}_j - \mathbf{u}_i - r_{\mathrm{D}}\,(\boldsymbol{\vartheta}_i + \boldsymbol{\vartheta}_j) \times \hat{\mathbf{n}}_{ij}, \tag{D.138}$$

rather than by the relative center displacement alone. This construction yields contact measures that vanish under rigid translation, compatible rigid rotation, and uniform internal phase displacement.

The third completed result is the parity-even quadratic contact action. The baseline active vacuum admits normal, tangential, bending, twisting, and phase-difference quadratic terms. It excludes the tangential–bending pseudoscalar unless an explicit chiral pseudoscalar is introduced. The unpolarized active vacuum therefore contains no baseline term proportional to

$$\boldsymbol{\delta}_{\mathrm{t}}^{(ij)} \cdot \boldsymbol{\delta}_{\mathrm{b}}^{(ij)}. \tag{D.139}$$

The fourth completed result is the primitive-cell bookkeeping. The six undirected nearest-neighbor bonds contribute potential energy once, while the generalized FCC scaffold inertia associated with the retained translational, microrotational, and possible phase coordinates is assigned once through

$$\mathbf{M}_{\mathrm{cell}}^{(0)}. \tag{D.140}$$

No independently additive condensate inertia is included in this primitive-cell scaffold normalization. The coherent condensate kinematics and pressure constraint are treated separately in Appendix E.

The fifth completed result is the affine FCC homogenization. The six nearest-neighbor directions produce a cubic continuum with

$$C_{11}^{(\mathrm{FCC})} = \frac{A_{\mathrm{ct}} d_{\mathrm{nn}}^2}{V_{\mathrm{p}}} \left(\kappa_{\mathrm{n}} + \kappa_{\mathrm{t}}\right), \tag{D.141}$$

$$C_{12}^{(\mathrm{FCC})} = \frac{A_{\mathrm{ct}} d_{\mathrm{nn}}^2}{2V_{\mathrm{p}}} \left(\kappa_{\mathrm{n}} - \kappa_{\mathrm{t}}\right), \tag{D.142}$$

and

$$C_{44}^{(\mathrm{FCC})} = \frac{A_{\mathrm{ct}} d_{\mathrm{nn}}^2}{2V_{\mathrm{p}}} \left(\kappa_{\mathrm{n}} + \kappa_{\mathrm{t}}\right). \tag{D.143}$$

FCC geometry guarantees cubic symmetry. Exact leading isotropy follows only when

$$\kappa_{\mathrm{n}} = \kappa_{\mathrm{t}}. \tag{D.144}$$

The sixth completed result is the effective scaffold modal normalization,

$$A_{\mathrm{ct}}^{(\mathrm{modal})} = \frac{M_{\mathrm{D}}}{\mu_{\mathrm{D}}} = 2\pi \ell_{\mathrm{S}}^2. \tag{D.145}$$

This quantity is a surface-to-cell normalization area for the reduced transverse scaffold transfer coordinate. It is not interpreted as a directly established literal contact patch on each Wigner–Seitz face.

The seventh completed result is the baseline primitive-cell scaffold density and tangent shear normalization,

$$\rho_{\mathrm{sh}}^{(\mathrm{micro},0)} = \beta_{\mathrm{geo}} \rho_{\mathrm{D}}, \qquad K_{\mathrm{sh}}^{(\mathrm{micro},0)} = \beta_{\mathrm{geo}} \rho_{\mathrm{D}} c_{\mathrm{E}}^2. \tag{D.146}$$

Here ρ_{D} is the density of the solid nodal phase, whereas $\rho_{\mathrm{sh}}^{(\mathrm{micro},0)}$ is the corresponding nodal mass averaged over the complete FCC primitive-cell volume. The factor β_{geo} is therefore the geometric volume-averaging factor of the solid scaffold and does not represent a reduction of the intrinsic nodal density ρ_{D}.

The coefficient $K_{\mathrm{sh}}^{(\mathrm{micro},0)}$ is the unstrained primitive-cell tangent shear modulus of that scaffold. It is a constitutive stiffness and is not itself a static shear stress, a gravitational-wave stress, a measure of local gravitational loading, a localized defect impedance coefficient, or an effective macroscopic gravitational-wave response coefficient.

Several microscopic completions remain outside the scope of this appendix. The explicit matrices $\mathbf{B}_a(\mathbf{k})$, the full finite-$\mathbf{k}$ eigenvalue spectrum, and the rotational, torsional, and phase-sector branches are not evaluated here.

Likewise, the affine stability conditions do not constitute a global lattice-stability proof. The complete theory must still show

$$\omega_s^2(\mathbf{k}) \geq 0 \tag{D.147}$$

for every branch s and every wave vector $\mathbf{k}$ in the first Brillouin zone.

The internal phase sector also remains to be classified. Since the contact energy depends on $\Delta\varphi_{ij}$, a uniform phase displacement is a zero-energy direction of the bond energy. Whether this direction is gauge-redundant, locally locked, gapped, defect-confined, or dynamically active through an independent phase inertia is not determined by the present transverse homogenization.

The chiral extension is similarly deferred. Parity-odd terms may enter only with an explicit pseudoscalar chirality and must vanish in the unpolarized vacuum average.

The mapping from the primitive-cell FCC dynamics derived here to a macroscopic gravitational-wave tensor response is not part of the present homogenization. That problem requires a separate collective-mode projection and macroscopic response construction and is developed in Appendix N.

The interstitial-condensate pressure constraint, the absence of an ordinary finite-frequency longitudinal acoustic scalar branch in the coherent sector, and the localized defect-induced relative-flow impedance are developed separately in Appendix E. The gravitational endpoint-transfer map and its referred-inertia specialization are developed separately in Appendix J.

The status of the present appendix is therefore precise: it establishes the baseline FCC scaffold contact action, objective bond kinematics, primitive-cell kinetic bookkeeping, affine acoustic tensor, isotropy condition, modal normalization, and microscopic scaffold coefficient scale. It does not include the gravity-specific endpoint closure, the complete parent finite-wave-number spectrum, the independent phase-sector dynamics, an independently additive coherent condensate inertia, or the collective projection from microscopic FCC dynamics to the macroscopic gravitational-wave tensor sector.

Appendix E

Interstitial-Condensate Constraint and Defect Impedance

Abstract

This appendix establishes the mechanical response of the interstitial condensate within the active FCC vacuum. It defines the incrementally incompressible coherent branch and separates the singular tangent volume constraint from the finite gravitational yield pressure. It then formulates the localized relative-flow action of a topological defect, constructs the mode-resolved added-inertia functional, and defines the microscopic impedance projection as a boundary-value functional with the dimensions of an inverse penetration length. The surface-to-volume relation is a reduced constitutive matching between the normal-coupled interface representation and the solved condensate response; it does not by itself establish a universal intrinsic condensate density. Canonical defect-flow solutions and the numerical evaluation of the projection remain open boundary-value problems. The separate weak nonconservative response of a propagating photon carrier is developed in Appendix AP.

E.1 Scope and Constitutive Setting

The active vacuum is a space-filling dual-phase medium composed of the solid FCC scaffold and the connected interstitial condensate. The primitive-cell volume fractions satisfy

$$\beta_{\mathrm{geo}} = \frac{\pi}{3\sqrt{2}}, \qquad \beta_{\mathrm{IC}} = 1 - \beta_{\mathrm{geo}}, \qquad \beta_{\mathrm{geo}} + \beta_{\mathrm{IC}} = 1. \tag{E.1}$$

The FCC nodes occupy the close-packed solid fraction, while the interstitial condensate continuously fills the complementary octahedral and tetrahedral regions. No unoccupied third phase is introduced within the active FCC cell.

The analysis is restricted to the active phase,

$$0 \le \alpha_{\mathrm{G}} < 1, \qquad \dot{\alpha}_{\mathrm{G}} \approx 0, \tag{E.2}$$

where α_{G} specifies a gravitationally preloaded background that is quasistatic over the duration of the local disturbance. It is not itself treated as a propagating perturbation in the coherent branch.

The interstitial condensate has three distinct constitutive roles. In the coherent branch, it is carried with the FCC scaffold without relative flow and supplies the incremental pressure response that constrains local volumetric change. Under localized differential motion, it may redistribute relative to the scaffold and produce a conservative hydrodynamic reaction, together with any separately resolved dissipative defect impedance. A separate weak nonconservative carrier–reservoir response may transfer modal energy from a propagating photon branch and is developed in Appendix AP. These roles must not be combined into a single undifferentiated density or kinetic coefficient.

Let $\mathbf{u}(\mathbf{x}, t)$ denote the homogenized FCC scaffold displacement and $\mathbf{w}(\mathbf{x}, t)$ the interstitial-condensate displacement. Their relative velocity is

$$\mathbf{v}_{\mathrm{rel}} = \dot{\mathbf{w}} - \dot{\mathbf{u}}. \tag{E.3}$$

The coherent and localized branches are distinguished by

$$\mathbf{v}_{\mathrm{rel}} = \mathbf{0} \quad \text{(coherent)}, \qquad \mathbf{v}_{\mathrm{rel}} \neq \mathbf{0} \quad \text{(localized relative flow)}. \tag{E.4}$$

In the coherent branch, entrainment fixes the relative kinematics of the two phases but does not by itself establish an independently additive condensate contribution to the primitive-cell inertia. In the localized branch, nonzero relative motion generates the mode-dependent hydrodynamic impedance developed later. The separate photon carrier–reservoir response is not identified with this localized defect-flow impedance.

Finite gravitational loading must be distinguished from the incremental constitutive response. The background may sustain finite pressure and approach the FCC saturation threshold as $\alpha_{\mathrm{G}} \to 1^{-}$ while the coherent perturbation remains incrementally volume preserving. The resulting constraint does not prohibit quasistatic background compaction, nonlinear lattice rearrangement, or the FCC-to-SC phase transition.

The incremental actions are written about the current gravitationally preloaded configuration. Finite-deformation geometric-stiffness and acoustoelastic corrections are outside the retained tangent order. The localized construction later defines an equivalent mode-resolved impedance density whose numerical value and possible universality require an explicit defect-flow solution.

E.2 Coherent Scaffold–Condensate Kinematics

In the entrained coherent branch, $\mathbf{w} = \mathbf{u}$ up to an irrelevant time-independent reference displacement. Consequently,

$$\dot{\mathbf{w}} = \dot{\mathbf{u}}, \qquad \mathbf{v}_{\mathrm{rel}} = \mathbf{0}. \tag{E.5}$$

The associated infinitesimal strain and volumetric strain are

$$\varepsilon_{ij} = \frac{1}{2}\left(\partial_i u_j + \partial_j u_i\right), \qquad \varepsilon_{\mathrm{V}} = \operatorname{tr} \boldsymbol{\varepsilon} = \nabla \cdot \mathbf{u}. \tag{E.6}$$

Let $\rho_{\mathrm{eff}}^{(0)}$ denote the unstrained inertia coefficient assigned to the selected coherent transfer coordinate. At the primitive-cell microscopic scale established in Appendix D,

$$\rho_{\mathrm{eff}}^{(0)} = \rho_{\mathrm{sh}}^{(\mathrm{micro},0)} = \beta_{\mathrm{geo}} \rho_{\mathrm{D}}. \tag{E.7}$$

This is the nodal scaffold mass averaged over the complete primitive-cell volume. Condensate entrainment fixes the coherent relative kinematics but does not independently add a condensate inertia to $\rho_{\mathrm{eff}}^{(0)}$. Any additional coherent condensate kinetic coefficient requires an explicit coupled two-field kinetic action.

The gravitational endpoint-transfer constraint gives the referred inertia

$$\rho_{\mathrm{eff}}(\alpha_{\mathrm{G}}) = \frac{\rho_{\mathrm{eff}}^{(0)}}{(1-\alpha_{\mathrm{G}})^4}, \tag{E.8}$$

and the coherent kinetic-energy density is

$$\mathcal{T}_{\mathrm{coh}} = \frac{1}{2}\rho_{\mathrm{eff}}(\alpha_{\mathrm{G}})\dot{\mathbf{u}}\cdot\dot{\mathbf{u}}. \tag{E.9}$$

The coefficient $\rho_{\mathrm{eff}}(\alpha_{\mathrm{G}})$ is a referred inertia of the selected coordinate, not a literal equilibrium density of the complete dual-phase vacuum. Its uniform extension to the finite-wave-number photon branch is a separate constitutive inheritance adopted in Appendix AP. The localized condensate impedance density introduced later belongs to a distinct relative-flow coordinate and must not be added independently to this coherent kinetic term.

Let $K_{\mathrm{sh}}^{(0)}$ denote the shear coefficient paired with $\rho_{\mathrm{eff}}^{(0)}$ at the same descriptive scale:

$$K_{\mathrm{sh}}^{(0)} = \rho_{\mathrm{eff}}^{(0)} c_{\mathrm{E}}^2. \tag{E.10}$$

At the primitive-cell microscopic scale,

$$K_{\mathrm{sh}}^{(0)} = K_{\mathrm{sh}}^{(\mathrm{micro},0)} = \rho_{\mathrm{sh}}^{(\mathrm{micro},0)} c_{\mathrm{E}}^2. \tag{E.11}$$

At the retained tangent order,

$$K_{\mathrm{sh}}(\alpha_{\mathrm{G}}) = K_{\mathrm{sh}}^{(0)}, \qquad 0 \le \alpha_{\mathrm{G}} < 1. \tag{E.12}$$

Before imposing the coherent volume constraint, introduce the finite diagnostic regularization coefficient B_{IC}. The regularized elastic-energy density and isotropic tangent tensor are

$$\mathcal{W}_B = K_{\mathrm{sh}}^{(0)}\varepsilon_{ij}\varepsilon_{ij} + \frac{1}{2}B_{\mathrm{IC}}\varepsilon_{\mathrm{V}}^2, \tag{E.13}$$

and

$$C_{ijkl}^{(B)} = B_{\mathrm{IC}}\delta_{ij}\delta_{kl} + K_{\mathrm{sh}}^{(0)}\left(\delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk}\right). \tag{E.14}$$

For propagation direction

$$\hat{\mathbf{s}} = \frac{\mathbf{k}}{|\mathbf{k}|}, \tag{E.15}$$

the acoustic tensor is

$$\Gamma_{ij} = C_{ikjl}^{(B)} s_k s_l = K_{\mathrm{sh}}^{(0)}\delta_{ij} + \left(B_{\mathrm{IC}} + K_{\mathrm{sh}}^{(0)}\right) s_i s_j. \tag{E.16}$$

Its translational eigenvalues are

$$\lambda_{\mathrm{T}} = K_{\mathrm{sh}}^{(0)}, \qquad \lambda_{\mathrm{L}} = B_{\mathrm{IC}} + 2K_{\mathrm{sh}}^{(0)}. \tag{E.17}$$

The corresponding total bulk coefficient is

$$K_{\mathrm{bulk}}^{(B)} = B_{\mathrm{IC}} + \frac{2}{3}K_{\mathrm{sh}}^{(0)}. \tag{E.18}$$

The coefficient B_{IC} is introduced only to expose the hypothetical finite longitudinal acoustic branch. It is not identified with the finite FCC saturation-pressure scale; the tangent volume constraint and the nonlinear phase-transition pressure are distinct constitutive quantities.

E.3 Finite-Compressibility Regularization

The quadratic action of the regularized coherent branch is

$$S_B^{(2)} = \int \left[\frac{1}{2}\rho_{\mathrm{eff}}(\alpha_{\mathrm{G}})\dot{u}_i\dot{u}_i - K_{\mathrm{sh}}^{(0)}\varepsilon_{ij}\varepsilon_{ij} - \frac{1}{2}B_{\mathrm{IC}}\varepsilon_{\mathrm{V}}^2 \right] \mathrm{d}^3x\,\mathrm{d}t. \tag{E.19}$$

At the presently derived primitive-cell level, the kinetic coefficient reduces to the FCC scaffold inertia normalization. The condensate enters the coherent reduction through entrainment and the volumetric pressure response rather than through an independently calibrated additive kinetic density.

Variation with respect to $\mathbf{u}$ gives

$$\sigma_{ij} = 2K_{\mathrm{sh}}^{(0)}\varepsilon_{ij} + B_{\mathrm{IC}}\varepsilon_{\mathrm{V}}\delta_{ij}, \tag{E.20}$$

and

$$\rho_{\mathrm{eff}}(\alpha_{\mathrm{G}})\ddot{\mathbf{u}} = K_{\mathrm{sh}}^{(0)}\nabla^2\mathbf{u} + \left(B_{\mathrm{IC}} + K_{\mathrm{sh}}^{(0)}\right)\nabla\left(\nabla\cdot\mathbf{u}\right). \tag{E.21}$$

For the plane-wave field

$$\mathbf{u} = \mathbf{e}\exp\left[i\left(\mathbf{k}\cdot\mathbf{x} - \omega t\right)\right], \tag{E.22}$$

the transverse and longitudinal branches satisfy

$$\omega_{\mathrm{T}}^2 = \frac{K_{\mathrm{sh}}^{(0)}}{\rho_{\mathrm{eff}}(\alpha_{\mathrm{G}})}k^2, \qquad \omega_{\mathrm{L}}^2 = \frac{B_{\mathrm{IC}} + 2K_{\mathrm{sh}}^{(0)}}{\rho_{\mathrm{eff}}(\alpha_{\mathrm{G}})}k^2. \tag{E.23}$$

In the unstrained active vacuum, $\alpha_{\mathrm{G}} = 0$, so

$$c_{\mathrm{T}}(0) = c_{\mathrm{E}}, \qquad c_{\mathrm{L}}^2(0) = c_{\mathrm{E}}^2\left(\frac{B_{\mathrm{IC}}}{K_{\mathrm{sh}}^{(0)}} + 2\right). \tag{E.24}$$

Mechanical stability requires

$$K_{\mathrm{bulk}}^{(B)} > 0 \qquad \Longrightarrow \qquad \frac{B_{\mathrm{IC}}}{K_{\mathrm{sh}}^{(0)}} > -\frac{2}{3}, \tag{E.25}$$

and therefore

$$c_{\mathrm{L}}^2(0) > \frac{4}{3}c_{\mathrm{E}}^2, \qquad c_{\mathrm{L}}(0) > \sqrt{\frac{4}{3}}\,c_{\mathrm{E}}. \tag{E.26}$$

For $B_{\mathrm{IC}} \geq 0$,

$$c_{\mathrm{L}}(0) \geq \sqrt{2}\,c_{\mathrm{E}}. \tag{E.27}$$

Thus an ordinary finite isotropic elastic model cannot simultaneously satisfy $c_{\mathrm{T}} = c_{\mathrm{E}}$, retain c_{E} as the active-phase propagation ceiling, and support an independent stable finite-frequency longitudinal acoustic branch generated by B_{IC}.

The finite-B_{IC} theory therefore serves only as a diagnostic regularization. It does not uniquely derive incompressibility from stability; rather, it motivates a reduced coherent constitutive branch in which local volumetric fluctuations are excluded from the finite-energy acoustic spectrum.

E.4 Incrementally Incompressible Coherent Branch

The coherent active-FCC branch is defined by the singular constitutive reduction

$$B_{\mathrm{IC}} \to \infty. \tag{E.28}$$

Finite perturbation energy then requires

$$\frac{1}{2} B_{\mathrm{IC}} \varepsilon_{\mathrm{V}}^2 < \infty \qquad \Longrightarrow \qquad \varepsilon_{\mathrm{V}} \to 0, \tag{E.29}$$

so that

$$\nabla \cdot \mathbf{u} = 0. \tag{E.30}$$

This is an incremental constraint about a prescribed gravitationally loaded background. It neither requires zero finite background compaction nor prohibits approach to the nonlinear saturation boundary.

Introduce the incremental condensate pressure $\delta p_{\mathrm{IC}}(\mathbf{x}, t)$ as the Lagrange multiplier enforcing the volume constraint. The reduced coherent action is

$$S_{\mathrm{coh}}^{(2)} = \int \left[\frac{1}{2} \rho_{\mathrm{eff}}(\alpha_{\mathrm{G}}) \dot{u}_i \dot{u}_i - K_{\mathrm{sh}}^{(0)} \varepsilon_{ij} \varepsilon_{ij} + \delta p_{\mathrm{IC}} \nabla \cdot \mathbf{u} \right] \mathrm{d}^3 x \, \mathrm{d}t. \tag{E.31}$$

At the primitive-cell microscopic scale,

$$\rho_{\mathrm{eff}}^{(0)} = \rho_{\mathrm{sh}}^{(\mathrm{micro},0)}. \tag{E.32}$$

The condensate enters this reduced action through entrainment and the pressure constraint; no independently additive coherent condensate kinetic density is introduced at the present constitutive order.

A constituent-continuity check is consistent with the same constraint. Let ϱ_{IC} denote a formal local condensate constituent-density field and define

$$\widetilde{\rho}_{\mathrm{IC}} = \beta_{\mathrm{IC}} \varrho_{\mathrm{IC}}. \tag{E.33}$$

The quantity ϱ_{IC} is used only for this continuity construction. No independently calibrated equilibrium value or additive coherent inertia is inferred from it.

The local conservation law is

$$\frac{\partial \widetilde{\rho}_{\mathrm{IC}}}{\partial t} + \nabla \cdot (\widetilde{\rho}_{\mathrm{IC}} \mathbf{v}_{\mathrm{IC}}) = 0. \tag{E.34}$$

For the entrained branch,

$$\mathbf{v}_{\mathrm{IC}} = \dot{\mathbf{u}}, \tag{E.35}$$

and, over the incremental disturbance,

$$\frac{D\beta_{\mathrm{IC}}}{Dt} = 0, \qquad \frac{D\varrho_{\mathrm{IC}}}{Dt} = 0. \tag{E.36}$$

The continuity equation then gives

$$\nabla \cdot \dot{\mathbf{u}} = 0, \tag{E.37}$$

which integrates to $\nabla \cdot \mathbf{u} = 0$ for an initially volume-preserving incremental reference state. This is a consistency check on the selected coherent branch, not an independent derivation of incompressibility. The fields ϱ_{IC} and $\widetilde{\rho}_{\mathrm{IC}}$ remain distinct from the later defect impedance density $\rho_{\mathrm{IC}}^{(\mathrm{imp})}$.

Variation of the constrained action gives

$$\delta\sigma_{ij} = -\delta p_{\mathrm{IC}}\delta_{ij} + 2K_{\mathrm{sh}}^{(0)}\varepsilon_{ij}, \tag{E.38}$$

and

$$\rho_{\mathrm{eff}}(\alpha_{\mathrm{G}})\ddot{\mathbf{u}} = K_{\mathrm{sh}}^{(0)}\nabla^2\mathbf{u} - \nabla\delta p_{\mathrm{IC}}, \qquad \nabla\cdot\mathbf{u} = 0. \tag{E.39}$$

In a source-free homogeneous region,

$$\nabla^2\delta p_{\mathrm{IC}} = 0. \tag{E.40}$$

With an applied incremental force density $\mathbf{f}$,

$$\rho_{\mathrm{eff}}(\alpha_{\mathrm{G}})\ddot{\mathbf{u}} = K_{\mathrm{sh}}^{(0)}\nabla^2\mathbf{u} - \nabla\delta p_{\mathrm{IC}} + \mathbf{f}, \tag{E.41}$$

and

$$\nabla^2\delta p_{\mathrm{IC}} = \nabla\cdot\mathbf{f}. \tag{E.42}$$

The elliptic pressure equation is the compatibility condition of the constrained branch. It does not define an independently propagating field or an additional channel of instantaneous information.

For a plane wave, incompressibility requires

$$\mathbf{k}\cdot\mathbf{e} = 0. \tag{E.43}$$

The longitudinal mode of the finite-B_{IC} regularization satisfies

$$\omega_{\mathrm{L}}^2 = \frac{B_{\mathrm{IC}} + 2K_{\mathrm{sh}}^{(0)}}{\rho_{\mathrm{eff}}(\alpha_{\mathrm{G}})}k^2, \tag{E.44}$$

so for fixed $k \neq 0$,

$$B_{\mathrm{IC}} \to \infty \qquad \Longrightarrow \qquad \omega_{\mathrm{L}} \to \infty. \tag{E.45}$$

The longitudinal translational excitation is therefore removed from the finite-frequency coherent spectrum rather than converted into a superluminal propagating signal.

For either admissible transverse polarization, the long-wavelength branch satisfies

$$\omega_{\mathrm{T}}^2 = \frac{K_{\mathrm{sh}}^{(0)}}{\rho_{\mathrm{eff}}(\alpha_{\mathrm{G}})}k^2\left[1 + o(1)\right]. \tag{E.46}$$

Using

$$K_{\mathrm{sh}}^{(0)} = \rho_{\mathrm{eff}}^{(0)}c_{\mathrm{E}}^2, \qquad \rho_{\mathrm{eff}}(\alpha_{\mathrm{G}}) = \frac{\rho_{\mathrm{eff}}^{(0)}}{(1-\alpha_{\mathrm{G}})^4}, \tag{E.47}$$

one obtains

$$\omega_{\mathrm{T}}^2 = c_{\mathrm{E}}^2\left(1-\alpha_{\mathrm{G}}\right)^4 k^2\left[1 + o(1)\right], \tag{E.48}$$

and hence

$$c_{\mathrm{P}} = c_{\mathrm{E}}\left(1-\alpha_{\mathrm{G}}\right)^2. \tag{E.49}$$

The translational acoustic sector of the coherent active vacuum therefore contains two finite-frequency transverse polarizations. This statement does not determine the independent dynamical status of internal phase, microrotational, torsional, chiral, or localized-defect modes. The selected finite-wave-number photon realization is developed separately in Appendix AP.

E.5 Static Longitudinal Pressure and the Finite FCC Yield Scale

Incremental incompressibility does not imply the absence of hydrostatic stress. Decompose the interstitial-condensate pressure as

$$p_{\mathrm{IC}}(\mathbf{x},t) = \overline{p}_{\mathrm{IC}}(\mathbf{x}) + \delta p_{\mathrm{IC}}(\mathbf{x},t), \tag{E.50}$$

where $\overline{p}_{\mathrm{IC}}$ supports the quasistatic gravitational preload and δp_{IC} enforces the incremental coherent volume constraint.

The local gravitational loading is

$$\tau_{\mathrm{L}} = \alpha_{\mathrm{G}} \tau_{\mathrm{D}}, \tag{E.51}$$

where τ_{D} is the active Soft Floor surface-tension scale. The corresponding finite volumetric yield-pressure scale is

$$\tau_{\mathrm{D,bulk}} \equiv \frac{\tau_{\mathrm{D}}}{r_{\mathrm{D}}}. \tag{E.52}$$

The background condensate pressure is therefore

$$\overline{p}_{\mathrm{IC}} = \frac{\tau_{\mathrm{L}}}{r_{\mathrm{D}}} = \alpha_{\mathrm{G}} \tau_{\mathrm{D,bulk}}, \tag{E.53}$$

or equivalently

$$\alpha_{\mathrm{G}} = \frac{\overline{p}_{\mathrm{IC}}}{\tau_{\mathrm{D,bulk}}}. \tag{E.54}$$

Within the active phase,

$$0 \le \overline{p}_{\mathrm{IC}} < \tau_{\mathrm{D,bulk}}. \tag{E.55}$$

At $\alpha_{\mathrm{G}} = 0$, $\overline{p}_{\mathrm{IC}} = 0$, while

$$\alpha_{\mathrm{G}} \to 1^{-} \qquad \Longrightarrow \qquad \overline{p}_{\mathrm{IC}} \to \tau_{\mathrm{D,bulk}}. \tag{E.56}$$

At equality, the active FCC constitutive coordinates terminate and the local structure enters the saturated phase-transition regime.

The tangent incompressibility parameter and the finite saturation pressure have distinct roles:

$$B_{\mathrm{IC}} \to \infty, \qquad \nabla \cdot \mathbf{u} = 0, \tag{E.57}$$

whereas

$$\tau_{\mathrm{D,bulk}} < \infty \tag{E.58}$$

sets the maximum quasistatic pressure sustainable by the active FCC phase. Therefore,

$$B_{\mathrm{IC}} \neq \tau_{\mathrm{D,bulk}}. \tag{E.59}$$

The total incremental stress about the preloaded state is

$$\delta\sigma_{ij} = -\delta p_{\mathrm{IC}} \delta_{ij} + 2K_{\mathrm{sh}}^{(0)} \varepsilon_{ij}, \tag{E.60}$$

and the corresponding total stress may be written

$$\sigma_{ij} = -\overline{p}_{\mathrm{IC}} \delta_{ij} - \delta p_{\mathrm{IC}} \delta_{ij} + 2K_{\mathrm{sh}}^{(0)} \varepsilon_{ij}. \tag{E.61}$$

The background term satisfies the quasistatic equilibrium equations independently of the incremental disturbance. Finite-deformation geometric-stiffness corrections from the preload are outside the retained tangent order.

Using

$$\alpha_{\mathrm{G}} = \frac{\overline{p}_{\mathrm{IC}}}{\tau_{\mathrm{D,bulk}}}, \tag{E.62}$$

the locally uniform endpoint-transfer factor becomes

$$\mathcal{C} = \left(1 - \frac{\overline{p}_{\mathrm{IC}}}{\tau_{\mathrm{D,bulk}}}\right)^2, \tag{E.63}$$

and the referred coherent inertia is

$$\rho_{\mathrm{eff}} = \frac{\rho_{\mathrm{eff}}^{(0)}}{\left(1 - \overline{p}_{\mathrm{IC}}/\tau_{\mathrm{D,bulk}}\right)^4}. \tag{E.64}$$

The transverse propagation speed is therefore

$$c_{\mathrm{P}} = c_{\mathrm{E}} \left(1 - \frac{\overline{p}_{\mathrm{IC}}}{\tau_{\mathrm{D,bulk}}}\right)^2. \tag{E.65}$$

The static longitudinal pressure and the dynamic transverse propagation law are thus coupled through the occupied active capacity while remaining mechanically distinct.

E.6 Phase-Sector Status and Translational Acoustic Mode Count

The objective contact action developed in Appendix D contains the internal phase difference

$$\Delta\varphi_{ij} = \varphi_j - \varphi_i, \tag{E.66}$$

with local phase energy

$$\mathcal{U}_{\varphi}^{(ij)} = \kappa_{\varphi} r_{\mathrm{D}}^2 \left[1 - \cos(\Delta\varphi_{ij})\right]. \tag{E.67}$$

In the harmonic regime,

$$\mathcal{U}_{\varphi}^{(ij)} = \frac{1}{2}\kappa_{\varphi} r_{\mathrm{D}}^2 (\Delta\varphi_{ij})^2 + \mathcal{O}\left((\Delta\varphi_{ij})^4\right). \tag{E.68}$$

Because the contact energy depends only on phase differences, the uniform transformation

$$\varphi_i \to \varphi_i + \varphi_0 \tag{E.69}$$

is a null direction of the phase-difference potential.

This fact does not establish an independent propagating bulk phase mode. Such a mode requires a separately derived phase kinetic sector, which is not supplied by the present constitutive reduction. The phase coordinate may therefore represent an independent propagating field, a constrained internal coordinate, or a defect-confined degree of freedom depending on the completed microscopic dynamics. That classification remains open.

The mode count established here applies only to the translational acoustic sector. The coherent constraint

$$\nabla \cdot \mathbf{u} = 0 \tag{E.70}$$

removes the longitudinal translational polarization and leaves two finite-frequency transverse translational polarizations.

For either transverse polarization,

$$\mathbf{k} \cdot \mathbf{e}_{\mathrm{T}} = 0, \tag{E.71}$$

with the long-wavelength relation

$$\omega_{\mathrm{T}}^2 = c_{\mathrm{E}}^2 (1 - \alpha_{\mathrm{G}})^4 k^2 \left[1 + o(1)\right]. \tag{E.72}$$

Under the leading isotropy condition

$$\kappa_{\mathrm{n}} = \kappa_{\mathrm{t}}, \tag{E.73}$$

the two transverse translational modes are degenerate at leading long-wavelength order. The selected reduced photon branch preserves this two-component degeneracy and is developed in Appendix AP. Finite-wave-number cubic anisotropy, chiral structure, nonuniform loading, higher-gradient contact terms, or additional phase–rotation coupling may lift that degeneracy in the completed parent theory.

Microrotational, torsional, internal-phase, chiral, and localized-defect modes remain outside this translational acoustic mode count.

E.7 Localized Defect–Condensate Relative-Flow Kinematics

The coherent branch satisfies

$$\mathbf{v}_{\mathrm{rel}} = \dot{\mathbf{w}} - \dot{\mathbf{u}} = \mathbf{0}. \tag{E.74}$$

A localized topological defect defines a distinct kinematic sector in which translation, boundary deformation, or internal reconfiguration can induce condensate motion relative to the local FCC scaffold:

$$\mathbf{v}_{\mathrm{rel}} \neq \mathbf{0}. \tag{E.75}$$

Let $\Omega_{\mathrm{IC}}^{(\mathrm{def})}$ denote the connected interstitial-condensate domain influenced by the defect and $\partial\Omega_{\mathrm{def}}$ the effective defect–condensate interface.

A single localized mode is described by a generalized coordinate $q(t)$ with

$$[q] = \mathrm{m}. \tag{E.76}$$

This length-valued normalization ensures that the boundary mode is dimensionless. Dimensionless internal coordinates require a separate coordinate metric and are not included in this scalar translational normalization.

Represent a material point on the defect boundary by

$$\mathbf{X}_{\partial} = \mathbf{X}_{\partial}(\boldsymbol{s}, q), \tag{E.77}$$

and define

$$\mathbf{b}_{\partial} \equiv \frac{\partial \mathbf{X}_{\partial}}{\partial q}, \qquad [\mathbf{b}_{\partial}] = 1. \tag{E.78}$$

The boundary velocity relative to the scaffold is

$$\dot{\mathbf{X}}_{\partial}^{(\mathrm{rel})} = \dot{q}\mathbf{b}_{\partial}. \tag{E.79}$$

For a linearized localized response,

$$\mathbf{v}_{\mathrm{rel}}(\mathbf{x}, t) = \dot{q}(t)\boldsymbol{\Upsilon}(\mathbf{x}), \tag{E.80}$$

where $\boldsymbol{\Upsilon}$ is the dimensionless condensate response to unit generalized defect velocity.

The field $\boldsymbol{\Upsilon}$ depends on defect geometry, interstitial connectivity, outer boundary conditions, and the selected mode. At conservative inviscid order, the no-penetration condition is

$$\boldsymbol{\Upsilon} \cdot \hat{\mathbf{n}}_{\mathrm{d}} = \mathbf{b}_{\partial} \cdot \hat{\mathbf{n}}_{\mathrm{d}} \qquad \text{on } \partial\Omega_{\mathrm{def}}, \tag{E.81}$$

where $\hat{\mathbf{n}}_{\mathrm{d}}$ points from the defect into the condensate.

Only the normal boundary velocity is transmitted by this baseline inviscid condition. Tangential defect motion requires an additional tangential traction, interfacial locking, or no-slip law to contribute to the condensate response.

The kinetic contribution generated by $\boldsymbol{\Upsilon}$ is therefore an added inertia of the localized defect coordinate, not an independent contribution to the coherent acoustic inertia.

E.8 Conservative Defect-Flow Boundary-Value Problem

The localized interstitial-condensate response is incrementally incompressible:

$$\nabla \cdot \boldsymbol{\Upsilon} = 0 \tag{E.82}$$

throughout $\Omega_{\mathrm{IC}}^{(\mathrm{def})}$.

On the minimum-energy zero-circulation branch,

$$\nabla \times \boldsymbol{\Upsilon} = \mathbf{0}, \tag{E.83}$$

so that

$$\boldsymbol{\Upsilon} = \nabla \Phi_{\mathrm{rel}}. \tag{E.84}$$

Since $[\boldsymbol{\Upsilon}] = 1$,

$$[\Phi_{\mathrm{rel}}] = \mathrm{m}. \tag{E.85}$$

The physical velocity potential is $\dot{q}\Phi_{\mathrm{rel}}$.

The reduced potential satisfies

$$\nabla^2 \Phi_{\mathrm{rel}} = 0 \tag{E.86}$$

within $\Omega_{\mathrm{IC}}^{(\mathrm{def})}$, with the inner boundary condition

$$\frac{\partial \Phi_{\mathrm{rel}}}{\partial n_{\mathrm{d}}} = \mathbf{b}_{\partial} \cdot \hat{\mathbf{n}}_{\mathrm{d}} \qquad \text{on } \partial\Omega_{\mathrm{def}}. \tag{E.87}$$

For an isolated defect in an unbounded condensate domain,

$$\nabla \Phi_{\mathrm{rel}} \to \mathbf{0} \qquad \text{as } |\mathbf{x}| \to \infty. \tag{E.88}$$

For a periodic FCC calculation, the corresponding periodic boundary conditions and cell-scale flux constraint replace the far-field condition.

Let $\partial\Omega_{\mathrm{out}}$ denote the outer boundary of the condensate domain. Flux compatibility requires

$$-\int_{\partial\Omega_{\mathrm{def}}} \mathbf{b}_{\partial} \cdot \hat{\mathbf{n}}_{\mathrm{d}} \, \mathrm{d}A + \int_{\partial\Omega_{\mathrm{out}}} \boldsymbol{\Upsilon} \cdot \hat{\mathbf{n}}_{\mathrm{out}} \, \mathrm{d}A = 0. \tag{E.89}$$

For an isolated defect with vanishing far-field flux,

$$\int_{\partial\Omega_{\mathrm{def}}} \mathbf{b}_{\partial} \cdot \hat{\mathbf{n}}_{\mathrm{d}} \, \mathrm{d}A = 0. \tag{E.90}$$

Rigid translation satisfies this condition because

$$\int_{\partial\Omega_{\mathrm{def}}} \hat{\mathbf{n}}_{\mathrm{d}}\,\mathrm{d}A = \mathbf{0}. \tag{E.91}$$

A purely radial breathing mode that changes the enclosed defect volume does not satisfy the isolated-domain condition unless its flux is balanced by outer-boundary flow, compensating scaffold deformation, or a coupled phase-conversion process. It is therefore not an admissible isolated perturbation of the strictly incompressible conservative branch.

The conservative response may equivalently be characterized as

$$\boldsymbol{\Upsilon} = \arg\min_{\mathbf{v}} \int_{\Omega_{\mathrm{IC}}^{(\mathrm{def})}} |\mathbf{v}|^2\,\mathrm{d}V, \tag{E.92}$$

subject to

$$\nabla\cdot\mathbf{v} = 0, \qquad \mathbf{v}\cdot\hat{\mathbf{n}}_{\mathrm{d}} = \mathbf{b}_{\partial}\cdot\hat{\mathbf{n}}_{\mathrm{d}} \qquad \text{on } \partial\Omega_{\mathrm{def}}, \tag{E.93}$$

together with the selected outer-boundary condition.

A circulation-carrying or chiral defect requires

$$\boldsymbol{\Upsilon} = \nabla\Phi_{\mathrm{rel}} + \boldsymbol{\Upsilon}_{\mathrm{circ}}, \tag{E.94}$$

with

$$\nabla\cdot\boldsymbol{\Upsilon}_{\mathrm{circ}} = 0, \qquad \nabla\times\boldsymbol{\Upsilon}_{\mathrm{circ}} \neq \mathbf{0}. \tag{E.95}$$

Such branches lie outside the baseline zero-circulation impedance projection. For a prescribed admissible geometry, boundary mode, and outer condition, the Neumann problem determines Φ_{rel} up to an additive constant on a simply connected domain. Multiply connected domains may additionally contain harmonic circulation sectors that require separate specification.

E.9 Normal Boundary Weighting and Impedance Projection

The conservative boundary-value problem transmits the normal component of the defect-boundary velocity into the interstitial condensate. Define

$$b_{\mathrm{n}}(\boldsymbol{s}) \equiv \mathbf{b}_{\partial}(\boldsymbol{s})\cdot\hat{\mathbf{n}}_{\mathrm{d}}(\boldsymbol{s}). \tag{E.96}$$

The mode-weighted normal interface area is

$$A_{\mathrm{imp}}^{(\mathrm{n})} \equiv \int_{\partial\Omega_{\mathrm{def}}} |b_{\mathrm{n}}|^2\,\mathrm{d}A, \qquad [A_{\mathrm{imp}}^{(\mathrm{n})}] = \mathrm{m}^2. \tag{E.97}$$

The quantity $A_{\mathrm{imp}}^{(\mathrm{n})}$ is not generally the total geometric defect area. It is the normal-coupled modal area transmitted by the no-penetration condition; boundary regions with vanishing normal motion do not contribute.

The condensate participation volume is

$$V_{\mathrm{imp}} \equiv \int_{\Omega_{\mathrm{IC}}^{(\mathrm{def})}} |\boldsymbol{\Upsilon}|^2\,\mathrm{d}V, \qquad [V_{\mathrm{imp}}] = \mathrm{m}^3. \tag{E.98}$$

It is an inertia-weighted participation volume rather than the geometric volume of the entire connected interstitial domain.

Define the localized impedance projection by

$$\iota_{\mathrm{V}}^{(\mathrm{def})} \equiv \frac{A_{\mathrm{imp}}^{(\mathrm{n})}}{V_{\mathrm{imp}}}, \qquad [\iota_{\mathrm{V}}^{(\mathrm{def})}] = \mathrm{m}^{-1}. \tag{E.99}$$

This quantity must be distinguished from the periodic FCC scaffold modal projection established in Appendix D,

$$\iota_{\mathrm{tr}}^{(\mathrm{modal})} = \frac{A_{\mathrm{ct}}^{(\mathrm{modal})}}{V_{\mathrm{p}}} = \frac{\rho_{\mathrm{sh}}^{(\mathrm{micro},0)}}{\mu_{\mathrm{D}}}. \tag{E.100}$$

The two projections satisfy

$$\iota_{\mathrm{V}}^{(\mathrm{def})} \not\equiv \iota_{\mathrm{tr}}^{(\mathrm{modal})}. \tag{E.101}$$

The quantity $\iota_{\mathrm{tr}}^{(\mathrm{modal})}$ belongs to the periodic scaffold normalization, whereas $\iota_{\mathrm{V}}^{(\mathrm{def})}$ belongs to a localized relative-condensate-flow boundary-value problem. Equality requires an independent demonstration that the corresponding mode functionals coincide.

In terms of the solved fields,

$$\iota_{\mathrm{V}}^{(\mathrm{def})} = \frac{\displaystyle\int_{\partial\Omega_{\mathrm{def}}} |\mathbf{b}_{\partial} \cdot \hat{\mathbf{n}}_{\mathrm{d}}|^2 \, \mathrm{d}A}{\displaystyle\int_{\Omega_{\mathrm{IC}}^{(\mathrm{def})}} |\boldsymbol{\Upsilon}|^2 \, \mathrm{d}V}. \tag{E.102}$$

The projection is invariant under a dimensionless rescaling $q' = aq$, since

$$\mathbf{b}'_{\partial} = a^{-1}\mathbf{b}_{\partial}, \qquad \boldsymbol{\Upsilon}' = a^{-1}\boldsymbol{\Upsilon}, \tag{E.103}$$

implies

$$A_{\mathrm{imp}}^{(\mathrm{n})\prime} = a^{-2} A_{\mathrm{imp}}^{(\mathrm{n})}, \qquad V'_{\mathrm{imp}} = a^{-2} V_{\mathrm{imp}}, \qquad \iota_{\mathrm{V}}^{(\mathrm{def})\prime} = \iota_{\mathrm{V}}^{(\mathrm{def})}. \tag{E.104}$$

Define the effective impedance penetration length by

$$\ell_{\mathrm{imp}}^{(\mathrm{def})} \equiv \frac{V_{\mathrm{imp}}}{A_{\mathrm{imp}}^{(\mathrm{n})}}, \tag{E.105}$$

so that

$$\iota_{\mathrm{V}}^{(\mathrm{def})} = \frac{1}{\ell_{\mathrm{imp}}^{(\mathrm{def})}}. \tag{E.106}$$

The quantity $\ell_{\mathrm{imp}}^{(\mathrm{def})}$ is a mode measure and need not equal the defect radius, shell thickness, or lattice spacing.

The empirical convention

$$\iota_{\mathrm{V}} = 1 \ \mathrm{m}^{-1} \tag{E.107}$$

corresponds to

$$\ell_{\mathrm{imp}} = 1 \ \mathrm{m}, \tag{E.108}$$

and remains a calibration assumption until a specified defect-flow boundary-value problem produces the same mode-integral ratio.

E.10 Mode-Resolved Condensate Impedance Density

Adopt the reduced normal-coupled surface normalization

$$T_{\partial}^{(\mathrm{n})} \equiv \frac{1}{2}\mu_{\mathrm{D}} A_{\mathrm{imp}}^{(\mathrm{n})} \dot{q}^2. \tag{E.109}$$

This is a constitutive interface representation of the condensate-coupled normal mode. The coefficient μ_{D} serves as the baseline surface-inertia normalization of the coupled interface response; it is not identified with an intrinsic volumetric density of the interstitial condensate.

Represent the same reduced kinetic coefficient in volumetric form as

$$T_{\mathrm{vol}} \equiv \frac{1}{2}\rho_{\mathrm{IC}}^{(\mathrm{imp})} V_{\mathrm{imp}} \dot{q}^2. \tag{E.110}$$

Equivalence of the two representations gives

$$\mu_{\mathrm{D}} A_{\mathrm{imp}}^{(\mathrm{n})} = \rho_{\mathrm{IC}}^{(\mathrm{imp})} V_{\mathrm{imp}}, \tag{E.111}$$

and therefore

$$\rho_{\mathrm{IC}}^{(\mathrm{imp})} \equiv \mu_{\mathrm{D}} \iota_{\mathrm{V}}^{(\mathrm{def})} = \frac{\mu_{\mathrm{D}}}{\ell_{\mathrm{imp}}^{(\mathrm{def})}}. \tag{E.112}$$

Its dimensions are

$$[\rho_{\mathrm{IC}}^{(\mathrm{imp})}] = \mathrm{kg\,m^{-3}}. \tag{E.113}$$

The quantity $\rho_{\mathrm{IC}}^{(\mathrm{imp})}$ is an equivalent mode-resolved impedance density associated with the localized relative-flow coordinate. It is neither automatically the intrinsic equilibrium density of the condensate nor an independently additive density of the coherent scaffold coordinate.

The corresponding conservative added-inertia coefficient is

$$m_{\mathrm{add}} = \mu_{\mathrm{D}} A_{\mathrm{imp}}^{(\mathrm{n})} = \rho_{\mathrm{IC}}^{(\mathrm{imp})} V_{\mathrm{imp}}. \tag{E.114}$$

This coefficient belongs exclusively to the localized relative-condensate-flow problem. It must not be added to the primitive-cell scaffold inertia $\rho_{\mathrm{sh}}^{(\mathrm{micro},0)}$ merely because the condensate is entrained in the coherent branch. Any independently additive coherent condensate kinetic coefficient requires an explicit coupled two-field kinetic action.

The localized projection may depend on geometry, topology, boundary mode, and outer condition,

$$\iota_{\mathrm{V}}^{(\mathrm{def})} = \iota_{\mathrm{V}}^{(\mathrm{def})}\left(\text{geometry}, \text{topology}, \text{boundary mode}, \text{outer condition}\right). \tag{E.115}$$

In a conservative frequency-dependent calculation, the response may define a real nonnegative projection $\iota_{\mathrm{V}}^{(\mathrm{def})}(\omega)$ with quasistatic limit

$$\iota_{\mathrm{V},0}^{(\mathrm{def})} \equiv \lim_{\omega\to 0} \iota_{\mathrm{V}}^{(\mathrm{def})}(\omega), \tag{E.116}$$

provided the limit exists.

A dissipative complex impedance is a distinct response object and must be defined through a force–velocity relation such as

$$\widehat{Q}_{\mathrm{def}}(\omega) = \mathcal{Z}_{\mathrm{def}}(\omega)\widehat{\dot{q}}(\omega). \tag{E.117}$$

It cannot be obtained by assigning an imaginary part to the positive norm ratio $A_{\mathrm{imp}}^{(\mathrm{n})}/V_{\mathrm{imp}}$. Dissipative and radiative corrections therefore lie outside the conservative action retained here. The localized defect impedance $\mathcal{Z}_{\mathrm{def}}(\omega)$ is not identified with the propagating-photon response developed in Appendix AP.

A universal condensate impedance density may be introduced only if $\iota_{\mathrm{V},0}^{(\mathrm{def})}$ is common to a specified stable defect class. Otherwise the mode-resolved notation $\rho_{\mathrm{IC}}^{(\mathrm{imp})}$ must be retained.

E.11 Reduced Swept-Volume Approximation for Localized Defects

The exact participation volume is

$$V_{\mathrm{imp}} = \int_{\Omega_{\mathrm{IC}}^{(\mathrm{def})}} |\boldsymbol{\Upsilon}|^2 \, \mathrm{d}V. \tag{E.118}$$

For comparison with the thin-layer defect parametrization, consider a structural layer of equilibrium thickness r_{amp} surrounding a spherical Soft Floor node of radius r_{D}. Its geometric shell volume is

$$V_{\mathrm{sweep}} = \frac{4\pi}{3} \left[(r_{\mathrm{D}} + r_{\mathrm{amp}})^3 - r_{\mathrm{D}}^3 \right]. \tag{E.119}$$

Expanding,

$$V_{\mathrm{sweep}} = 4\pi r_{\mathrm{D}}^2 r_{\mathrm{amp}} \left[1 + \frac{r_{\mathrm{amp}}}{r_{\mathrm{D}}} + \frac{1}{3} \left(\frac{r_{\mathrm{amp}}}{r_{\mathrm{D}}} \right)^2 \right]. \tag{E.120}$$

Hence, for $r_{\mathrm{amp}} \ll r_{\mathrm{D}}$,

$$V_{\mathrm{sweep}} = 4\pi r_{\mathrm{D}}^2 r_{\mathrm{amp}} \left[1 + \mathcal{O}\left(\frac{r_{\mathrm{amp}}}{r_{\mathrm{D}}} \right) \right]. \tag{E.121}$$

Define the leading geometric shell volume by

$$V_{\mathrm{eff}} \equiv 4\pi r_{\mathrm{D}}^2 r_{\mathrm{amp}}. \tag{E.122}$$

The kinetic participation volume need not equal this geometric volume. Define

$$\mathcal{G}_{\mathrm{imp}} \equiv \frac{V_{\mathrm{imp}}}{V_{\mathrm{sweep}}}. \tag{E.123}$$

The value of $\mathcal{G}_{\mathrm{imp}}$ is determined by the solved defect mode and may depend on geometry, boundary kinematics, and $r_{\mathrm{amp}}/r_{\mathrm{D}}$. A controlled thin-layer reduction requires a finite limiting value of $\mathcal{G}_{\mathrm{imp}}$ for the selected defect family.

Then

$$V_{\mathrm{imp}} = 4\pi \mathcal{G}_{\mathrm{imp}} r_{\mathrm{D}}^2 r_{\mathrm{amp}} \left[1 + \mathcal{O}\left(\frac{r_{\mathrm{amp}}}{r_{\mathrm{D}}} \right) \right]. \tag{E.124}$$

The closure $\mathcal{G}_{\mathrm{imp}} = 1$ is therefore mode-specific rather than geometric.

Using $m_{\mathrm{add}} = \rho_{\mathrm{IC}}^{(\mathrm{imp})} V_{\mathrm{imp}}$,

$$m_{\mathrm{add}} = 4\pi r_{\mathrm{D}}^2 \rho_{\mathrm{IC}}^{(\mathrm{imp})} \mathcal{G}_{\mathrm{imp}} r_{\mathrm{amp}} \left[1 + \mathcal{O}\left(\frac{r_{\mathrm{amp}}}{r_{\mathrm{D}}} \right) \right]. \tag{E.125}$$

Define

$$K_{\mathrm{D}}^{(\mathrm{def})} \equiv 4\pi r_{\mathrm{D}}^2 \rho_{\mathrm{IC}}^{(\mathrm{imp})} \mathcal{G}_{\mathrm{imp}} = 4\pi r_{\mathrm{D}}^2 \mu_{\mathrm{D}} \iota_{\mathrm{V}}^{(\mathrm{def})} \mathcal{G}_{\mathrm{imp}}. \tag{E.126}$$

Then

$$m_{\mathrm{add}} = K_{\mathrm{D}}^{(\mathrm{def})} r_{\mathrm{amp}} \left[1 + \mathcal{O}\left(\frac{r_{\mathrm{amp}}}{r_{\mathrm{D}}} \right) \right], \tag{E.127}$$

with

$$[K_{\mathrm{D}}^{(\mathrm{def})}] = \mathrm{kg\,m^{-1}}. \tag{E.128}$$

The reduced relation $K_{\mathrm{D}} = 4\pi r_{\mathrm{D}}^2 \rho_{\mathrm{IC}}$ is recovered only when the projected impedance density is universal within the selected defect class and $\mathcal{G}_{\mathrm{imp}} = 1$.

E.12 Phase-Participation Function and Branch-Level Sine Closure

The localized boundary-value problem fixes the hydrodynamic inertia of a prescribed reference defect mode. A multiplicative phase law is admissible only when the phase dependence can be separated from the reference geometry and normalized flow field.

Under that factorization, introduce the nonnegative periodic participation function

$$0 \le f_\varphi(\Delta\varphi) \le 1. \tag{E.129}$$

For a spatially uniform phase mismatch,

$$T_{\mathrm{def}} = \frac{1}{2}\rho_{\mathrm{IC}}^{(\mathrm{imp})} V_{\mathrm{imp}} f_\varphi(\Delta\varphi)\dot{q}^2, \tag{E.130}$$

so that

$$M_{\mathrm{top}}(\Delta\varphi) = \rho_{\mathrm{IC}}^{(\mathrm{imp})} V_{\mathrm{imp}} f_\varphi(\Delta\varphi). \tag{E.131}$$

The factorization must not double-count phase dependence. If $\mathbf{b}_\partial$, Ω_{def}, or $\boldsymbol{\Upsilon}$ already depends explicitly on $\Delta\varphi$, the phase-dependent boundary-value functional is primary and an additional multiplicative f_φ may be introduced only after a nonredundant separation is established.

The participation function satisfies

$$f_\varphi(\Delta\varphi + 2\pi) = f_\varphi(\Delta\varphi). \tag{E.132}$$

For an unpolarized reciprocal defect sector,

$$f_\varphi(-\Delta\varphi) = f_\varphi(\Delta\varphi), \tag{E.133}$$

whereas an individual chiral branch need not be even.

For a phase-created defect in the factorized description,

$$f_\varphi(0) = 0. \tag{E.134}$$

If a geometric boundary persists at phase matching, its phase-independent added inertia must instead be retained separately,

$$M_{\mathrm{add}}(\Delta\varphi) = M_{\mathrm{geom}} + M_\varphi f_\varphi(\Delta\varphi). \tag{E.135}$$

The sine closure is admissible branchwise. On the positive branch,

$$f_\varphi(\Delta\varphi) = \sin(\Delta\varphi), \qquad 0 \le \Delta\varphi \le \pi, \tag{E.136}$$

while on the reciprocal negative branch,

$$f_\varphi(\Delta\varphi) = -\sin(\Delta\varphi), \qquad -\pi \le \Delta\varphi \le 0. \tag{E.137}$$

The reciprocal nonnegative envelope is therefore

$$f_\varphi^{(\mathrm{rec})}(\Delta\varphi) = |\sin(\Delta\varphi)|. \tag{E.138}$$

The sign of $\sin(\Delta\varphi)$ may encode orientation in a chiral force or circulation sector, but it cannot make the quadratic inertial coefficient negative.

For a nonuniform phase mismatch, the phase factor remains inside the weighted boundary integral,

$$T_{\mathrm{def}} = \frac{1}{2}\mu_{\mathrm{D}}\dot{q}^2 \int_{\partial\Omega_{\mathrm{def}}} |\mathbf{b}_\partial \cdot \hat{\mathbf{n}}_{\mathrm{d}}|^2 f_\varphi[\Delta\varphi(\boldsymbol{s})]\,\mathrm{d}A. \tag{E.139}$$

The scalar factorization therefore assumes a phase mismatch that is uniform, or effectively uniform under the normal-mode weighting, over the active interface.

E.13 Recovery Conditions for the Hydrodynamic Mass Law

For a factorized reference defect mode,

$$M_{\mathrm{top}} = \rho_{\mathrm{IC}}^{(\mathrm{imp})} V_{\mathrm{imp}} f_{\varphi}(\Delta\varphi). \tag{E.140}$$

Using the thin-layer reduction,

$$M_{\mathrm{top}} = K_{\mathrm{D}}^{(\mathrm{def})} r_{\mathrm{amp}} f_{\varphi}(\Delta\varphi) \left[1 + \mathcal{O}\left(\frac{r_{\mathrm{amp}}}{r_{\mathrm{D}}}\right)\right]. \tag{E.141}$$

The historical hydrodynamic mass law is recovered at leading order under

$$r_{\mathrm{amp}} \ll r_{\mathrm{D}}, \qquad \mathcal{G}_{\mathrm{imp}} = 1, \qquad \rho_{\mathrm{IC}}^{(\mathrm{imp})} = \rho_{\mathrm{IC}}, \tag{E.142}$$

together with a uniform factorized phase mismatch and the positive-branch closure

$$f_{\varphi}(\Delta\varphi) = \sin(\Delta\varphi), \qquad 0 \le \Delta\varphi \le \pi. \tag{E.143}$$

Here $\rho_{\mathrm{IC}}^{(\mathrm{imp})} = \rho_{\mathrm{IC}}$ is a universality closure for the projected defect impedance density; it does not identify ρ_{IC} with an independently derived intrinsic equilibrium condensate density.

With

$$V_{\mathrm{eff}} = 4\pi r_{\mathrm{D}}^2 r_{\mathrm{amp}}, \tag{E.144}$$

the leading reduction is

$$M_{\mathrm{top}} = \rho_{\mathrm{IC}} V_{\mathrm{eff}} \sin(\Delta\varphi) \left[1 + \mathcal{O}\left(\frac{r_{\mathrm{amp}}}{r_{\mathrm{D}}}\right)\right]. \tag{E.145}$$

Defining

$$K_{\mathrm{D}} = 4\pi r_{\mathrm{D}}^2 \rho_{\mathrm{IC}}, \tag{E.146}$$

gives

$$M_{\mathrm{top}} = K_{\mathrm{D}} r_{\mathrm{amp}} \sin(\Delta\varphi) \left[1 + \mathcal{O}\left(\frac{r_{\mathrm{amp}}}{r_{\mathrm{D}}}\right)\right]. \tag{E.147}$$

Thus the historical expression is a controlled thin-layer reduction of the mode-resolved boundary-value formulation rather than the unrestricted microscopic law.

For the reciprocal envelope,

$$M_{\mathrm{top}} = \rho_{\mathrm{IC}} V_{\mathrm{eff}} |\sin(\Delta\varphi)|. \tag{E.148}$$

When a persistent impermeable boundary remains at phase matching,

$$M_{\mathrm{add}} = M_{\mathrm{geom}} + \rho_{\mathrm{IC}}^{(\mathrm{imp})} V_{\mathrm{imp}} f_{\varphi}(\Delta\varphi). \tag{E.149}$$

This localized added inertia is distinct from the coherent primitive-cell scaffold inertia.

Under the TFT identification that the same mode-resolved topological loading serves as both the inertial coefficient and the coupling coefficient of the restorative tension potential,

$$m_{\mathrm{i}} = M_{\mathrm{top}}, \qquad \mathbf{F}_{\mathrm{grav}} = -M_{\mathrm{top}} \nabla \Phi_{\tau}, \tag{E.150}$$

one obtains

$$\mathbf{a} = \frac{\mathbf{F}_{\mathrm{grav}}}{m_{\mathrm{i}}} = -\nabla \Phi_{\tau}. \tag{E.151}$$

This cancellation is conditional on using the same normalized loading functional in both the inertial and restorative couplings; it is not an independent derivation of that identification.

E.14 Empirical Projection and Defect-Flow Calibration

The localized projection

$$\iota_{\mathrm{V}}^{(\mathrm{def})} = \frac{\displaystyle\int_{\partial\Omega_{\mathrm{def}}} |\mathbf{b}_{\partial} \cdot \hat{\mathbf{n}}_{\mathrm{d}}|^2 \, \mathrm{d}A}{\displaystyle\int_{\Omega_{\mathrm{IC}}^{(\mathrm{def})}} |\boldsymbol{\Upsilon}|^2 \, \mathrm{d}V} \tag{E.152}$$

is fully defined once the defect boundary, boundary mode, connected interstitial domain, and outer condition are specified. Its numerical value remains undetermined until the corresponding boundary-value problem is solved.

The assignment

$$\iota_{\mathrm{V}} = 1 \ \mathrm{m}^{-1} \tag{E.153}$$

is therefore empirical. It corresponds to

$$\ell_{\mathrm{imp}} = 1 \ \mathrm{m}, \tag{E.154}$$

and gives

$$\rho_{\mathrm{IC}}^{(\mathrm{emp})} = \mu_{\mathrm{D}} \left(1 \ \mathrm{m}^{-1}\right). \tag{E.155}$$

For $\mathcal{G}_{\mathrm{imp}} = 1$,

$$K_{\mathrm{D}}^{(\mathrm{emp})} = 4\pi r_{\mathrm{D}}^2 \mu_{\mathrm{D}} \left(1 \ \mathrm{m}^{-1}\right). \tag{E.156}$$

The particle-amplitude calibration depends explicitly on the adopted projection scale. With the existing interstitial-volume coefficient,

$$r_{\mathrm{D}}(\iota_{\mathrm{V}}) = \left(\frac{G m_{\mathrm{VEV}}}{5.8722 \, c_{\mathrm{E}}^2 \iota_{\mathrm{V}}}\right)^{1/2}, \tag{E.157}$$

so that

$$r_{\mathrm{D}} \propto \iota_{\mathrm{V}}^{-1/2}. \tag{E.158}$$

Consequently, calibrations using $\rho_{\mathrm{IC}} = \mu_{\mathrm{D}} \iota_{\mathrm{V}}$ inherit the adopted projection scale. A revised microscopic projection propagates into r_{D}, μ_{D}, ρ_{IC}, K_{D}, M_{top}, and quantities derived from them.

A complete microscopic calculation must solve the normal-flow problem in the connected FCC interstitial geometry with controlled outer conditions and demonstrate numerical convergence. Its conservative low-frequency limit must satisfy

$$\lim_{\omega \to 0} \iota_{\mathrm{V}}^{(\mathrm{def})}(\omega) = \iota_{\mathrm{V},0}^{(\mathrm{def})}, \tag{E.159}$$

provided the limit exists.

A universal projected impedance density may be defined only if this limit is common to a specified stable defect class,

$$\iota_{\mathrm{V},0}^{(\mathrm{def})} = \iota_{\mathrm{V},0}. \tag{E.160}$$

Then

$$\rho_{\mathrm{IC}} \equiv \mu_{\mathrm{D}} \iota_{\mathrm{V},0}. \tag{E.161}$$

Under this closure, ρ_{IC} is a universal projected impedance density for that defect class, not an independently established intrinsic equilibrium density of the condensate.

If a common geometry factor $\mathcal{G}_0$ also exists,

$$K_{\mathrm{D}} = 4\pi r_{\mathrm{D}}^2 \mu_{\mathrm{D}} \iota_{\mathrm{V},0} \mathcal{G}_0. \tag{E.162}$$

The historical relation $K_{\mathrm{D}} = 4\pi r_{\mathrm{D}}^2 \rho_{\mathrm{IC}}$ follows only for $\mathcal{G}_0 = 1$. Otherwise the defect-resolved quantities $\rho_{\mathrm{IC}}^{(\mathrm{imp})}$, $\iota_{\mathrm{V}}^{(\mathrm{def})}$, and $K_{\mathrm{D}}^{(\mathrm{def})}$ must be retained.

The conservative structure is therefore precise. The coherent branch satisfies $\mathbf{v}_{\mathrm{rel}} = \mathbf{0}$ and carries two finite-frequency transverse translational modes under the incremental volume constraint. Entrainment does not independently add condensate inertia to the primitive-cell scaffold normalization. The localized branch satisfies $\mathbf{v}_{\mathrm{rel}} \neq \mathbf{0}$ and acquires a conservative hydrodynamic added inertia determined by the defect boundary-value problem. The projection $\iota_{\mathrm{V}}^{(\mathrm{def})}$, its possible universality, and the corresponding canonical defect-flow solutions remain open microscopic calculations. The separate weak nonconservative response of a propagating photon carrier is developed in Appendix AP and does not modify the conservative defect added-inertia functional established here.

Appendix F

Particle Amplitude Scales and Stability Validation

Subject: Conditional particle-amplitude calibration and structural scale-consistency test of the reduced hydrodynamic mass model.

F.1 Objective and Calibration Status

Appendix C establishes the baseline FCC surface inertia μ_{D}. Under the current empirical low-frequency volumetric projection,

$$\iota_V = 1\,\mathrm{m}^{-1}, \tag{F.1}$$

the corresponding calibrated condensate impedance density is

$$\rho_{\mathrm{IC}}^{(\mathrm{emp})} = \mu_{\mathrm{D}}\iota_V \approx 1.8074 \times 10^{53}\,\mathrm{kg\,m}^{-3}. \tag{F.2}$$

This quantity is not yet an independently derived intrinsic equilibrium density of the interstitial condensate. As developed in Appendix E, its microscopic replacement is the mode-resolved projection

$$\rho_{\mathrm{IC}}^{(\mathrm{imp})} = \mu_{\mathrm{D}}\iota_V^{(\mathrm{def})}. \tag{F.3}$$

Definition III identifies the inertial mass of a fundamental massive particle with the conservative topological loading coefficient generated by defect-induced condensate added inertia.

The present appendix applies the reduced radial thin-layer model under the calibration closures

$$\iota_V^{(\mathrm{def})} = \iota_V, \qquad \mathcal{G}_{\mathrm{imp}} = 1, \qquad f_\varphi(\Delta\varphi) = \sin(\Delta\varphi) = 1. \tag{F.4}$$

The resulting amplitudes provide a conditional structural scale check:

- **Top-Quark High-Mass Benchmark:** The inferred amplitude must remain below the FCC support-node radius,
$$r_{\mathrm{amp}} < r_{\mathrm{D}}. \tag{F.5}$$
- **Electron Low-Mass Charged Benchmark:** The inferred amplitude must remain above the Hard Floor spacing while remaining much smaller than the FCC node radius,
$$\ell_{\mathrm{S}} < r_{\mathrm{amp}} \ll r_{\mathrm{D}}. \tag{F.6}$$

These conditions test compatibility with the adopted TFT scale hierarchy. They do not independently derive the microscopic defect-flow projection, phase-participation function, or particle topology.

F.2 Reduced Mass–Amplitude Relation

A general TFT particle is a localized topological defect having a phase, torsional, radial, or mixed boundary mode. For the present calibration, the defect is represented by the leading radial breathing-mode reduction supported by an FCC node of radius r_{D}.

Appendix E gives the thin-layer relation

$$m_{\mathrm{i}} = M_{\mathrm{top}} = 4\pi r_{\mathrm{D}}^2 \mu_{\mathrm{D}} \iota_V^{(\mathrm{def})} \mathcal{G}_{\mathrm{imp}} r_{\mathrm{amp}} f_\varphi(\Delta\varphi) \left[1 + \mathcal{O}\left(\frac{r_{\mathrm{amp}}}{r_{\mathrm{D}}}\right)\right]. \tag{F.7}$$

Under the adopted calibration closures, define

$$V_{\mathrm{eff}} \equiv 4\pi r_{\mathrm{D}}^2 r_{\mathrm{amp}}, \tag{F.8}$$

and

$$K_{\mathrm{D}}^{(\mathrm{cal})} \equiv 4\pi r_{\mathrm{D}}^2 \rho_{\mathrm{IC}}^{(\mathrm{emp})}. \tag{F.9}$$

Using the calibrated TFT constants,

$$K_{\mathrm{D}}^{(\mathrm{cal})} \approx 126.07\,\mathrm{kg\,m^{-1}}. \tag{F.10}$$

The mass law therefore reduces to

$$m_{\mathrm{i}} = K_{\mathrm{D}}^{(\mathrm{cal})} r_{\mathrm{amp}} \left[1 + \mathcal{O}\left(\frac{r_{\mathrm{amp}}}{r_{\mathrm{D}}}\right)\right]. \tag{F.11}$$

At leading order,

$$r_{\mathrm{amp}} \simeq \frac{m_{\mathrm{i}}}{K_{\mathrm{D}}^{(\mathrm{cal})}}. \tag{F.12}$$

This inversion is asymptotically controlled only when

$$\frac{r_{\mathrm{amp}}}{r_{\mathrm{D}}} \ll 1. \tag{F.13}$$

F.3 Validation Case A: Top-Quark High-Mass Benchmark

The top quark is used as the high-mass fundamental-particle benchmark. Its adopted mass is

$$m_{\mathrm{t}} \approx 3.0838 \times 10^{-25}\,\mathrm{kg}. \tag{F.14}$$

The leading calibrated amplitude is

$$r_{\mathrm{amp}}^{(\mathrm{t})} \simeq \frac{3.0838 \times 10^{-25}}{126.07} \approx 2.4461 \times 10^{-27}\,\mathrm{m}. \tag{F.15}$$

The normalized amplitude is

$$\frac{r_{\mathrm{amp}}^{(\mathrm{t})}}{r_{\mathrm{D}}} = \frac{2.4461 \times 10^{-27}}{7.4504 \times 10^{-27}} \approx 0.3283. \tag{F.16}$$

Thus,

$$r_{\mathrm{amp}}^{(\mathrm{t})} < r_{\mathrm{D}}. \tag{F.17}$$

The top-quark estimate therefore satisfies the adopted geometric amplitude bound. However,

$$\frac{r_{\mathrm{amp}}^{(\mathrm{t})}}{r_{\mathrm{D}}} \approx 0.3283 \tag{F.18}$$

is not asymptotically small. The result lies in a high-amplitude regime for which nonlinear boundary geometry, phase-dependent condensate flow, and higher-order corrections may be significant.

The calculation demonstrates conditional geometric compatibility; it does not establish that the top-quark defect lies within a strictly linear thin-layer regime or prove an absolute upper mass limit.

F.4 Validation Case B: Electron Low-Amplitude Benchmark

The electron is used as the low-mass charged-particle benchmark. Its adopted mass is

$$m_{\mathrm{e}} \approx 9.1094 \times 10^{-31}\,\mathrm{kg}. \tag{F.19}$$

The leading calibrated amplitude is

$$r_{\mathrm{amp}}^{(\mathrm{e})} \simeq \frac{9.1094 \times 10^{-31}}{126.07} \approx 7.2257 \times 10^{-33}\,\mathrm{m}. \tag{F.20}$$

Using the Hard Floor spacing

$$\ell_{\mathrm{S}} \approx 1.6163 \times 10^{-35}\,\mathrm{m}, \tag{F.21}$$

the substrate-scale ratio is

$$\frac{r_{\mathrm{amp}}^{(\mathrm{e})}}{\ell_{\mathrm{S}}} = \frac{7.2257 \times 10^{-33}}{1.6163 \times 10^{-35}} \approx 447.05. \tag{F.22}$$

Relative to the FCC node radius,

$$\frac{r_{\mathrm{amp}}^{(\mathrm{e})}}{r_{\mathrm{D}}} \approx 9.70 \times 10^{-7}. \tag{F.23}$$

Therefore,

$$\ell_{\mathrm{S}} < r_{\mathrm{amp}}^{(\mathrm{e})} \ll r_{\mathrm{D}}. \tag{F.24}$$

The calibrated electron amplitude lies above the adopted Hard Floor spacing and deeply within the controlled small-amplitude FCC regime. Unlike the top-quark estimate, the electron result is mechanically compatible with the leading thin-layer expansion.

Its very small defect amplitude also remains consistent with the experimentally point-like appearance of the electron: the TFT support node retains the universal scale r_{D}, while the externally activated deformation amplitude is much smaller.

F.5 Summary

Under the empirical projection and unit geometry and phase closures, the leading amplitude estimates are summarized below.

Table F.1: Conditional Particle-Amplitude Calibration and Structural Scale Checks

Particle	**Mass (kg)**	r_{amp}	**Normalized Scale**	**Interpretation**
Top Quark	3.0838×10^{-25}	$2.4461 \times 10^{-27}\,\mathrm{m}$	$0.3283\, r_{\mathrm{D}}$	Passes the geometric amplitude bound, but is not asymptotically within the thin-layer regime. Nonlinear corrections may be significant.
Electron	9.1094×10^{-31}	$7.2257 \times 10^{-33}\,\mathrm{m}$	$447.05\,\ell_{\mathrm{S}}$, $9.70 \times 10^{-7} r_{\mathrm{D}}$	Above the adopted substrate spacing and deeply within the controlled small-amplitude regime.

Both calibrated benchmarks satisfy

$$\ell_{\mathrm{S}} < r_{\mathrm{amp}} < r_{\mathrm{D}}. \tag{F.25}$$

This establishes conditional compatibility with the TFT structural hierarchy. It does not independently validate the empirical projection

$$\iota_V = 1\,\mathrm{m}^{-1}, \tag{F.26}$$

the approximation

$$\mathcal{G}_{\mathrm{imp}} = 1, \tag{F.27}$$

or the selected maximal-participation branch

$$f_\varphi(\Delta\varphi) = 1. \tag{F.28}$$

A microscopic revision of $\iota_V^{(\mathrm{def})}$, $\mathcal{G}_{\mathrm{imp}}$, or $f_\varphi(\Delta\varphi)$ will propagate directly into the inferred particle amplitudes.

F.6 Relation to the Support-Node Resonance

The particle-dependent amplitude r_{amp} must be distinguished from the characteristic resonance scale of the fixed FCC support node.

Within the current lattice-resolution ansatz, a minimal transverse excitation with wavelength

$$\lambda_{\mathrm{min}} = 2r_{\mathrm{D}} \tag{F.29}$$

has the characteristic support-scale frequency

$$f_{\mathrm{D}} = \frac{c_{\mathrm{E}}}{2r_{\mathrm{D}}}. \tag{F.30}$$

For the reduced radial breathing-mode ansatz, one complete expansion–contraction sequence has a total geometric transit length of

$$4r_{\mathrm{D}}. \tag{F.31}$$

The corresponding characteristic frequency is

$$f_{\mathrm{m}} = \frac{c_{\mathrm{E}}}{4r_{\mathrm{D}}} = \frac{1}{2} f_{\mathrm{D}}. \tag{F.32}$$

This doubled radial transit provides a kinematic correspondence with the TFT fermion-cycle construction. It does not, by path length alone, constitute a complete derivation of spin-1/2. A complete spinorial derivation must separately demonstrate that the localized state transforms nontrivially under a 2π rotation and returns to its original physical configuration only after a 4π rotation.

Within the present rest-energy identification,

$$E_0 = m_{\mathrm{i}} c_{\mathrm{E}}^2, \tag{F.33}$$

the corresponding proper-time period is

$$t_{\mathrm{p}} = \frac{h}{E_0}. \tag{F.34}$$

For fixed topology, impedance projection, geometry factor, and phase participation, the particle-amplitude hierarchy determines the conservative topological loading and therefore the rest-energy and proper-time hierarchy. The proper-time scale is governed by conservative defect–condensate loading, not by dissipative drag.

Appendix G

The Fractal Architecture of the Spacetime Lattice

Subject: Cross-scale consistency of the action and gravitational-coupling normalizations across Substrate, Soft Floor, and Matter.

Note: This appendix does not derive h, $\hbar$, or G from parameter-free first principles. The substrate layer is normalized using empirical Planck-scale combinations, and the following relations test whether the same mass-moment structure consistently organizes the Soft Floor and nucleon layers.

G.1 Fractal Projection Principle

Appendix B introduced the raw structural mass moment ($J_i = \rho_i r_i^4$) and established the topology-normalized Scale-Invariant Mass Moment:

$$\hat{J} \equiv \frac{J_i}{\mathcal{F}_i} \tag{G.1}$$

as the absolute quantity that remains fixed under topological projection. In this appendix, that invariant is used to organize the vertical architecture of TFT across three characteristic layers:

- **Layer S (Substrate):** The Hard Floor SC lattice (ℓ_{S}), normalized by the empirical Planck-scale combinations of $\hbar$, G, and c_{E}.
- **Layer D (Soft Floor):** The vacuum FCC lattice (r_{D}), where the Planck-normalized action and coupling scales are represented at the active-vacuum level.
- **Layer N (Nucleon):** The matter vortex (r_{N}), where the same normalized action and coupling structure is represented at the matter-vortex level.

The working ansatz is that the universal action and gravitational coupling scales can be derived through layer-specific representations of this absolute invariant structure. In schematic form, the invariant macroscopic observables emerge as:

$$h \propto (\text{universal geometric factor}) \cdot \hat{J} c_{\mathrm{E}} \tag{G.2}$$

and

$$G \propto \frac{\text{constant}}{\hat{J}} \tag{G.3}$$

The remainder of this appendix develops these two projection threads in turn.

G.2 Action-Scale Consistency

G.2.1 Substrate Scale

At the Substrate level, the relevant geometry is taken to be rectilinear. The associated action scale is therefore written as

$$h_{\mathrm{S}} \approx \rho_{\mathrm{S}} c_{\mathrm{E}} \ell_{\mathrm{S}}^4 \tag{G.4}$$

Numerically,

$$h_{\mathrm{S}} \approx 1.0546 \times 10^{-34}\ \mathrm{J \cdot s} \tag{G.5}$$

which is identified, within TFT, with the reduced action scale ($\hbar$).

G.2.2 Soft Floor Scale

At the Soft Floor level, the localized node is modeled as a phase-locked sphere of radius r_{D}. The action is evaluated directly from the kinematic definition

$$h_{\mathrm{D}} = E \cdot T \tag{G.6}$$

Using the spherical energy content

$$E = \rho_{\mathrm{D}} c_{\mathrm{E}}^2 \left(\frac{4}{3} \pi r_{\mathrm{D}}^3 \right) \tag{G.7}$$

and the characteristic transit time

$$T = \frac{r_{\mathrm{D}}}{c_{\mathrm{E}}} \tag{G.8}$$

one obtains

$$h_{\mathrm{D}} = \left[\frac{4}{3} \pi \rho_{\mathrm{D}} c_{\mathrm{E}}^2 r_{\mathrm{D}}^3 \right] \left[\frac{r_{\mathrm{D}}}{c_{\mathrm{E}}} \right] = \frac{4}{3} \pi \rho_{\mathrm{D}} c_{\mathrm{E}} r_{\mathrm{D}}^4 \tag{G.9}$$

If one further substitutes the relation $\rho_{\mathrm{D}} = 1.5 \cdot \rho_{\mathrm{Q}}$ (where ρ_{Q} is the uncompressed quantum baseline density derived in Appendix L), then

$$h_{\mathrm{D}} = \frac{4}{3} \pi (1.5 \cdot \rho_{\mathrm{Q}}) c_{\mathrm{E}} r_{\mathrm{D}}^4 = 2\pi \rho_{\mathrm{Q}} c_{\mathrm{E}} r_{\mathrm{D}}^4 \tag{G.10}$$

which makes explicit the preservation of the 2π rotational structure under spherical compression.

For the adopted numerical values,

$$r_{\mathrm{D}} \approx 7.4504 \times 10^{-27}\ \mathrm{m}, \qquad \rho_{\mathrm{D}} \approx 1.7124 \times 10^{62}\ \mathrm{kg/m^3} \tag{G.11}$$

the resulting action is

$$h_{\mathrm{D}} \approx 6.6261 \times 10^{-34}\ \mathrm{J \cdot s} \tag{G.12}$$

which returns the empirical action scale under the adopted Planck-normalized projection law.

G.2.3 Matter Scale

At the nucleon level, the relevant bound state is modeled as a topological vortex. The corresponding action is written as

$$h_{\mathrm{N}} = 2\pi \rho_{\mathrm{N}} c_{\mathrm{E}} r_{\mathrm{N}}^4 \tag{G.13}$$

For

$$r_{\mathrm{N}} \approx 0.88000 \times 10^{-15}\ \mathrm{m}, \qquad \rho_{\mathrm{N}} \approx 5.8658 \times 10^{17}\ \mathrm{kg/m^3} \tag{G.14}$$

this yields

$$h_{\mathrm{N}} \approx 6.6261 \times 10^{-34}\ \mathrm{J \cdot s} \tag{G.15}$$

again returning the empirical action scale under the adopted Planck-normalized projection law.

G.2.4 Interpretation

The three layers differ in geometry, but not in the underlying invariant structure. The Substrate is rectilinear, the Soft Floor spherical, and the nucleon vortical; yet each is treated as a projection of the same structural mass moment J_i. In TFT, this is taken to indicate that matter is not an independent ontological sector, but a higher-scale geometric realization of the same conserved action structure.

G.3 Gravitational-Coupling Consistency

The gravitational constant is interpreted in TFT as the coupling efficiency between a layer-specific structural mass moment and the Substrate area

$$A_{\mathrm{S}} = \ell_{\mathrm{S}}^2 \tag{G.16}$$

The corresponding gravitational coupling projection law is written as

$$G_i = \mathcal{F}_i \left(\frac{c_{\mathrm{E}}^2 A_{\mathrm{S}}}{J_i} \right) \tag{G.17}$$

G.3.1 Substrate Scale

At the Substrate level, $\mathcal{F}_{\mathrm{S}} = 1.0$, so that

$$J_{\mathrm{S}} = \rho_{\mathrm{S}} \ell_{\mathrm{S}}^4 \tag{G.18}$$

Numerically,

$$J_{\mathrm{S}} \approx 3.5177 \times 10^{-43}\ \mathrm{kg \cdot m} \tag{G.19}$$

Hence,

$$G_{\mathrm{S}} = 1.0 \left(\frac{c_{\mathrm{E}}^2 \ell_{\mathrm{S}}^2}{\rho_{\mathrm{S}} \ell_{\mathrm{S}}^4} \right) \approx 6.6743 \times 10^{-11}\ \mathrm{m^3 \cdot kg^{-1} \cdot s^{-2}} \tag{G.20}$$

which is consistent with the empirical gravitational coupling under the adopted substrate normalization.

G.3.2 Soft Floor Scale

At the Soft Floor level, spherical coupling gives $\mathcal{F}_{\mathrm{D}} = 1.5$. The structural mass moment is

$$J_{\mathrm{D}} = \rho_{\mathrm{D}} r_{\mathrm{D}}^4 \tag{G.21}$$

Numerically,

$$J_{\mathrm{D}} \approx 5.2765 \times 10^{-43}\ \mathrm{kg \cdot m} \tag{G.22}$$

Therefore,

$$G_{\mathrm{D}} = 1.5 \left(\frac{c_{\mathrm{E}}^2 A_{\mathrm{S}}}{J_{\mathrm{D}}} \right) \approx 6.6743 \times 10^{-11}\ \mathrm{m^3 \cdot kg^{-1} \cdot s^{-2}} \tag{G.23}$$

again demonstrating consistency with the empirical gravitational coupling under the adopted substrate normalization.

G.3.3 Matter Scale

At the nucleon scale, TFT reverts to $\mathcal{F}_{\mathrm{N}} = 1.0$ for the vortical/cylindrical configuration. Using

$$J_{\mathrm{N}} = \rho_{\mathrm{N}} r_{\mathrm{N}}^4 \tag{G.24}$$

with

$$J_{\mathrm{N}} \approx 3.5177 \times 10^{-43}\ \mathrm{kg \cdot m} \tag{G.25}$$

one obtains

$$G_{\mathrm{N}} = 1.0 \left(\frac{c_{\mathrm{E}}^2 A_{\mathrm{S}}}{J_{\mathrm{N}}} \right) \approx 6.6743 \times 10^{-11}\ \mathrm{m^3 \cdot kg^{-1} \cdot s^{-2}} \tag{G.26}$$

This again confirms consistency with the empirical gravitational coupling.

G.3.4 Impedance Matching

A notable feature of the construction is the near-equality

$$J_{\mathrm{S}} \approx 3.5177 \times 10^{-43}\ \mathrm{kg \cdot m}, \qquad J_{\mathrm{N}} \approx 3.5177 \times 10^{-43}\ \mathrm{kg \cdot m} \tag{G.27}$$

Within TFT, this is interpreted as an approximate impedance match between nucleonic matter and the Substrate. This matching is one of the principal motivations for identifying the nucleon as the preferred matter-scale projection of the deeper lattice architecture.

G.4 Consolidated Verification

The foregoing relations may be summarized compactly as follows.

For action,

$$h_{\mathrm{S}} \to \hbar, \qquad h_{\mathrm{D}} \to h, \qquad h_{\mathrm{N}} \to h \tag{G.28}$$

For gravitational coupling,

$$G_{\mathrm{S}} \to G, \qquad G_{\mathrm{D}} \to G, \qquad G_{\mathrm{N}} \to G \tag{G.29}$$

These relations do not, by themselves, establish the physical interpretation uniquely. They do, however, show that the proposed mass-moment structure is numerically self-consistent within the TFT framework across all three physical scales.

G.5 Unified Interpretation

The vertical architecture may therefore be summarized in three layers.

At the Hard Floor scale, near 10^{-35} m, the Substrate provides the Planck-normalized reference scale for action and coupling.

At the Soft Floor scale, near 10^{-26} m, spherical phase-locking introduces the geometric factors required to map the active vacuum to the macroscopic observables h and G.

At the nucleon scale, near 10^{-15} m, a vortical matter configuration preserves the action scale while maintaining the Substrate coupling scale to high numerical agreement.

The TFT interpretation is thus not that these are three separate physical regimes, but that they are three geometric realizations of the same topology-normalized Scale-Invariant Mass Moment:

$$\hat{J} \equiv \frac{J_i}{\mathcal{F}_i} = \frac{\rho_i r_i^4}{\mathcal{F}_i} \tag{G.30}$$

G.6 Note on the Nucleon Radius

Experimental analyses commonly distinguish between a proton charge radius near 0.84 fm and a larger scattering/CODATA-scale radius near 0.88 fm. Within TFT, the larger value is associated with the mechanical boundary relevant to inertial and gravitational coupling of the fundamental nucleon (r_{N}), whereas the smaller value is interpreted as the proton charge-distribution radius lying within that boundary.

Accordingly, the TFT construction favors

$$r_{\mathrm{N}} \approx 0.88 \text{ fm} \tag{G.31}$$

as the mechanically relevant nucleon radius for the consistency relations developed above.

Appendix H

Global Calibration of the Active Vacuum Scale and Strain Unification

Abstract: In Tension Field Theory (TFT), the microscopic Coherence Boundary ($2r_{\mathrm{D}}$) is not derived dimensionlessly in the present formulation. It is empirically calibrated against the electroweak symmetry-breaking scale through a TFT matching ansatz between the mass-equivalent VEV scale and the hydrodynamic capacity of the interstitial phase. This appendix makes that calibration explicit, including the dependence of r_{D} on the macroscopic SI projection convention ι_{V}. It then evaluates the resulting kinematic ceiling $E_{\max}$ and shows that the calibrated scale is algebraically consistent with the macroscopic damping relation $E_{\max} \equiv h\Gamma_{\mathrm{D}} N_{\mathrm{D}}$. This identity is a post-calibration consistency relation, not an independent derivation of the active-vacuum scale.

H.1 Empirical Calibration of the Active-Vacuum Node Radius from the VEV

The framework must physically accommodate the baseline electroweak symmetry-breaking scale without localized lattice fracture. In the present formulation, we calibrate the fundamental active-vacuum node radius r_{D} by equating the mass-equivalent electroweak VEV scale to the hydrodynamic capacity of the Interstitial Condensate ρ_{IC}.

This is a TFT calibration ansatz, not a Standard Model derivation. In standard field theory, the VEV is a continuous scalar-field scale permeating space; it is not a localized mass packet occupying a finite geometric void. In the present TFT calibration, the electroweak VEV scale is interpreted as a mass-equivalent baseline resistance scale of the interstitial phase. This empirical matching condition anchors the active-vacuum node radius until a future field-coupling derivation replaces the calibration convention.

First, we convert the empirical 246.22 GeV scale into its SI mass equivalent m_{VEV}, using $m = E/c_{\mathrm{E}}^2$ and 1 eV $\approx 1.60218 \times 10^{-19}$ J:

$$E = 246.22 \times 10^{9}\ \mathrm{eV} \cdot (1.60218 \times 10^{-19}\ \mathrm{J/eV}) \approx 3.9449 \times 10^{-8}\ \mathrm{J}, \tag{H.1}$$

$$m_{\mathrm{VEV}} = \frac{3.9449 \times 10^{-8}\ \mathrm{J}}{(2.99792 \times 10^{8}\ \mathrm{m/s})^2} \approx 4.3893 \times 10^{-25}\ \mathrm{kg}. \tag{H.2}$$

Note: This mass equivalent represents the calibration scale assigned to the hydrodynamic resting capacity of the active interstitial phase. It is not a literal baryonic, fermionic, or localized Higgs rest mass.

Next, we define the 3D vacuum fluid density ρ_{IC}. Because the baseline inertia of the active vacuum,

$$\mu_{\mathrm{D}} = \frac{c_{\mathrm{E}}^2}{G r_{\mathrm{D}}}, \tag{H.3}$$

acts as a 2D surface inertia distributed across the node boundary, calculating the volumetric fluid capacity requires translating this surface inertia into an effective 3D interstitial density. To bridge this microscopic impedance structure to the macroscopic SI units used in G, we employ the macroscopic SI calibration convention $\iota_{\mathrm{V}} \equiv 1\ \mathrm{m}^{-1}$. Thus,

$$\rho_{\mathrm{IC}} = \left(\frac{c_{\mathrm{E}}^2}{G r_{\mathrm{D}}}\right) \iota_{\mathrm{V}}. \tag{H.4}$$

We then determine the total available Interstitial Volume V_{IC} within a single FCC unit cell. The total volume of an FCC unit cell with edge length $a = 2\sqrt{2} r_{\mathrm{D}}$ is

$$V_{\mathrm{cell}} = 16\sqrt{2} r_{\mathrm{D}}^3 \approx 22.6274 r_{\mathrm{D}}^3. \tag{H.5}$$

The unit cell contains exactly four solid nodes, occupying

$$V_{\mathrm{nodes}} = \frac{16\pi}{3} r_{\mathrm{D}}^3 \approx 16.7552 r_{\mathrm{D}}^3. \tag{H.6}$$

The total interstitial volume is therefore

$$V_{\mathrm{IC}} = V_{\mathrm{cell}} - V_{\mathrm{nodes}} \approx 22.6274 r_{\mathrm{D}}^3 - 16.7552 r_{\mathrm{D}}^3 = 5.8722 r_{\mathrm{D}}^3. \tag{H.7}$$

We now impose the calibrated matching condition:

$$m_{\mathrm{VEV}} = \rho_{\mathrm{IC}} V_{\mathrm{IC}}. \tag{H.8}$$

Substituting the projected interstitial density and FCC interstitial volume gives

$$m_{\mathrm{VEV}} = \left(\frac{c_{\mathrm{E}}^2}{G r_{\mathrm{D}}}\right) \iota_{\mathrm{V}} (5.8722 r_{\mathrm{D}}^3), \tag{H.9}$$

or

$$m_{\mathrm{VEV}} = 5.8722 \left(\frac{c_{\mathrm{E}}^2}{G}\right) \iota_{\mathrm{V}} r_{\mathrm{D}}^2. \tag{H.10}$$

For a general projection scale ι_{V}, the active-vacuum node radius is therefore

$$r_{\mathrm{D}}(\iota_{\mathrm{V}}) = \sqrt{\frac{G m_{\mathrm{VEV}}}{5.8722 c_{\mathrm{E}}^2 \iota_{\mathrm{V}}}}. \tag{H.11}$$

This makes explicit that $r_{\mathrm{D}} \propto \iota_{\mathrm{V}}^{-1/2}$. Under the present macroscopic SI calibration convention $\iota_{\mathrm{V}} \equiv 1\ \mathrm{m}^{-1}$, and using $c_{\mathrm{E}}^2/G \approx 1.3466 \times 10^{27}$ kg/m, the calibration condition becomes

$$4.3893 \times 10^{-25} = 5.8722 \cdot (1.3466 \times 10^{27}) \cdot r_{\mathrm{D}}^2, \tag{H.12}$$

$$4.3893 \times 10^{-25} = 7.9075 \times 10^{27} \cdot r_{\mathrm{D}}^2, \tag{H.13}$$

$$r_{\mathrm{D}}^2 \approx 5.5508 \times 10^{-53}\ \mathrm{m}^2. \tag{H.14}$$

Solving for the fundamental active-vacuum node radius yields the empirical FCC Soft Floor calibration scale:

$$r_{\mathrm{D}} \approx 7.4504 \times 10^{-27}\ \mathrm{m}. \tag{H.15}$$

This value should therefore be read as the TFT baseline calibration of the active vacuum, not as a parameter-free derivation from the Standard Model.

H.2 Post-Calibration Consistency Check Against the Kinematic Ceiling ($E_{\max}$)

To test the calibrated node radius against the microscopic kinematic ceiling, we evaluate the energy required to compress a photon-like transverse excitation to the physical diameter of one active-vacuum node, $\lambda_{\min} = 2r_{\mathrm{D}}$. This is a consistency check performed after the empirical calibration of r_{D}, not an independent derivation of the lattice scale.

Using

$$E_{\max} = \frac{hc_{\mathrm{E}}}{2r_{\mathrm{D}}}, \tag{H.16}$$

and $hc_{\mathrm{E}} \approx 1.2398 \times 10^{-15}$ GeV $\cdot$ m, the calibrated value $r_{\mathrm{D}} \approx 7.4504 \times 10^{-27}$ m gives

$$E_{\max} \approx 8.3203 \times 10^{10} \text{ GeV}. \tag{H.17}$$

This value lies within the broad electroweak vacuum-instability range often quoted for Standard Model extrapolations. Because r_{D} has already been calibrated using the VEV scale, this agreement should be interpreted only as a post-calibration consistency check, not as an independent prediction.

H.3 The Macroscopic Strain Limit (c_{E}^2)

With the calibrated microscopic boundary fixed, we evaluate the corresponding macroscopic boundary. As derived in Appendix AQ, the visco-elastic damping rate of the active Spacetime Gravitational Floor ($\Gamma_{\mathrm{D}} \approx 2.3671 \times 10^{-18}$ s^{-1}) imposes a constant kinematic impedance acceleration (a_{D}) on any propagating transverse wave. As established in Appendix L, this fundamental cosmic impedance is defined as:

$$a_{\mathrm{D}} = c_{\mathrm{E}}\Gamma_{\mathrm{D}} \tag{H.18}$$

To find the total specific work (W_{total}) extracted from a wave as it travels to the absolute Viscous Cosmic Horizon (R_{U}), we multiply this impedance acceleration by the horizon coordinate distance. Because $R_{\mathrm{U}} = c_{\mathrm{E}}/\Gamma_{\mathrm{D}}$:

$$W_{\text{total}} = a_{\mathrm{D}} \cdot R_{\mathrm{U}} = (c_{\mathrm{E}}\Gamma_{\mathrm{D}}) \left(\frac{c_{\mathrm{E}}}{\Gamma_{\mathrm{D}}}\right) = c_{\mathrm{E}}^2 \tag{H.19}$$

This mathematically establishes that R_{U} is exactly the spatial distance required for the SGF to absorb c_{E}^2 of kinematic energy, confirming the invariant strain capacity of the visco-elastic medium.

H.4 The Unified Equation: The Scale-Invariant Identity

We can demonstrate the algebraic consistency relation between the macroscopic strain limit (R_{U}) and the microscopic quantum node ($2r_{\mathrm{D}}$) using the fundamental Kinematic Lattice Index ($N_{\mathrm{D}} = R_{\mathrm{U}}/2r_{\mathrm{D}}$).

By isolating the microscopic geometry ($2r_{\mathrm{D}} = R_{\mathrm{U}}/N_{\mathrm{D}}$) and substituting it into the quantum vibrational capacity definition ($E_{\max} = hc_{\mathrm{E}}/2r_{\mathrm{D}}$), we express the Kinematic Ceiling as:

$$E_{\max} = \frac{hc_{\mathrm{E}}}{\left(\frac{R_{\mathrm{U}}}{N_{\mathrm{D}}}\right)} \tag{H.20}$$

Substituting the kinematic identity of the Viscous Cosmic Horizon ($R_{\mathrm{U}} = c_{\mathrm{E}}/\Gamma_{\mathrm{D}}$):

$$E_{\max} = \frac{h c_{\mathrm{E}} N_{\mathrm{D}}}{\left(\frac{c_{\mathrm{E}}}{\Gamma_{\mathrm{D}}}\right)} \tag{H.21}$$

Simplifying this yields the Scale-Invariant Identity of the active vacuum:

$$E_{\max} \equiv h \Gamma_{\mathrm{D}} N_{\mathrm{D}} \tag{H.22}$$

H.5 Conclusion

This appendix establishes the empirical calibration procedure for the active-vacuum node radius r_{D} under the macroscopic SI projection convention $\iota_{\mathrm{V}} \equiv 1\ \mathrm{m}^{-1}$. The calculation explicitly shows that $r_{\mathrm{D}} \propto \iota_{\mathrm{V}}^{-1/2}$, so the calibrated scale is not parameter-free in the present formulation.

The identity

$$E_{\max} \equiv h \Gamma_{\mathrm{D}} N_{\mathrm{D}} \tag{H.23}$$

is an algebraic consistency relation among the calibrated microscopic cutoff, the macroscopic damping scale, and the dimensionless lattice index. It confirms that the definitions commute across the microscopic and macroscopic limits of the TFT active vacuum. It should not be interpreted as an independent derivation of $E_{\max}$, r_{D}, or the electroweak scale.

Appendix J

Gravitational Endpoint Transfer

Gravitational Constraint, Coordinate Reduction, Referred Inertia, and Dispersion

Subject: Gravity-specific constrained-coordinate reduction of the active FCC Soft Floor and derivation of its referred inertia and long-wavelength propagation law.

J.1 Scope and Status of the Construction

Appendix D develops the gravity-independent FCC contact geometry, objective bond kinematics, parity-even contact action, primitive-cell assembly, and long-wavelength acoustic tensor of the active Soft Floor. The present appendix applies the gravitational loading constraint to that baseline mechanical carrier.

The construction is restricted to the active FCC phase,

$$0 \leq \alpha_{\mathrm{G}} < 1, \tag{J.1}$$

and to a gravitational background that is quasistatic during one local transfer event,

$$\dot{\alpha}_{\mathrm{G}} \approx 0. \tag{J.2}$$

The analysis develops the sequence

$$\begin{gathered} \text{gravitational capacity reduction} \\ \longrightarrow \text{work-conjugate endpoint map} \\ \longrightarrow \text{serial source-target constraint} \\ \longrightarrow \text{latent-to-completed coordinate reduction} \\ \longrightarrow \text{referred inertia} \\ \longrightarrow \text{constrained FCC dispersion.} \end{gathered} \tag{J.3}$$

The single-endpoint map is a reduced work-conjugate constitutive construction. It is not claimed to have been derived from a complete parent potential containing all node, contact, condensate, phase, and Tension-Column degrees of freedom. The present appendix instead shows that, once the

endpoint map is defined through the active-capacity balance, its inertial and dispersive consequences follow from a conservative constrained action.

The principal statuses are:

Result	**Status in this appendix**
$\tau_{\mathrm{av}} = \tau_{\mathrm{D}} - \tau_{\mathrm{L}}$	active-capacity subtraction within the reduced constitutive model
$\mathcal{C}_i = 1 - \alpha_{\mathrm{G}}^{(i)}$	derived from the work-conjugate endpoint map
$\mathcal{C}_{ij} = \mathcal{C}_i \mathcal{C}_j$	derived by serial source release and target acceptance
$u = \mathcal{C} y$	holonomic latent-to-completed coordinate constraint
$\mathbf{M}_{\mathrm{cell}}^{(\mathrm{eff})} = \mathbf{T}_{\mathrm{cell}}^{-\mathsf{T}} \mathbf{M}_{\mathrm{cell}}^{(0)} \mathbf{T}_{\mathrm{cell}}^{-1}$	mass-matrix congruence within the stated quasistatic holonomic reduction
$\rho_{\mathrm{eff}} = \rho_{\mathrm{eff}}^{(0)} / \mathcal{C}^2$	referred inertia in the coherent translational sector
$c_{\mathrm{P}} = c_{\mathrm{E}} \mathcal{C}$	derived from the constrained directional and FCC acoustic equations
full parent microscopic origin of $\mathcal{C}_i$	not yet completed

J.2 Gravitational Loading and Available Active Capacity

For endpoint i, define the dimensionless gravitational loading fraction by

$$\alpha_{\mathrm{G}}^{(i)} = \frac{\tau_{\mathrm{L}}^{(i)}}{\tau_{\mathrm{D}}}, \tag{J.4}$$

where $\tau_{\mathrm{L}}^{(i)}$ is the local mass-induced loading and τ_{D} is the baseline active surface-tension capacity.

The active capacity remaining for additional local transfer is

$$\tau_{\mathrm{av}}^{(i)} = \tau_{\mathrm{D}} - \tau_{\mathrm{L}}^{(i)}. \tag{J.5}$$

Substituting the definition of $\alpha_{\mathrm{G}}^{(i)}$ gives

$$\tau_{\mathrm{av}}^{(i)} = \tau_{\mathrm{D}} \left(1 - \alpha_{\mathrm{G}}^{(i)} \right). \tag{J.6}$$

Define the single-endpoint residual-capacity factor

$$\mathcal{C}_i \equiv 1 - \alpha_{\mathrm{G}}^{(i)}. \tag{J.7}$$

Then

$$\tau_{\mathrm{av}}^{(i)} = \tau_{\mathrm{D}} \mathcal{C}_i. \tag{J.8}$$

Within the active phase,

$$0 < \mathcal{C}_i \leq 1. \tag{J.9}$$

The limits are

$$\alpha_{\mathrm{G}}^{(i)} = 0 \quad \Longrightarrow \quad \mathcal{C}_i = 1, \tag{J.10}$$

and

$$\alpha_{\mathrm{G}}^{(i)} \to 1^- \quad \Longrightarrow \quad \mathcal{C}_i \to 0^+. \tag{J.11}$$

The linear dependence in Equation (J.7) is therefore not inferred from the limiting values alone. It follows from the adopted linear subtraction of the local gravitational loading from the available active tension capacity.

J.3 Work-Conjugate Single-Endpoint Coordinate Map

Let y_i denote the latent node–condensate reconfiguration presented to endpoint i, and let u_i denote the completed displacement accepted by the active FCC contact state.

Introduce the dimensionless normalized coordinates

$$\widehat{y}_i \equiv \frac{y_i}{d_{\mathrm{nn}}}, \qquad \widehat{u}_i \equiv \frac{u_i}{d_{\mathrm{nn}}}, \tag{J.12}$$

where

$$d_{\mathrm{nn}} = 2r_{\mathrm{D}} \tag{J.13}$$

is the nearest-neighbor FCC separation.

The coordinate $\widehat{y}_i$ measures the normalized reconfiguration presented to the endpoint, while $\widehat{u}_i$ measures the normalized deformation transmitted into the active FCC contact state.

The reduced endpoint closure is obtained by equating the incremental work density represented in the two coordinate descriptions:

$$\tau_{\mathrm{D}}\, \delta\widehat{u}_i = \tau_{\mathrm{av}}^{(i)}\, \delta\widehat{y}_i. \tag{J.14}$$

Using

$$\tau_{\mathrm{av}}^{(i)} = \tau_{\mathrm{D}}\mathcal{C}_i, \tag{J.15}$$

Equation (J.14) becomes

$$\tau_{\mathrm{D}}\, \delta\widehat{u}_i = \tau_{\mathrm{D}}\mathcal{C}_i\, \delta\widehat{y}_i. \tag{J.16}$$

Therefore,

$$\delta\widehat{u}_i = \mathcal{C}_i\, \delta\widehat{y}_i. \tag{J.17}$$

For a quasistatic gravitational background, $\mathcal{C}_i$ is constant during the local transfer event. Integrating from the common undeformed reference state gives

$$\widehat{u}_i = \mathcal{C}_i\widehat{y}_i. \tag{J.18}$$

Multiplying by d_{nn} gives the single-endpoint coordinate map

$$u_i = \mathcal{C}_i y_i. \tag{J.19}$$

Thus $\mathcal{C}_i$ is the fraction of the latent reconfiguration admitted into the completed active-FCC coordinate.

J.4 Serial Source–Target Composition

Consider a completed nearest-neighbor transfer from source endpoint i to target endpoint j.

Let y_{ij} denote the latent transfer amplitude presented to the source endpoint. The source releases only the fraction permitted by its residual active capacity:

$$y_{ij}^{(\mathrm{rel})} = \mathcal{C}_i y_{ij}. \tag{J.20}$$

The target endpoint acts on the amplitude already released by the source:

$$u_{ij} = \mathcal{C}_j y_{ij}^{(\mathrm{rel})}. \tag{J.21}$$

Substitution gives

$$u_{ij} = \mathcal{C}_i \mathcal{C}_j y_{ij}. \tag{J.22}$$

Define the completed two-endpoint transfer factor by

$$\mathcal{C}_{ij} \equiv \mathcal{C}_i \mathcal{C}_j. \tag{J.23}$$

Using Equation (J.7),

$$\mathcal{C}_{ij} = \left(1 - \alpha_{\mathrm{G}}^{(i)}\right)\left(1 - \alpha_{\mathrm{G}}^{(j)}\right). \tag{J.24}$$

The completed coordinate therefore satisfies

$$u_{ij} = \mathcal{C}_{ij} y_{ij}. \tag{J.25}$$

The product is not a probability rule. It is the composition of two serial coordinate constraints: source release followed by target acceptance and closure.

For a gravitational loading that varies negligibly across one FCC connection,

$$\alpha_{\mathrm{G}}^{(i)} \approx \alpha_{\mathrm{G}}^{(j)} \approx \alpha_{\mathrm{G}}, \tag{J.26}$$

and the local two-endpoint factor reduces to

$$\mathcal{C} = \left(1 - \alpha_{\mathrm{G}}\right)^2. \tag{J.27}$$

J.5 Constrained Directional Action

Appendix D establishes the baseline transverse nearest-neighbor action of the unstrained FCC carrier. The gravitational specialization distinguishes the latent reconfiguration coordinate y_n from the completed active-FCC displacement u_n.

For a locally uniform, quasistatic gravitational loading, impose the holonomic constraint

$$u_n = \mathcal{C} y_n. \tag{J.28}$$

A constrained directional Lagrangian per unit participating interface area is

$$\begin{aligned}\mathcal{L}_\perp = \sum_n \Bigg[&\frac{1}{2}\mu_{\mathrm{D}} \dot{y}_n^2 - \frac{\tau_{\mathrm{D}}}{2 d_{\mathrm{nn}}^2}\left(u_{n+1} - u_n\right)^2 \\ &+ \lambda_n \left(u_n - \mathcal{C} y_n\right) \Bigg].\end{aligned} \tag{J.29}$$

Variation with respect to λ_n gives Equation (J.28). Since

$$y_n = \frac{u_n}{\mathcal{C}}, \tag{J.30}$$

and

$$\dot{\mathcal{C}} \approx 0, \tag{J.31}$$

one has

$$\dot{y}_n = \frac{\dot{u}_n}{\mathcal{C}}. \tag{J.32}$$

Eliminating the latent coordinate gives the reduced completed-coordinate Lagrangian

$$\mathcal{L}_{\perp}^{(\mathrm{red})} = \sum_n \left[\frac{1}{2} \frac{\mu_{\mathrm{D}}}{\mathcal{C}^2} \dot{u}_n^2 - \frac{\tau_{\mathrm{D}}}{2 d_{\mathrm{nn}}^2} \left(u_{n+1} - u_n \right)^2 \right]. \tag{J.33}$$

The active-phase tangent stiffness remains the baseline FCC stiffness at the retained constitutive order. The gravitational constraint instead modifies the kinetic coefficient referred to the completed coordinate.

J.6 Referred Surface Inertia

Comparison of Equation (J.33) with the standard kinetic form identifies the effective completed-coordinate surface inertia:

$$\mu_{\mathrm{eff}} = \frac{\mu_{\mathrm{D}}}{\mathcal{C}^2}. \tag{J.34}$$

For the locally uniform two-endpoint factor,

$$\mathcal{C} = \left(1 - \alpha_{\mathrm{G}} \right)^2, \tag{J.35}$$

the referred surface inertia becomes

$$\mu_{\mathrm{eff}} = \frac{\mu_{\mathrm{D}}}{\left(1 - \alpha_{\mathrm{G}} \right)^4}. \tag{J.36}$$

The inverse fourth power is therefore not introduced by algebraically solving an already assumed wave-speed relation. It follows directly from the constrained kinetic-coordinate transformation:

$$u = \mathcal{C} y \quad \Longrightarrow \quad \dot{y} = \frac{\dot{u}}{\mathcal{C}} \quad \Longrightarrow \quad \mu_{\mathrm{eff}} = \frac{\mu_{\mathrm{D}}}{\mathcal{C}^2}. \tag{J.37}$$

The coefficient μ_{eff} is the referred surface inertia of the directional contact representation, whereas ρ_{eff} denotes the corresponding volumetric inertia coefficient at a specified continuum scale. The two quantities are related through the appropriate surface-to-volume projection and are not interchangeable.

J.7 Primitive-Cell Transfer Operator

The scalar endpoint constraint must be embedded into the complete primitive-cell coordinate space.

Let $\mathbf{y}_{\mathrm{cell}}$ denote the latent generalized primitive-cell coordinate, and let $\mathbf{q}_{\mathrm{cell}}$ denote the corresponding completed active-FCC coordinate.

Let $\mathbb{P}_{\mathrm{tr}}$ be the projector onto the coherent translational transfer sector. It satisfies

$$\mathbb{P}_{\mathrm{tr}}^2 = \mathbb{P}_{\mathrm{tr}}, \qquad \mathbb{P}_{\mathrm{tr}}^{\mathsf{T}} = \mathbb{P}_{\mathrm{tr}}. \tag{J.38}$$

The local gravitational transfer operator is

$$\mathbf{T}_{\text{cell}} = \mathbf{I} + (\mathcal{C} - 1)\,\mathbb{P}_{\text{tr}}. \tag{J.39}$$

The completed and latent coordinates are related by

$$\mathbf{q}_{\text{cell}} = \mathbf{T}_{\text{cell}}\mathbf{y}_{\text{cell}}. \tag{J.40}$$

The operator acts as multiplication by $\mathcal{C}$ on the coherent translational sector and as the identity on the complementary retained sectors:

$$\mathbf{T}_{\text{cell}}\mathbb{P}_{\text{tr}} = \mathcal{C}\mathbb{P}_{\text{tr}}, \tag{J.41}$$

and

$$\mathbf{T}_{\text{cell}}\,(\mathbf{I} - \mathbb{P}_{\text{tr}}) = \mathbf{I} - \mathbb{P}_{\text{tr}}. \tag{J.42}$$

For

$$\mathcal{C} > 0, \tag{J.43}$$

the inverse operator is

$$\mathbf{T}_{\text{cell}}^{-1} = \mathbf{I} + \left(\mathcal{C}^{-1} - 1\right)\mathbb{P}_{\text{tr}}. \tag{J.44}$$

This follows directly from the idempotence of $\mathbb{P}_{\text{tr}}$.

J.8 Primitive-Cell Mass-Matrix Congruence

Let $\mathbf{M}_{\text{cell}}^{(0)}$ be the gravity-neutral primitive-cell mass matrix constructed in Appendix D. The latent-coordinate kinetic energy is

$$T_{\text{cell}} = \frac{1}{2}\dot{\mathbf{y}}_{\text{cell}}^{\mathsf{T}}\mathbf{M}_{\text{cell}}^{(0)}\dot{\mathbf{y}}_{\text{cell}}. \tag{J.45}$$

Using

$$\mathbf{y}_{\text{cell}} = \mathbf{T}_{\text{cell}}^{-1}\mathbf{q}_{\text{cell}}, \tag{J.46}$$

and the quasistatic condition

$$\dot{\mathbf{T}}_{\text{cell}} \approx \mathbf{0}, \tag{J.47}$$

the kinetic energy becomes

$$T_{\text{cell}} = \frac{1}{2}\dot{\mathbf{q}}_{\text{cell}}^{\mathsf{T}}\mathbf{T}_{\text{cell}}^{-\mathsf{T}}\mathbf{M}_{\text{cell}}^{(0)}\mathbf{T}_{\text{cell}}^{-1}\dot{\mathbf{q}}_{\text{cell}}. \tag{J.48}$$

Therefore the completed-coordinate mass matrix is

$$\mathbf{M}_{\text{cell}}^{(\text{eff})} = \mathbf{T}_{\text{cell}}^{-\mathsf{T}}\mathbf{M}_{\text{cell}}^{(0)}\mathbf{T}_{\text{cell}}^{-1}. \tag{J.49}$$

Equation (J.49) is the mass-matrix congruence associated with the stated quasistatic holonomic transfer constraint.

Under the primitive-cell bookkeeping of Appendix D, the coherent translational mass block is isotropic and decoupled from the retained complementary coordinates at leading order. In that sector,

$$\mathbb{P}_{\text{tr}}\mathbf{M}_{\text{cell}}^{(\text{eff})}\mathbb{P}_{\text{tr}} = \frac{1}{\mathcal{C}^2}\mathbb{P}_{\text{tr}}\mathbf{M}_{\text{cell}}^{(0)}\mathbb{P}_{\text{tr}}. \tag{J.50}$$

Thus the cell-level operator reproduces the scalar referred-inertia result while preserving the unmodified complementary sectors at the retained order.

J.9 Constrained FCC Dynamic Matrix

Appendix D defines the gravity-neutral FCC Bloch stiffness

$$\mathbf{K}_{\mathrm{FCC}}^{(0)}(\mathbf{k}) = A_{\mathrm{ct}} \sum_{a=1}^{6} \mathbf{B}_a^{\dagger}(\mathbf{k}) \mathbf{H}_{\mathrm{c}} \mathbf{B}_a(\mathbf{k}). \tag{J.51}$$

At the retained active-phase tangent order, the gravitational coordinate reduction acts on the kinetic operator while the baseline completed-coordinate contact stiffness remains

$$\mathbf{K}_{\mathrm{FCC}}\left(\mathbf{k}, \alpha_{\mathrm{G}}\right) = \mathbf{K}_{\mathrm{FCC}}^{(0)}(\mathbf{k}). \tag{J.52}$$

The gravity-constrained generalized eigenvalue problem is therefore

$$\det\left[\mathbf{K}_{\mathrm{FCC}}^{(0)}(\mathbf{k}) - \omega^2 \mathbf{M}_{\mathrm{cell}}^{(\mathrm{eff})}\right] = 0. \tag{J.53}$$

The gravitational dependence enters through the congruence-transformed mass matrix rather than through an independent softening of the baseline tangent contact stiffness.

This avoids counting the same gravitational reduction simultaneously in both the stiffness and inertia sectors.

J.10 Directional Lattice Dispersion

Variation of the reduced directional Lagrangian in Equation (J.33) gives

$$\frac{\mu_{\mathrm{D}}}{\mathcal{C}^2} \ddot{u}_n = \frac{\tau_{\mathrm{D}}}{d_{\mathrm{nn}}^2} \left(u_{n+1} - 2u_n + u_{n-1}\right). \tag{J.54}$$

For a plane wave,

$$u_n(t) = u_0 \exp\left[i\left(k n d_{\mathrm{nn}} - \omega t\right)\right], \tag{J.55}$$

one obtains

$$u_{n+1} - 2u_n + u_{n-1} = -4u_n \sin^2\left(\frac{k d_{\mathrm{nn}}}{2}\right). \tag{J.56}$$

The constrained directional dispersion relation is therefore

$$\omega^2 = \frac{4\tau_{\mathrm{D}} \mathcal{C}^2}{\mu_{\mathrm{D}} d_{\mathrm{nn}}^2} \sin^2\left(\frac{k d_{\mathrm{nn}}}{2}\right). \tag{J.57}$$

Using

$$c_{\mathrm{E}}^2 = \frac{\tau_{\mathrm{D}}}{\mu_{\mathrm{D}}}, \tag{J.58}$$

the dispersion becomes

$$\omega^2\left(k, \alpha_{\mathrm{G}}\right) = \frac{4 c_{\mathrm{E}}^2 \mathcal{C}^2}{d_{\mathrm{nn}}^2} \sin^2\left(\frac{k d_{\mathrm{nn}}}{2}\right). \tag{J.59}$$

In the long-wavelength limit,

$$k d_{\mathrm{nn}} \ll 1, \tag{J.60}$$

Equation (J.59) gives

$$\omega^2 = c_{\mathrm{E}}^2 \mathcal{C}^2 k^2 + \mathcal{O}\left(k^4 d_{\mathrm{nn}}^2\right). \tag{J.61}$$

Therefore,

$$\lim_{k\to 0}\frac{\omega}{k}=c_{\mathrm{E}}\mathcal{C}. \tag{J.62}$$

Using Equation (J.27),

$$c_{\mathrm{P}}=c_{\mathrm{E}}\left(1-\alpha_{\mathrm{G}}\right)^{2}. \tag{J.63}$$

Thus the propagation law follows through the mechanical sequence

$$\text{work-conjugate endpoint map}\longrightarrow\mathcal{C}\longrightarrow\text{referred inertia}\longrightarrow\text{discrete dispersion}\longrightarrow c_{\mathrm{P}}. \tag{J.64}$$

J.11 Full FCC Long-Wavelength Reduction

The directional derivation must agree with the three-dimensional FCC acoustic tensor developed in Appendix D.

Let $K_{\mathrm{sh}}^{(0)}$ and $\rho_{\mathrm{eff}}^{(0)}$ denote the matched baseline shear coefficient and coherent translational inertia coefficient at one chosen descriptive scale. They satisfy

$$\frac{K_{\mathrm{sh}}^{(0)}}{\rho_{\mathrm{eff}}^{(0)}}=c_{\mathrm{E}}^{2}. \tag{J.65}$$

At the primitive-cell microscopic scale presently derived in Appendix D, these scale-neutral coefficients are identified with

$$\rho_{\mathrm{eff}}^{(0)}=\rho_{\mathrm{sh}}^{(\mathrm{micro},0)},\qquad K_{\mathrm{sh}}^{(0)}=K_{\mathrm{sh}}^{(\mathrm{micro},0)}. \tag{J.66}$$

Here $\rho_{\mathrm{sh}}^{(\mathrm{micro},0)}$ is the primitive-cell FCC scaffold inertia normalization derived in Appendix D. The identification in Equation (J.66) does not introduce an independently additive condensate kinetic density. Coherent condensate entrainment fixes the relative kinematics, while any additional coherent condensate inertia would require a separately derived coupled two-field kinetic action.

The gravitationally referred density in the coherent transverse sector is

$$\rho_{\mathrm{eff}}\left(\alpha_{\mathrm{G}}\right)=\frac{\rho_{\mathrm{eff}}^{(0)}}{\mathcal{C}^{2}}. \tag{J.67}$$

At the retained tangent order,

$$K_{\mathrm{sh}}\left(\alpha_{\mathrm{G}}\right)=K_{\mathrm{sh}}^{(0)}. \tag{J.68}$$

The long-wavelength transverse acoustic equation is therefore

$$\omega_{\mathrm{T}}^{2}=\frac{K_{\mathrm{sh}}^{(0)}}{\rho_{\mathrm{eff}}\left(\alpha_{\mathrm{G}}\right)}k^{2}+\mathcal{O}\left(k^{4}d_{\mathrm{nn}}^{2}\right). \tag{J.69}$$

Substituting Equation (J.67) gives

$$\omega_{\mathrm{T}}^{2}=\frac{K_{\mathrm{sh}}^{(0)}}{\rho_{\mathrm{eff}}^{(0)}}\mathcal{C}^{2}k^{2}+\mathcal{O}\left(k^{4}d_{\mathrm{nn}}^{2}\right). \tag{J.70}$$

Using Equation (J.65),

$$\omega_{\mathrm{T}}^{2}=c_{\mathrm{E}}^{2}\mathcal{C}^{2}k^{2}+\mathcal{O}\left(k^{4}d_{\mathrm{nn}}^{2}\right). \tag{J.71}$$

For locally uniform gravitational loading,

$$\omega_{\mathrm{T}}^2 = c_{\mathrm{E}}^2 \left(1 - \alpha_{\mathrm{G}}\right)^4 k^2 + \mathcal{O}\left(k^4 d_{\mathrm{nn}}^2\right). \tag{J.72}$$

Consequently,

$$c_{\mathrm{P}} = c_{\mathrm{E}} \left(1 - \alpha_{\mathrm{G}}\right)^2. \tag{J.73}$$

The same gravitational factor therefore follows from both the constrained directional sequence and the full FCC long-wavelength acoustic tensor.

The baseline coefficients in this section must be taken at the same descriptive scale. Primitive-cell microscopic coefficients must not be mixed with independently inferred macroscopic continuum coefficients.

J.12 Exact Nonuniform Endpoint Correction

For a selected FCC connection, define the local mean loading by

$$\alpha_{\mathrm{G}} = \frac{\alpha_{\mathrm{G}}^{(i)} + \alpha_{\mathrm{G}}^{(j)}}{2}, \tag{J.74}$$

and the endpoint difference by

$$\delta\alpha_{\mathrm{G}} = \alpha_{\mathrm{G}}^{(j)} - \alpha_{\mathrm{G}}^{(i)}. \tag{J.75}$$

Then

$$\alpha_{\mathrm{G}}^{(i)} = \alpha_{\mathrm{G}} - \frac{\delta\alpha_{\mathrm{G}}}{2}, \qquad \alpha_{\mathrm{G}}^{(j)} = \alpha_{\mathrm{G}} + \frac{\delta\alpha_{\mathrm{G}}}{2}. \tag{J.76}$$

Substitution into Equation (J.24) gives

$$\begin{aligned} \mathcal{C}_{ij} &= \left(1 - \alpha_{\mathrm{G}} + \frac{\delta\alpha_{\mathrm{G}}}{2}\right)\left(1 - \alpha_{\mathrm{G}} - \frac{\delta\alpha_{\mathrm{G}}}{2}\right) \\ &= \left(1 - \alpha_{\mathrm{G}}\right)^2 - \frac{\left(\delta\alpha_{\mathrm{G}}\right)^2}{4}. \end{aligned} \tag{J.77}$$

The first-order endpoint-gradient contribution cancels exactly.

The bond-resolved propagation speed is

$$c_{\mathrm{P}}^{(i\to j)} = c_{\mathrm{E}} \left[\left(1 - \alpha_{\mathrm{G}}\right)^2 - \frac{\left(\delta\alpha_{\mathrm{G}}\right)^2}{4}\right]. \tag{J.78}$$

The locally uniform continuum approximation is controlled by

$$\frac{\left(\delta\alpha_{\mathrm{G}}\right)^2}{4} \ll \left(1 - \alpha_{\mathrm{G}}\right)^2, \tag{J.79}$$

or equivalently,

$$\left|\delta\alpha_{\mathrm{G}}\right| \ll 2\left|1 - \alpha_{\mathrm{G}}\right|. \tag{J.80}$$

For a smooth spherical exterior field,

$$\alpha_{\mathrm{G}}(R) = \frac{GM}{Rc_{\mathrm{E}}^2}, \tag{J.81}$$

the relative change across one radial nearest-neighbor separation is

$$\frac{|\delta\alpha_{\mathrm{G}}|}{\alpha_{\mathrm{G}}} \sim \frac{2r_{\mathrm{D}}}{R}. \tag{J.82}$$

The continuum correction is therefore negligible throughout ordinary macroscopic exterior regions. It cannot, however, be neglected automatically near the saturation boundary, where $1-\alpha_{\mathrm{G}}$ becomes small, or across a sharp FCC-to-SC phase interface.

J.13 Refraction and Effective Optical Index

The local propagation index of the coherent transverse branch is

$$n_\tau = \frac{c_{\mathrm{E}}}{c_{\mathrm{P}}}. \tag{J.83}$$

For locally uniform gravitational loading,

$$n_\tau = \frac{1}{(1-\alpha_{\mathrm{G}})^2}. \tag{J.84}$$

In the weak-field limit,

$$\alpha_{\mathrm{G}} \ll 1, \tag{J.85}$$

the expansion is

$$n_\tau = 1 + 2\alpha_{\mathrm{G}} + 3\alpha_{\mathrm{G}}^2 + \mathcal{O}\left(\alpha_{\mathrm{G}}^3\right). \tag{J.86}$$

The leading coefficient 2 is the continuum expression of the two serial endpoint constraints required to complete one nearest-neighbor transfer.

Internal phase mismatch may alter excitation amplitude, polarization, mode participation, or defect coupling. It does not supply an additional universal multiplicative factor in the coherent transverse propagation speed unless such a factor is separately derived from the microscopic eigenvalue problem.

J.14 Saturation and Loss of the Active Coordinate

In the unstrained active vacuum,

$$\alpha_{\mathrm{G}} = 0, \tag{J.87}$$

so

$$\mathcal{C} = 1, \qquad \mu_{\mathrm{eff}} = \mu_{\mathrm{D}}, \qquad c_{\mathrm{P}} = c_{\mathrm{E}}. \tag{J.88}$$

As the active FCC phase approaches saturation,

$$\alpha_{\mathrm{G}} \to 1^-, \tag{J.89}$$

one has

$$\mathcal{C} \to 0^+. \tag{J.90}$$

The referred surface inertia diverges:

$$\mu_{\mathrm{eff}} = \frac{\mu_{\mathrm{D}}}{\mathcal{C}^2} \to \infty, \tag{J.91}$$

while the completed transverse propagation speed vanishes:

$$c_{\mathrm{P}} = c_{\mathrm{E}}\mathcal{C} \to 0. \tag{J.92}$$

The mechanical interpretation is

$$\text{finite active-side tangent stiffness} + \text{divergent referred inertia} = \text{causal arrest}. \tag{J.93}$$

The divergence does not represent an ordinary infinite material density of the SC substrate. It indicates that the completed active-FCC coordinate becomes singular and loses validity at the phase boundary.

The present construction applies only while both endpoints remain active:

$$0 \le \alpha_{\mathrm{G}}^{(i)} < 1, \qquad 0 \le \alpha_{\mathrm{G}}^{(j)} < 1. \tag{J.94}$$

The FCC endpoint constraint is not analytically continued through the FCC-to-SC phase transition.

J.15 Microscopic Completion Criterion

The present appendix gives a conservative reduced derivation of the gravitational endpoint constraint and its kinetic and dispersive consequences. It does not complete the underlying parent microphysics.

A complete node–contact–condensate–Tension-Column action must derive, rather than impose, the single-endpoint relation

$$u_i = \left(1 - \alpha_{\mathrm{G}}^{(i)}\right) y_i. \tag{J.95}$$

After elimination of any auxiliary condensate and vertical-constraint variables, the resulting reduced primitive-cell dynamics must reproduce or revise the transfer operator

$$\mathbf{T}_{\mathrm{cell}} = \mathbf{I} + (\mathcal{C} - 1)\,\mathbb{P}_{\mathrm{tr}}, \tag{J.96}$$

and the referred mass matrix

$$\mathbf{M}_{\mathrm{cell}}^{(\mathrm{eff})} = \mathbf{T}_{\mathrm{cell}}^{-\mathsf{T}} \mathbf{M}_{\mathrm{cell}}^{(0)} \mathbf{T}_{\mathrm{cell}}^{-1}. \tag{J.97}$$

The long-wavelength coherent transverse branch must satisfy

$$\lim_{k \to 0} \frac{\omega_{\mathrm{T}}\,(k, \alpha_{\mathrm{G}})}{k} = c_{\mathrm{E}}\,(1 - \alpha_{\mathrm{G}})^2\,. \tag{J.98}$$

Equivalently,

$$\frac{c_{\mathrm{P}}^2\,(\alpha_{\mathrm{G}})}{c_{\mathrm{E}}^2} = (1 - \alpha_{\mathrm{G}})^4\,. \tag{J.99}$$

The complete finite-wave-number theory must also verify

$$\omega_s^2\,(\mathbf{k}, \alpha_{\mathrm{G}}) \ge 0 \tag{J.100}$$

for every physical branch s, every wave vector in the first Brillouin zone, and every background satisfying

$$0 \le \alpha_{\mathrm{G}} < 1. \tag{J.101}$$

If the completed parent action produces a different endpoint dependence, transfer operator, inertia scaling, or long-wavelength dispersion, then the reduced closure developed here must be modified or rejected.

J.16 Conclusion

Appendix D establishes the gravity-independent FCC contact carrier. The present appendix applies the gravitational endpoint constraint to that carrier and derives the resulting kinetic and dispersive reduction.

The completed mechanical chain is

$$
\begin{gathered}
\tau_{\mathrm{av}}^{(i)} = \tau_{\mathrm{D}} \left(1 - \alpha_{\mathrm{G}}^{(i)}\right) \\
\Downarrow \\
u_i = \left(1 - \alpha_{\mathrm{G}}^{(i)}\right) y_i \\
\Downarrow \\
\mathcal{C}_{ij} = \left(1 - \alpha_{\mathrm{G}}^{(i)}\right) \left(1 - \alpha_{\mathrm{G}}^{(j)}\right) \\
\Downarrow \\
\mathbf{M}_{\mathrm{cell}}^{(\mathrm{eff})} = \mathbf{T}_{\mathrm{cell}}^{-\mathsf{T}} \mathbf{M}_{\mathrm{cell}}^{(0)} \mathbf{T}_{\mathrm{cell}}^{-1} \\
\Downarrow \\
\rho_{\mathrm{eff}} = \frac{\rho_{\mathrm{eff}}^{(0)}}{\mathcal{C}^2} \\
\Downarrow \\
\omega_{\mathrm{T}}^2 = c_{\mathrm{E}}^2 \mathcal{C}^2 k^2 + \mathcal{O}\left(k^4 d_{\mathrm{nn}}^2\right) \\
\Downarrow \\
c_{\mathrm{P}} = c_{\mathrm{E}} \left(1 - \alpha_{\mathrm{G}}\right)^2 .
\end{gathered}
\tag{J.102}
$$

At the primitive-cell microscopic scale,

$$
\rho_{\mathrm{eff}}^{(0)} = \rho_{\mathrm{sh}}^{(\mathrm{micro},0)}, \qquad K_{\mathrm{sh}}^{(0)} = K_{\mathrm{sh}}^{(\mathrm{micro},0)},
\tag{J.103}
$$

while $\rho_{\mathrm{eff}}^{(0)}$ and $K_{\mathrm{sh}}^{(0)}$ remain the scale-neutral notation when the same constrained-coordinate structure is written at a more general continuum level.

The endpoint law is therefore not left as a bare propagation postulate. It is represented as a reduced work-conjugate coordinate constraint whose referred inertia and long-wavelength dispersion follow from a conservative constrained action. The remaining open problem is the derivation of that constraint from the complete microscopic parent dynamics.

Appendix K

Derivation of Perihelion Precession from the Bound-Orbit Strain Action

Subject: Action-level derivation of the weak-field perihelion correction from conservative transport of a bound topological defect through the radially strained Soft Floor.

This appendix derives the weak-field perihelion correction from the variational dynamics of a massive bound defect in the active Soft Floor. The derivation applies to a static, spherically symmetric source and to a conservative orbit satisfying

$$\alpha_{\mathrm{G}} \ll 1, \qquad \frac{v^2}{c_{\mathrm{E}}^2} \ll 1. \tag{K.1}$$

The resulting action is a homogenized continuum description of the active FCC lattice. It is distinct from the optical propagation law for massless transverse waves. The optical sector governs refractive signal propagation, whereas the present action governs the transport of a localized three-dimensional topological defect whose phase structure remains bound during orbital motion.

From this point onward, all quantities denoted by g represent positive inward acceleration magnitudes unless a vector direction is written explicitly.

K.1 Newtonian Closed-Orbit Baseline

A static spherical source of mass M produces the baryonic restorative acceleration

$$g_{\mathrm{b}}(r) = \frac{GM}{r^2}. \tag{K.2}$$

The corresponding inward vector acceleration is

$$\mathbf{a}_{\mathrm{b}} = -\frac{GM}{r^2}\hat{\mathbf{r}}. \tag{K.3}$$

Introduce the reciprocal radial coordinate

$$u = \frac{1}{r}. \tag{K.4}$$

For a central inverse-square field, the Newtonian orbital equation is

$$\frac{\mathrm{d}^2 u}{\mathrm{d}\varphi^2} + u = \frac{GM}{\ell_{\mathrm{orb}}^2}, \tag{K.5}$$

where $\ell_{\rm orb}$ is the conserved specific orbital angular momentum.

The Newtonian solution is

$$u(\varphi) = \frac{1}{p}\left(1 + e\cos\varphi\right), \tag{K.6}$$

with

$$p = \frac{\ell_{\rm orb}^2}{GM} = a(1-e^2). \tag{K.7}$$

Here, a is the orbital semi-major axis and e is the eccentricity. The angular dependence is exactly periodic in 2π, so a pure inverse-square field produces a closed Keplerian ellipse.

Perihelion precession therefore requires a conservative correction to the inverse-square orbital dynamics.

K.2 Radial Soft Floor Strain Potential

In TFT, the central source establishes a radial strain state in the active Soft Floor. The dimensionless gravitational strain is

$$\alpha_{\rm G}(r) = \frac{GM}{rc_{\rm E}^2}. \tag{K.8}$$

The corresponding specific tension potential is

$$\Phi_\tau(r) = -c_{\rm E}^2\alpha_{\rm G}(r). \tag{K.9}$$

Therefore,

$$\Phi_\tau(r) = -\frac{GM}{r}. \tag{K.10}$$

The potential has dimensions

$$[\Phi_\tau] = \mathrm{m}^2/\mathrm{s}^2. \tag{K.11}$$

Its radial derivative gives the source-generated acceleration:

$$-\frac{\mathrm{d}\Phi_\tau}{\mathrm{d}r} = -\frac{GM}{r^2}. \tag{K.12}$$

Thus, the inward acceleration magnitude is

$$g_{\rm b}(r) = \frac{GM}{r^2}. \tag{K.13}$$

The Newtonian potential is therefore recovered as the specific mechanical tension potential of the active Soft Floor.

K.3 Coordinate Bridge to the Areal-Radius Representation

The effective Soft Floor measurement tensor developed in Section 11.4.2 is expressed in locally isotropic spatial coordinates. In the weak-field limit,

$$\alpha_{\rm G} \ll 1, \tag{K.14}$$

its line element is

$$\mathrm{d}s_\tau^2 \approx -\left[1-2\alpha_{\rm G}(r_{\rm iso})\right]c_{\rm E}^2\mathrm{d}t^2 + \left[1+2\alpha_{\rm G}(r_{\rm iso})\right]\left[\mathrm{d}r_{\rm iso}^2 + r_{\rm iso}^2\left(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\varphi^2\right)\right]. \tag{K.15}$$

Here, r_{iso} is the isotropic radial coordinate associated with the spatial representation used in Chapter 11.

For the bound-orbit problem, it is convenient to introduce the areal radius r, defined so that a spherical strain shell has physical area $4\pi r^2$. To first weak-field order,

$$r^2 = [1 + 2\alpha_{\mathrm{G}}(r_{\mathrm{iso}})]\, r_{\mathrm{iso}}^2. \tag{K.16}$$

Therefore,

$$r = r_{\mathrm{iso}}\,[1 + \alpha_{\mathrm{G}}(r_{\mathrm{iso}})] + \mathcal{O}(\alpha_{\mathrm{G}}^2). \tag{K.17}$$

For the spherical source field,

$$\alpha_{\mathrm{G}}(r_{\mathrm{iso}}) = \frac{GM}{r_{\mathrm{iso}} c_{\mathrm{E}}^2}. \tag{K.18}$$

Consequently,

$$\frac{\mathrm{d}\alpha_{\mathrm{G}}}{\mathrm{d}r_{\mathrm{iso}}} = -\frac{\alpha_{\mathrm{G}}}{r_{\mathrm{iso}}}, \tag{K.19}$$

and differentiation of the areal-radius relation gives

$$\mathrm{d}r = \mathrm{d}r_{\mathrm{iso}} + \mathcal{O}(\alpha_{\mathrm{G}}^2). \tag{K.20}$$

The angular sector then becomes

$$[1 + 2\alpha_{\mathrm{G}}(r_{\mathrm{iso}})]\, r_{\mathrm{iso}}^2 \left(\mathrm{d}\theta^2 + \sin^2\theta\, \mathrm{d}\varphi^2\right) = r^2 \left(\mathrm{d}\theta^2 + \sin^2\theta\, \mathrm{d}\varphi^2\right) + \mathcal{O}(\alpha_{\mathrm{G}}^2). \tag{K.21}$$

Similarly,

$$[1 + 2\alpha_{\mathrm{G}}(r_{\mathrm{iso}})]\, \mathrm{d}r_{\mathrm{iso}}^2 = [1 - 2\alpha_{\mathrm{G}}(r)]^{-1}\, \mathrm{d}r^2 + \mathcal{O}(\alpha_{\mathrm{G}}^2), \tag{K.22}$$

where

$$\alpha_{\mathrm{G}}(r_{\mathrm{iso}}) = \alpha_{\mathrm{G}}(r) + \mathcal{O}(\alpha_{\mathrm{G}}^2). \tag{K.23}$$

The weak-field Soft Floor line element may therefore be written in areal-radius form as

$$\mathrm{d}s_\tau^2 \approx -\left[1 - 2\alpha_{\mathrm{G}}(r)\right] c_{\mathrm{E}}^2 \mathrm{d}t^2 + [1 - 2\alpha_{\mathrm{G}}(r)]^{-1}\, \mathrm{d}r^2 + r^2 \left(\mathrm{d}\theta^2 + \sin^2\theta\, \mathrm{d}\varphi^2\right). \tag{K.24}$$

For an orbit confined to the equatorial plane,

$$\theta = \frac{\pi}{2}, \qquad \mathrm{d}\theta = 0, \tag{K.25}$$

this reduces to

$$\mathrm{d}s_\tau^2 \approx -\left[1 - 2\alpha_{\mathrm{G}}(r)\right] c_{\mathrm{E}}^2 \mathrm{d}t^2 + [1 - 2\alpha_{\mathrm{G}}(r)]^{-1}\, \mathrm{d}r^2 + r^2 \mathrm{d}\varphi^2. \tag{K.26}$$

This expression is the areal-coordinate weak-field representation of the effective Soft Floor tensor developed in Chapter 11. It is not introduced as an independent geometric field postulate.

K.4 Leading Bound-Orbit Strain Action

The preceding coordinate transformation expresses the Chapter 11 Soft Floor response in the areal radial coordinate appropriate to central-orbit dynamics. At the homogenized continuum level, the motion of a massive bound topological defect is represented by the quadratic specific action associated with this effective strain tensor.

$$\boxed{\mathcal{L}_{\rm orb} = \frac{1}{2}\left[-\left(1-2\alpha_{\rm G}\right)c_{\rm E}^2\dot{t}^2 + \left(1-2\alpha_{\rm G}\right)^{-1}\dot{r}^2 + r^2\dot{\varphi}^2\right]}. \tag{K.27}$$

The reciprocal radial coefficient is understood at the retained weak-field order,

$$\left(1-2\alpha_{\rm G}\right)^{-1} = 1 + 2\alpha_{\rm G} + \mathcal{O}(\alpha_{\rm G}^2). \tag{K.28}$$

The action is therefore the areal-coordinate continuum representation of the strained Soft Floor. It does not treat the effective tensor as fundamental spacetime geometry; the tensor supplies the variational bookkeeping for the transport of a bound defect through the material strain field.

The overdot denotes differentiation with respect to the proper-time parameter $t_{\rm p}$:

$$\dot{t} = \frac{{\rm d}t}{{\rm d}t_{\rm p}}, \qquad \dot{r} = \frac{{\rm d}r}{{\rm d}t_{\rm p}}, \qquad \dot{\varphi} = \frac{{\rm d}\varphi}{{\rm d}t_{\rm p}}. \tag{K.29}$$

The action retains radial motion explicitly through $\dot{r}$. Tangential transport appears through $r\dot{\varphi}$, while no assumption of a purely circular orbit is required.

K.5 Conserved Energy and Canonical Angular Momentum

The coordinates t and φ do not appear explicitly in $\mathcal{L}_{\rm orb}$. They are therefore cyclic coordinates.

Time-translation symmetry gives the conserved specific energy

$$\boxed{\mathcal{E}_{\rm orb} = \left(1-2\alpha_{\rm G}\right)c_{\rm E}^2\dot{t}}. \tag{K.30}$$

Azimuthal symmetry gives the conserved canonical specific angular momentum

$$\boxed{\ell_{\rm orb} = \frac{\partial\mathcal{L}_{\rm orb}}{\partial\dot{\varphi}} = r^2\dot{\varphi}}. \tag{K.31}$$

The same conserved quantity may be evaluated before the coordinate transformation. In the isotropic radial coordinate,

$$\ell_{\rm orb} = \left[1 + 2\alpha_{\rm G}(r_{\rm iso})\right] r_{\rm iso}^2\dot{\varphi}. \tag{K.32}$$

Using the areal-radius definition,

$$r^2 = \left[1 + 2\alpha_{\rm G}(r_{\rm iso})\right] r_{\rm iso}^2, \tag{K.33}$$

gives

$$\ell_{\rm orb} = r^2\dot{\varphi}. \tag{K.34}$$

Thus, the conserved angular momentum used in the orbital reduction follows from azimuthal symmetry and is preserved under the coordinate transformation.

The tangential transport speed measured with respect to the proper-time parameter is therefore

$$v_\perp = r\dot{\varphi} = \frac{\ell_{\rm orb}}{r}. \tag{K.35}$$

Hence,

$$v_\perp^2 = \frac{\ell_{\rm orb}^2}{r^2}. \tag{K.36}$$

The conservation law

$$\ell_{\mathrm{orb}} = r v_{\perp} \tag{K.37}$$

is therefore not imposed independently. It follows directly from azimuthal symmetry of the bound-orbit action.

For weak fields, the difference between proper-time and coordinate-time tangential speeds contributes beyond the retained leading orbital-strain term. The same symbol $v_{\perp}$ may therefore be used for the weak-field orbital speed appearing in the reduced acceleration law.

K.6 Cyclic Reduction of the Bound-Orbit Action

For a massive trajectory parameterized by proper time, the specific action satisfies the normalization

$$2\mathcal{L}_{\mathrm{orb}} = -c_{\mathrm{E}}^2. \tag{K.38}$$

Substitution of the conserved energy and angular momentum gives

$$-c_{\mathrm{E}}^2 = -\frac{\mathcal{E}_{\mathrm{orb}}^2}{(1-2\alpha_{\mathrm{G}})\, c_{\mathrm{E}}^2} + (1-2\alpha_{\mathrm{G}})^{-1}\, \dot{r}^2 + \frac{\ell_{\mathrm{orb}}^2}{r^2}. \tag{K.39}$$

Multiplying by $-(1-2\alpha_{\mathrm{G}})$ yields

$$(1-2\alpha_{\mathrm{G}})\, c_{\mathrm{E}}^2 = \frac{\mathcal{E}_{\mathrm{orb}}^2}{c_{\mathrm{E}}^2} - \dot{r}^2 - (1-2\alpha_{\mathrm{G}})\, \frac{\ell_{\mathrm{orb}}^2}{r^2}. \tag{K.40}$$

Rearranging,

$$\dot{r}^2 + (1-2\alpha_{\mathrm{G}}) \left(c_{\mathrm{E}}^2 + \frac{\ell_{\mathrm{orb}}^2}{r^2} \right) = \frac{\mathcal{E}_{\mathrm{orb}}^2}{c_{\mathrm{E}}^2}. \tag{K.41}$$

Dividing by two and expanding the strain term gives

$$\frac{1}{2}\dot{r}^2 + \frac{1}{2}c_{\mathrm{E}}^2 + \frac{\ell_{\mathrm{orb}}^2}{2r^2} - \alpha_{\mathrm{G}} c_{\mathrm{E}}^2 - \alpha_{\mathrm{G}} \frac{\ell_{\mathrm{orb}}^2}{r^2} = \frac{\mathcal{E}_{\mathrm{orb}}^2}{2c_{\mathrm{E}}^2}. \tag{K.42}$$

Using

$$\Phi_{\tau} = -\alpha_{\mathrm{G}} c_{\mathrm{E}}^2, \tag{K.43}$$

the radial first integral becomes

$$\frac{1}{2}\dot{r}^2 + \frac{\ell_{\mathrm{orb}}^2}{2r^2} + \Phi_{\tau}(r) + \Phi_{\tau}(r) \frac{\ell_{\mathrm{orb}}^2}{c_{\mathrm{E}}^2 r^2} = \frac{1}{2} \left(\frac{\mathcal{E}_{\mathrm{orb}}^2}{c_{\mathrm{E}}^2} - c_{\mathrm{E}}^2 \right). \tag{K.44}$$

The constant rest-capacity term has been transferred to the right-hand side. The remaining terms form the reduced radial energy balance.

K.7 Emergence of the Orbital Strain Potential

The first three terms of the reduced radial energy are the radial kinetic contribution, the ordinary centrifugal contribution, and the Newtonian Soft Floor potential.

The remaining mixed term defines the reduced orbital strain potential:

$$\boxed{\Phi_{\mathrm{orb}}^{(\mathrm{red})}(r) = \Phi_{\tau}(r) \frac{\ell_{\mathrm{orb}}^2}{c_{\mathrm{E}}^2 r^2}}. \tag{K.45}$$

Since

$$v_\perp^2 = \frac{\ell_{\rm orb}^2}{r^2}, \tag{K.46}$$

the same result is

$$\boxed{\Phi_{\rm orb}^{(\rm red)} = \Phi_\tau \frac{v_\perp^2}{c_{\rm E}^2}}. \tag{K.47}$$

Thus, the orbital coupling is not introduced as an independent velocity-dependent potential before variation. It emerges from the cyclic reduction of the bound-orbit action.

The unit coefficient follows directly from the linear-strain factor in the action. Specifically,

$$\frac{1}{2}\left(-2\alpha_{\rm G}\right)\frac{\ell_{\rm orb}^2}{r^2} = -\alpha_{\rm G}\frac{\ell_{\rm orb}^2}{r^2}, \tag{K.48}$$

and because

$$-\alpha_{\rm G} = \frac{\Phi_\tau}{c_{\rm E}^2}, \tag{K.49}$$

the coefficient multiplying

$$\Phi_\tau \frac{\ell_{\rm orb}^2}{c_{\rm E}^2 r^2} \tag{K.50}$$

is exactly unity.

No independent numerical fitting coefficient is required.

Substituting

$$\Phi_\tau = -\frac{GM}{r} \tag{K.51}$$

gives

$$\boxed{\Phi_{\rm orb}^{(\rm red)}(r) = -\frac{GM\ell_{\rm orb}^2}{c_{\rm E}^2 r^3}}. \tag{K.52}$$

The cubic radial dependence follows from the product

$$\Phi_\tau \propto r^{-1}, \qquad v_\perp^2 \propto r^{-2}, \tag{K.53}$$

so that

$$\Phi_{\rm orb}^{(\rm red)} \propto r^{-3}. \tag{K.54}$$

K.8 Radial Dynamics and the Coefficient 3

The reduced radial energy contains the effective potential

$$\frac{\ell_{\rm orb}^2}{2r^2} - \frac{GM}{r} - \frac{GM\ell_{\rm orb}^2}{c_{\rm E}^2 r^3}. \tag{K.55}$$

Differentiation gives the radial equation of motion

$$\ddot{r} = \frac{\ell_{\rm orb}^2}{r^3} - \frac{GM}{r^2} - \frac{3GM\ell_{\rm orb}^2}{c_{\rm E}^2 r^4}. \tag{K.56}$$

The first term is the outward centrifugal contribution. The remaining terms are the inward source-field accelerations.

The total inward strain-generated acceleration magnitude is therefore

$$g_{\mathrm{strain}}^{(\mathrm{red})}(r) = \frac{GM}{r^2} + \frac{3GM\ell_{\mathrm{orb}}^2}{c_{\mathrm{E}}^2 r^4}. \tag{K.57}$$

Using

$$g_{\mathrm{b}} = \frac{GM}{r^2} \tag{K.58}$$

and

$$v_\perp^2 = \frac{\ell_{\mathrm{orb}}^2}{r^2}, \tag{K.59}$$

the additional bound-orbit correction is

$$\boxed{g_{\mathrm{orb}} = 3g_{\mathrm{b}}\frac{v_\perp^2}{c_{\mathrm{E}}^2}}. \tag{K.60}$$

The coefficient 3 follows from

$$\frac{\mathrm{d}}{\mathrm{d}r}\left(r^{-3}\right) = -3r^{-4}. \tag{K.61}$$

It is therefore generated by the radial derivative of the action-derived cubic strain potential.

K.9 Why the Leading Mixed Term Is Tangential

An eccentric orbit contains both radial and tangential motion. The radial velocity has not been omitted: it appears explicitly in the action through

$$(1 - 2\alpha_{\mathrm{G}})^{-1}\,\dot{r}^2. \tag{K.62}$$

The radial degree of freedom describes motion along the pre-existing strain gradient and supplies the radial kinetic part of the variational equation.

The additional orbital potential arises from the angular sector after the cyclic coordinate φ is reduced. It therefore depends on the conserved transverse transport quantity

$$\ell_{\mathrm{orb}} = r^2\dot{\varphi}. \tag{K.63}$$

Mechanically, the mixed term represents the additional strain-locking cost of preserving a bound three-dimensional topological defect while transporting it across the concentric radial prestress shells.

Radial motion and tangential transport therefore enter the action through different channels:

$$\dot{r} \quad \text{governs radial evolution along the strain gradient,} \tag{K.64}$$

while

$$\ell_{\mathrm{orb}} \quad \text{governs conservative transport across the strain shells.} \tag{K.65}$$

The perihelion term is consequently transverse at leading mixed order without assuming a circular orbit.

K.10 Conversion to the Orbital Equation

From canonical angular-momentum conservation,

$$\dot{\varphi} = \frac{\ell_{\rm orb}}{r^2}. \tag{K.66}$$

With

$$u = \frac{1}{r}, \tag{K.67}$$

the radial derivative is

$$\dot{r} = -\ell_{\rm orb}\frac{\mathrm{d}u}{\mathrm{d}\varphi}, \tag{K.68}$$

and

$$\ddot{r} = -\ell_{\rm orb}^2 u^2 \frac{\mathrm{d}^2 u}{\mathrm{d}\varphi^2}. \tag{K.69}$$

Substituting these relations into

$$\ddot{r} = \frac{\ell_{\rm orb}^2}{r^3} - \frac{GM}{r^2} - \frac{3GM\ell_{\rm orb}^2}{c_{\rm E}^2 r^4} \tag{K.70}$$

gives

$$-\ell_{\rm orb}^2 u^2 \frac{\mathrm{d}^2 u}{\mathrm{d}\varphi^2} = \ell_{\rm orb}^2 u^3 - GMu^2 - \frac{3GM\ell_{\rm orb}^2}{c_{\rm E}^2} u^4. \tag{K.71}$$

Dividing by

$$-\ell_{\rm orb}^2 u^2 \tag{K.72}$$

yields

$$\boxed{\frac{\mathrm{d}^2 u}{\mathrm{d}\varphi^2} + u = \frac{GM}{\ell_{\rm orb}^2} + \frac{3GM}{c_{\rm E}^2} u^2}. \tag{K.73}$$

This is the standard weak-field post-Newtonian orbital equation.

In TFT, the nonlinear u^2 term is generated by the action-level coupling between the radial Soft Floor strain and the canonical angular transport of the bound defect.

K.11 Recovery of Perihelion Precession

The Newtonian solution is

$$u_{\rm N}(\varphi) = \frac{1}{p}\left(1 + e\cos\varphi\right), \tag{K.74}$$

where

$$p = \frac{\ell_{\rm orb}^2}{GM} = a(1-e^2). \tag{K.75}$$

The additional nonlinear term is

$$\frac{3GM}{c_{\rm E}^2} u^2. \tag{K.76}$$

To first order, substitution of the Newtonian solution into this term produces a resonant contribution proportional to $e\cos\varphi$. The resonance shifts the angular frequency of the radial oscillation.

The corrected orbit may be written as

$$u(\varphi) \approx \frac{1}{p}\left[1 + e\cos\left((1-\delta)\varphi\right)\right], \tag{K.77}$$

where

$$\delta = \frac{3GM}{pc_{\mathrm{E}}^2}. \tag{K.78}$$

The perihelion advance per orbit is

$$\Delta\varphi = 2\pi\delta. \tag{K.79}$$

Therefore,

$$\Delta\varphi = \frac{6\pi GM}{pc_{\mathrm{E}}^2}. \tag{K.80}$$

Using

$$p = a(1-e^2), \tag{K.81}$$

the perihelion advance is

$$\boxed{\Delta\varphi = \frac{6\pi GM}{a(1-e^2)c_{\mathrm{E}}^2}}. \tag{K.82}$$

The standard weak-field perihelion result is therefore recovered.

K.12 Mechanical Interpretation

The source mass establishes the radial Soft Floor strain potential

$$\Phi_\tau = -\frac{GM}{r}. \tag{K.83}$$

A massive orbiting body remains a bound topological defect while undergoing radial and tangential transport through this prestressed medium.

The bound-orbit action produces two conserved quantities:

$$\mathcal{E}_{\mathrm{orb}} \tag{K.84}$$

from time-translation symmetry, and

$$\ell_{\mathrm{orb}} \tag{K.85}$$

from azimuthal symmetry.

After the cyclic coordinates are reduced, the angular transport energy is modulated by the radial strain. The resulting mixed potential is

$$\Phi_{\mathrm{orb}}^{(\mathrm{red})} = \Phi_\tau \frac{v_\perp^2}{c_{\mathrm{E}}^2} = -\frac{GM\ell_{\mathrm{orb}}^2}{c_{\mathrm{E}}^2 r^3}. \tag{K.86}$$

Its radial derivative produces the additional inward acceleration

$$g_{\mathrm{orb}} = 3g_{\mathrm{b}}\frac{v_\perp^2}{c_{\mathrm{E}}^2}. \tag{K.87}$$

The orbit therefore accumulates a small phase advance during every radial cycle. The ellipse fails to return exactly to its previous orientation, producing perihelion precession.

In TFT, this effect is interpreted as conservative strain locking of a bound topological defect in the radially prestressed active vacuum, rather than as fundamental curvature of an empty manifold.

K.13 Distinction from the Galactic Condensate Response

The perihelion correction is mechanically distinct from the large-scale galactic response developed in Appendix L.

The geometry-corrected baryonic acceleration is

$$g_{b,\Pi}(R) = \Pi(R) g_b(R). \tag{K.88}$$

The environmental galactic acceleration is

$$g_{\rm obs}(R) = g_{b,\Pi}(R) + \Xi(R)\sqrt{a_{\rm gal} g_{b,\Pi}(R)}. \tag{K.89}$$

The condensate term is an environmental response controlled by the finite-coherence function $\Xi(R)$. It becomes significant in the coherent low-acceleration galactic regime.

In the high-acceleration solar-system regime,

$$\Xi(R) \to 0, \tag{K.90}$$

and, for a nearly spherical source,

$$\Pi(R) \approx 1. \tag{K.91}$$

Therefore,

$$g_{\rm obs}(R) \approx g_b(R). \tag{K.92}$$

Precision bound-orbit dynamics is then obtained by adding the local orbital strain correction:

$$\boxed{g_{\rm bound}(R) = g_{\rm obs}(R) + g_{\rm orb}(R)}. \tag{K.93}$$

Thus,

$$g_{\rm bound}(R) \approx g_b(R) + 3 g_b(R) \frac{v_\perp^2}{c_{\rm E}^2} \tag{K.94}$$

in the solar-system weak-field limit.

The two non-Newtonian channels therefore have different origins:

$$\Xi(R)\sqrt{a_{\rm gal} g_{b,\Pi}(R)} \tag{K.95}$$

is the coherent environmental response of the Vacuum Interstitial Condensate, whereas

$$3 g_b \frac{v_\perp^2}{c_{\rm E}^2} \tag{K.96}$$

is the local conservative bound-orbit correction derived from the massive-defect action.

The galactic term is negligible for solar-system perihelion dynamics. The bound-orbit term is negligible relative to the condensate response in the low-acceleration galactic outskirts.

K.14 Relation to the Effective Soft Floor Tensor and Constitutive Scope

The coordinate bridge established above shows that the bound-orbit action is compatible with the effective Soft Floor measurement tensor developed in Chapter 11. The locally isotropic representation and the areal-radius representation describe the same weak-field continuum response through the retained order.

The causal sequence remains

$$\text{source mass} \longrightarrow \text{radial Soft Floor strain} \longrightarrow \text{effective bound-defect action} \longrightarrow \text{orbital phase advance}. \tag{K.97}$$

The effective tensor is not interpreted as the fundamental cause of gravity. It packages the response of rods, clocks, wave paths, and bound-defect transport to the underlying material strain field.

The present result is an action-level derivation within the homogenized Soft Floor continuum. The derivation establishes the conserved canonical quantities, retains radial motion, and produces the reduced cubic orbital strain potential through cyclic reduction.

A microscopic completion requires derivation of the continuum action from the discrete FCC contact network and the interstitial condensate. In particular, the bond-level theory must determine the incremental radial and tangential compliance of the prestressed lattice and verify the coefficients appearing in the effective bound-orbit action.

K.15 Conclusion

The weak-field perihelion correction follows from the homogenized action of a massive bound topological defect moving through the radially strained Soft Floor. The action is written in the areal radial coordinate obtained from the locally isotropic effective Soft Floor tensor developed in Chapter 11.

The specific bound-orbit Lagrangian is

$$\mathcal{L}_{\mathrm{orb}} = \frac{1}{2}\left[-\left(1-2\alpha_{\mathrm{G}}\right)c_{\mathrm{E}}^{2}\dot{t}^{2} + \left(1-2\alpha_{\mathrm{G}}\right)^{-1}\dot{r}^{2} + r^{2}\dot{\varphi}^{2}\right]. \tag{K.98}$$

Azimuthal symmetry gives the conserved canonical angular momentum

$$\ell_{\mathrm{orb}} = r^{2}\dot{\varphi}. \tag{K.99}$$

Cyclic reduction produces the orbital strain potential

$$\Phi_{\mathrm{orb}}^{(\mathrm{red})} = \Phi_{\tau}\frac{v_{\perp}^{2}}{c_{\mathrm{E}}^{2}} = -\frac{GM\ell_{\mathrm{orb}}^{2}}{c_{\mathrm{E}}^{2}r^{3}}. \tag{K.100}$$

Its radial derivative gives

$$g_{\mathrm{orb}} = 3g_{\mathrm{b}}\frac{v_{\perp}^{2}}{c_{\mathrm{E}}^{2}}. \tag{K.101}$$

The resulting orbital equation is

$$\frac{\mathrm{d}^{2}u}{\mathrm{d}\varphi^{2}} + u = \frac{GM}{\ell_{\mathrm{orb}}^{2}} + \frac{3GM}{c_{\mathrm{E}}^{2}}u^{2}, \tag{K.102}$$

which yields

$$\boxed{\Delta\varphi = \frac{6\pi GM}{a(1-e^2)c_{\mathrm{E}}^2}}. \tag{K.103}$$

The perihelion advance is therefore recovered as the accumulated phase shift generated by the action-level coupling between radial Soft Floor prestress and canonical tangential transport of a bound topological defect.

Appendix L

Cosmic Impedance: The Mechanics of Dark Matter

Subject: Galaxy-scale acceleration generated by the coherent reactive response of the Vacuum Interstitial Condensate.

In standard cosmology, galactic mass discrepancies are modeled primarily through an additional non-baryonic matter component. Tension Field Theory attributes the corresponding excess acceleration to the mechanical response of the Vacuum Interstitial Condensate within the active FCC Soft Floor.

A baryonic tension field phase-loads the surrounding condensate and establishes a correlated restorative response. In the low-acceleration regime, this response contributes to orbital acceleration and appears, under an inverse-square interpretation, as additional dynamical mass. The galactic response is reactive rather than dissipative: the condensate stores and returns deformation energy without producing continuous orbital drag.

L.1 Derivation of the Lattice Impedance Acceleration

The active FCC Soft Floor possesses the baseline surface inertia

$$\mu_{\mathrm{D}}, \tag{L.1}$$

with dimensions

$$[\mu_{\mathrm{D}}] = \mathrm{kg/m^2}. \tag{L.2}$$

The corresponding lattice surface-tension scale is

$$\tau_{\mathrm{D}} = \mu_{\mathrm{D}} c_{\mathrm{E}}^2, \tag{L.3}$$

where c_{E} is the characteristic elastic propagation speed of the active vacuum. The dimensions of τ_{D} are

$$[\tau_{\mathrm{D}}] = \mathrm{N/m}. \tag{L.4}$$

Unlike the inverse-square field generated by a localized source, the background lattice impedance is associated with the global relaxation structure of the vacuum. The Viscous Cosmic Horizon (R_{U}) defines the maximum coherent relaxation length of this background field. A surface-tension contrast of order τ_{D} distributed across R_{U} produces the characteristic restorative stress

$$\left|\frac{\mathrm{d}\tau}{\mathrm{d}R}\right| \approx \frac{\tau_{\mathrm{D}}}{R_{\mathrm{U}}}. \tag{L.5}$$

The stress acting on the lattice surface inertia defines the Lattice Impedance Acceleration (a_{D}):

$$\frac{\tau_{\mathrm{D}}}{R_{\mathrm{U}}} = \mu_{\mathrm{D}} a_{\mathrm{D}}. \tag{L.6}$$

Substitution of

$$\tau_{\mathrm{D}} = \mu_{\mathrm{D}} c_{\mathrm{E}}^2 \tag{L.7}$$

gives

$$\frac{\mu_{\mathrm{D}} c_{\mathrm{E}}^2}{R_{\mathrm{U}}} = \mu_{\mathrm{D}} a_{\mathrm{D}}. \tag{L.8}$$

The surface inertia cancels, yielding

$$a_{\mathrm{D}} = \frac{c_{\mathrm{E}}^2}{R_{\mathrm{U}}}. \tag{L.9}$$

The quantity a_{D} is therefore the acceleration scale associated with the horizon-limited relaxation capacity of the active FCC lattice.

L.2 Connection to Vacuum Damping and the Galactic Acceleration Scale

In Appendix AQ, we derived the Vacuum Lattice Damping Rate ($\Gamma_{\mathrm{D}} = c_{\mathrm{E}}/R_{\mathrm{U}}$), which replaces the empirical Hubble constant. We can express the Lattice Impedance directly in terms of this viscosity:

$$a_{\mathrm{D}} = c_{\mathrm{E}} \cdot \Gamma_{\mathrm{D}} \tag{L.10}$$

This relation connects the characteristic vacuum relaxation rate to its corresponding acceleration scale. The galactic condensate response and the propagation damping mechanism share the same lattice relaxation scale, although they represent different mechanical channels. Propagation damping is dissipative, whereas the coherent galactic response is reactive.

Using

$$R_{\mathrm{U}} \approx 1.2665 \times 10^{26}\ \mathrm{m}, \tag{L.11}$$

the fundamental impedance acceleration is

$$a_{\mathrm{D}} = \frac{(299,792,458)^2}{1.2665 \times 10^{26}} \approx 7.0964 \times 10^{-10}\ \mathrm{m/s^2}. \tag{L.12}$$

For the reduced circular-orbit response, TFT defines the galactic acceleration scale by the closed-cycle projection

$$a_{\mathrm{gal}} \equiv \frac{a_{\mathrm{D}}}{2\pi}. \tag{L.13}$$

Numerically,

$$a_{\mathrm{gal}} \approx 1.1294 \times 10^{-10}\ \mathrm{m/s^2}. \tag{L.14}$$

The factor $1/(2\pi)$ is the closed-azimuthal normalization adopted for the galactic constitutive response. It is distinct from the source-dependent geometric transmission factor ($\Pi(R)$).

The projected scale a_{gal} provides the TFT mechanical counterpart of the empirical low-acceleration scale associated with galactic rotation dynamics.

L.3 The Mechanism: Inductive Reactance and Apparent Dynamical Mass

A baryonic tension gradient displaces and phase-loads the surrounding Vacuum Interstitial Condensate. The condensate responds through a correlated restorative deformation that contributes to the local acceleration field.

This behavior is analogous to inductive reactance or added-mass loading in a continuous medium. The surrounding medium contributes to the dynamical response without becoming an independent localized matter component. Because the response is reactive, it modifies the local acceleration field without requiring a continuous loss of orbital energy.

Let $g_b(R)$ denote the spherical-equivalent baryonic acceleration. The geometry-corrected radial field defined in Appendix M is

$$g_{b,\Pi}(R) = \Pi(R) g_b(R). \tag{L.15}$$

At the reduced constitutive level, the relative response of the Vacuum Interstitial Condensate is represented by the dimensionless coefficient

$$\chi_{\rm g}(R) = \sqrt{\frac{a_{\rm gal}}{g_{b,\Pi}(R)}}. \tag{L.16}$$

The coefficient $\chi_{\rm g}$ acts as an effective nonlinear gravitational susceptibility of the vacuum and measures the induced condensate response relative to the directly transmitted baryonic acceleration.

In the high-acceleration regime,

$$g_{b,\Pi} \gg a_{\rm gal}, \tag{L.17}$$

the response coefficient satisfies

$$\chi_{\rm g} \ll 1, \tag{L.18}$$

and the induced condensate contribution is small relative to the baryonic field.

In the low-acceleration regime,

$$g_{b,\Pi} \ll a_{\rm gal}, \tag{L.19}$$

the response coefficient satisfies

$$\chi_{\rm g} \gg 1, \tag{L.20}$$

and the coherent condensate contribution becomes dynamically significant.

In the spherical and unscreened limit, where

$$\Pi(R) = 1, \tag{L.21}$$

the resulting response may be represented through an apparent effective mass,

$$M_{\rm eff}(R) = M_b \left[1 + \chi_{\rm g}(R)\right]. \tag{L.22}$$

This quantity is not an additional material mass. It is the dynamical mass that would be inferred if the condensate-supported acceleration were represented entirely through an inverse-square gravitational law. For anisotropic systems, the acceleration relation provides the more general description.

L.4 The Unscreened Acceleration Law

Before finite-coherence screening is introduced, the environmental acceleration is

$$g_{\mathrm{obs}}(R) = g_{b,\Pi}(R)\left[1 + \chi_{\mathrm{g}}(R)\right]. \tag{L.23}$$

Substitution of the condensate-response coefficient gives

$$g_{\mathrm{obs}}(R) = g_{b,\Pi}(R) + \sqrt{a_{\mathrm{gal}} g_{b,\Pi}(R)}. \tag{L.24}$$

Using the geometric transmission relation

$$g_{b,\Pi}(R) = \Pi(R) g_b(R), \tag{L.25}$$

the acceleration law becomes

$$g_{\mathrm{obs}}(R) = \Pi(R) g_b(R) + \sqrt{a_{\mathrm{gal}} \Pi(R) g_b(R)}. \tag{L.26}$$

The first term is the directly transmitted baryonic restorative acceleration. The second term is the induced response of the Vacuum Interstitial Condensate.

In the coherent low-acceleration regime,

$$g_{b,\Pi} \ll a_{\mathrm{gal}}, \tag{L.27}$$

the direct baryonic term becomes subdominant, yielding

$$g_{\mathrm{obs}}(R) \approx \sqrt{a_{\mathrm{gal}} g_{b,\Pi}(R)}. \tag{L.28}$$

L.5 Flat Rotation Curves and the Baryonic Tully–Fisher Relation

For a finite baryonic distribution, the enclosed mass approaches an approximately constant value (M_b) outside the principal matter region. The spherical-equivalent baryonic acceleration is then

$$g_b(R) = \frac{G M_b}{R^2}. \tag{L.29}$$

Including geometric radial transmission gives

$$g_{b,\Pi}(R) = \Pi(R) \frac{G M_b}{R^2}. \tag{L.30}$$

In the coherent low-acceleration regime,

$$g_{\mathrm{obs}}(R) \approx \sqrt{a_{\mathrm{gal}} \Pi(R) \frac{G M_b}{R^2}}. \tag{L.31}$$

Therefore,

$$g_{\mathrm{obs}}(R) \approx \frac{\sqrt{a_{\mathrm{gal}} \Pi(R) G M_b}}{R}. \tag{L.32}$$

For circular motion,

$$g_{\mathrm{obs}}(R) = \frac{v^2(R)}{R}. \tag{L.33}$$

Substitution gives

$$v^2(R) = \sqrt{a_{\rm gal}\Pi(R)GM_b}. \tag{L.34}$$

Squaring yields

$$v^4(R) = \Pi(R)Ga_{\rm gal}M_b. \tag{L.35}$$

In the outer region, the bounded geometric transmission factor approaches the spherical far-field limit,

$$\Pi(R) \to 1. \tag{L.36}$$

The asymptotic relation becomes

$$v_\infty^4 = Ga_{\rm gal}M_b. \tag{L.37}$$

The orbital speed is therefore independent of radius in the coherent outer regime, producing a flat rotation curve and the Baryonic Tully–Fisher scaling.

L.6 The Unified Screening Function

The coherent condensate response cannot persist over all accelerations and distances. It is bounded by an inner activation condition and an outer coherence condition.

In high-acceleration regions, local deformation is accommodated without establishing an extended condensate response. At sufficiently large radius, the source-correlated phase relation becomes indistinguishable from the background vacuum fluctuations, terminating the galactic coupling.

These two limits are represented by the screening function

$$\Xi(R) = \left[1 + \left(\frac{g_{b,\Pi}(R)}{g_*}\right)^{n_1}\right]^{-1} \left[1 + \left(\frac{R}{R_{\rm c}}\right)^{n_2}\right]^{-1}. \tag{L.38}$$

The inner threshold (g_*) defines the acceleration above which coherent condensate loading is suppressed. A provisional galactic range is

$$g_* \sim (50\text{–}100)a_{\rm gal}. \tag{L.39}$$

The coherence radius ($R_{\rm c}$) defines the outer extent of the source-correlated condensate response. A representative range is

$$R_{\rm c} \sim 200\text{–}500 \text{ kpc}. \tag{L.40}$$

The positive exponents n_1 and n_2 control the sharpness of the inner and outer transitions. The baseline smooth-transition model uses

$$n_1 \approx n_2 \approx 2. \tag{L.41}$$

With finite-coherence screening, the global acceleration law becomes

$$g_{\rm obs}(R) = g_{b,\Pi}(R) + \Xi(R)\sqrt{a_{\rm gal}g_{b,\Pi}(R)}. \tag{L.42}$$

Equivalently,

$$g_{\rm obs}(R) = \Pi(R)g_b(R) + \Xi(R)\sqrt{a_{\rm gal}\Pi(R)g_b(R)}. \tag{L.43}$$

The screening function acts only on the induced condensate response. The directly transmitted baryonic term remains present in every regime.

L.7 Limiting Behavior

Inner high-acceleration region For

$$g_{b,\Pi} \gg g_*, \tag{L.44}$$

the inner screening factor approaches zero:

$$\Xi(R) \to 0. \tag{L.45}$$

The acceleration reduces to

$$g_{\rm obs}(R) \to g_{b,\Pi}(R). \tag{L.46}$$

Coherent intermediate region For

$$g_{b,\Pi} \lesssim g_*, \qquad R \ll R_{\rm c}, \tag{L.47}$$

the screening function approaches unity:

$$\Xi(R) \approx 1. \tag{L.48}$$

The environmental acceleration becomes

$$g_{\rm obs}(R) \approx g_{b,\Pi}(R) + \sqrt{a_{\rm gal} g_{b,\Pi}(R)}. \tag{L.49}$$

Deep galactic regime For

$$g_{b,\Pi} \ll a_{\rm gal}, \qquad R \ll R_{\rm c}, \tag{L.50}$$

the condensate contribution dominates:

$$g_{\rm obs}(R) \approx \sqrt{a_{\rm gal} g_{b,\Pi}(R)}. \tag{L.51}$$

Where $\Pi(R) \to 1$, this produces

$$v_\infty^4 = G a_{\rm gal} M_b. \tag{L.52}$$

Beyond the coherence radius For

$$R \gg R_{\rm c}, \tag{L.53}$$

the outer screening factor approaches zero:

$$\Xi(R) \to 0. \tag{L.54}$$

The acceleration returns to the directly transmitted baryonic field:

$$g_{\rm obs}(R) \to g_{b,\Pi}(R). \tag{L.55}$$

The outer cutoff prevents the $1/R$ impedance regime from extending indefinitely. Without this termination, the spherical-equivalent dynamical mass would increase linearly with radius and the corresponding potential would grow logarithmically without bound.

L.8 Scope and Validation

The cosmic-impedance law is a reduced galaxy-scale constitutive model for the coherent response of the Vacuum Interstitial Condensate. The fundamental acceleration (a_{D}) is fixed by the Absolute Optical Horizon and the vacuum relaxation rate, while (a_{gal}) is the closed-cycle scale entering the galactic response.

The factor $\Pi(R)$ describes source-dependent geometric transmission. The function $\Xi(R)$ controls the inner activation and outer coherence of the induced condensate contribution. The parameters g_*, R_{c}, n_1, and n_2 require calibration against galaxy rotation curves, high-acceleration orbital constraints, weak-lensing profiles, and numerical solutions of the coupled baryonic–condensate field.

The present formulation addresses the galaxy-scale excess-acceleration regime. Applications to galaxy clusters, merging systems, and nonspherical lensing geometries require the corresponding multidimensional tension and condensate-coherence solutions.

Appendix M

The Radial Projection Tensor and Geometric Transmission Factor

Subject: Radial decomposition and geometric transmission of anisotropic restorative tension fields.

M.1 Purpose and Scope

In Tension Field Theory, gravitational acceleration arises from the restorative tension gradient of the active vacuum. For a spherically symmetric source, the exterior field is purely radial, and conservation of radial tension flux yields the inverse-square acceleration law without an additional geometric correction.

Flattened, rotating, or otherwise anisotropic sources generate a directional tension field containing radial, tangential, and shear components. The radially transmitted component must therefore be distinguished from the total local tension state.

Two related quantities are introduced for this purpose. The radial tensor projector,

$$\Pi_{\mu\nu}, \tag{M.1}$$

extracts the radial component of a complete tension-stress field. The scalar geometric transmission factor,

$$\Pi(R), \tag{M.2}$$

represents the corresponding radial transmission efficiency in a reduced one-dimensional acceleration model.

The tensor projector is a geometric operation applied to the directional field. The scalar factor is an effective representation of source anisotropy when the full tensor field is not calculated explicitly.

M.2 Radial Tensor Projector

Let $\hat{r}_\mu$ denote the radial unit vector in the spatial sector,

$$\hat{r}_\mu = \frac{x_\mu}{R}, \tag{M.3}$$

with

$$R^2 = x_\alpha x^\alpha, \tag{M.4}$$

where the index contraction is restricted to the spatial coordinates.

The radial tensor projector is defined as

$$\Pi_{\mu\nu} = \hat{r}_\mu \hat{r}_\nu = \frac{x_\mu x_\nu}{R^2}. \tag{M.5}$$

It satisfies the idempotent relation

$$\Pi_\mu{}^\alpha \Pi_{\alpha\nu} = \Pi_{\mu\nu}, \tag{M.6}$$

so repeated application leaves an already radial field unchanged.

Let $\tau_{\mu\nu}$ denote the directional tension-stress tensor of the active vacuum. The tensor contains the radial, tangential, and shear components of the local restorative stress state. Its radial normal component is

$$\tau_{rr} = \hat{r}_\mu \tau^{\mu\nu} \hat{r}_\nu = \Pi_{\mu\nu} \tau^{\mu\nu}. \tag{M.7}$$

The tension-stress tensor and its radial projection have units

$$[\tau_{\mu\nu}] = [\tau_{rr}] = \mathrm{N/m^2}. \tag{M.8}$$

The scalar volumetric tension τ represents the isotropic component of the local tension state, whereas $\tau_{\mu\nu}$ describes its directional extension.

For a spherically symmetric field, the restorative stress is entirely radial, and the projector returns the complete field. For an anisotropic source, the contraction isolates only the component transmitted along $\hat{\mathbf{r}}$.

M.3 Scalar Geometric Transmission Factor

In a reduced radial model, the spherical-equivalent baryonic acceleration is defined as

$$g_b(R) = \frac{GM_b(< R)}{R^2}, \tag{M.9}$$

where $M_b(< R)$ is the baryonic mass enclosed within radius R.

For an anisotropic source, the radially transmitted acceleration may differ from this spherical-equivalent value. The projected baryonic acceleration is therefore written as

$$g_{b,\Pi}(R) = \Pi(R) g_b(R). \tag{M.10}$$

The scalar geometric transmission factor is consequently defined by

$$\Pi(R) = \frac{g_{b,\Pi}(R)}{g_b(R)}. \tag{M.11}$$

Its physical limits are

$$\Pi(R) = 1 \tag{M.12}$$

for isotropic spherical transmission,

$$\Pi(R) < 1 \tag{M.13}$$

for reduced radial transmission associated with flattening, shear, or tangential redistribution, and

$$\Pi(R) > 1 \tag{M.14}$$

for enhanced radial transmission associated with geometric convergence or focusing.

The scalar $\Pi(R)$ represents the net radial effect of the source geometry after the directional field has been reduced to a one-dimensional acceleration law. It does not retain the complete angular structure contained in $\tau_{\mu\nu}$.

M.4 Bounded Parametric Representation

When the full anisotropic tension field is unavailable, the scalar transmission factor may be represented by the bounded form

$$\Pi(R) = 1 \pm \frac{\delta}{1 + (R/R_{\rm d})^n}. \tag{M.15}$$

The minus sign describes reduced radial transmission, while the plus sign describes enhanced radial transmission or geometric focusing.

The parameter δ is the maximum fractional departure from spherical transmission, $R_{\rm d}$ is the characteristic geometric scale of the source, and $n > 0$ controls the radial decay of the anisotropic correction.

For $0 \le \delta < 1$, the transmission factor remains finite and positive. At the inner limit,

$$\Pi(0) = 1 \pm \delta. \tag{M.16}$$

At distances much larger than the characteristic source scale,

$$\Pi(R) \to 1 \qquad \text{for} \qquad R \gg R_{\rm d}. \tag{M.17}$$

The far-field expansion is

$$\Pi(R) \approx 1 \pm \delta \left(\frac{R_{\rm d}}{R}\right)^n, \qquad R \gg R_{\rm d}, \tag{M.18}$$

so the bounded expression preserves the intended asymptotic power-law correction while remaining regular near the source.

The quantities δ, $R_{\rm d}$, and n are source-dependent geometric parameters. They may be determined from the baryonic mass distribution, the source inertia tensor, or a direct numerical solution of the anisotropic TFT field equations.

M.5 Application to the Environmental Acceleration

The baryonic restorative field is first projected into the radial direction:

$$g_{b,\Pi}(R) = \Pi(R) g_b(R). \tag{M.19}$$

The interstitial-condensate response is driven by this locally transmitted baryonic acceleration. The total environmental acceleration is therefore

$$g_{\rm obs}(R) = g_{b,\Pi}(R) + \Xi(R)\sqrt{a_{\rm gal} g_{b,\Pi}(R)}. \tag{M.20}$$

Substitution of the projected field gives

$$g_{\rm obs}(R) = \Pi(R) g_b(R) + \Xi(R)\sqrt{a_{\rm gal}\Pi(R) g_b(R)}. \tag{M.21}$$

The first term represents the direct baryonic restorative acceleration. The second term represents the induced interstitial-condensate response. The screening function $\Xi(R)$ controls the activation and finite coherence of the condensate contribution, while $a_{\rm gal}$ is the galactically projected impedance acceleration defined in Appendix H.

The geometric factor enters linearly in the direct baryonic contribution and through its square root in the induced condensate contribution. In the spherical limit,

$$\Pi(R) = 1, \tag{M.22}$$

and the environmental law reduces to

$$g_{\rm obs}(R) = g_b(R) + \Xi(R)\sqrt{a_{\rm gal} g_b(R)}. \tag{M.23}$$

When $g_b(R)$ is obtained from the spherical-equivalent enclosed mass, $\Pi(R)$ represents the correction associated with the nonspherical source geometry. When the baryonic acceleration is calculated directly from the complete stellar disk, gas distribution, bulge, and other nonspherical components, the geometric transmission is already contained in the calculated field. In that case, the explicit scalar factor is set to unity or absorbed into the definition of $g_b(R)$.

For a complete anisotropic or rotating solution, the radial acceleration is obtained directly from the solved directional tension field. The tensor projector may then be applied as

$$\tau_{rr}(R,\theta) = \Pi_{\mu\nu}\tau^{\mu\nu}(R,\theta). \tag{M.24}$$

In a spherically symmetric exterior, the scalar transmission factor remains unity. In an axisymmetric or rotating strong field, the angular dependence of the tension field must be retained explicitly, and the scalar function $\Pi(R)$ serves only as a reduced radial representation.

The parametric transmission factor may be tested against numerical anisotropic field solutions and observed baryonic mass profiles. Its dependence on source geometry provides a direct measure of radial tension transmission in flattened and rotationally structured systems.

Appendix N

Kinematic Shear, Tensor Mechanics, and Field Unification

Abstract

This appendix develops the long-wavelength gravitational-wave sector of the active State-I vacuum and constructs its mechanical connection to the microscopic FCC scaffold established in Appendix D and the coherent dual-phase kinematics developed in Appendix E. The microscopic FCC scaffold possesses a finite transverse restoring coefficient and a primitive-cell inertia normalization whose ratio fixes the gravity-neutral propagation capacity c_{E}. In the conservative coherent branch, the interstitial condensate is entrained with the scaffold without relative condensate flow and supplies the corresponding incremental volume constraint.

The gravitational-wave response is represented by a collective transverse-traceless tensor $\mathsf{H}_{ij}^{(\mathrm{GW})}$, distinct from the ordinary affine Cauchy strain of the FCC displacement field. The two tensor polarization bases are derived directly from correlated dyads of the FCC nearest-neighbor bond families, and their degeneracy follows from the same isotropic contact closure that governs the long-wavelength scaffold continuum. This establishes a microscopic geometric origin for the $+$ and $\times$ tensor structures while separating the collective gravitational-wave coordinate from an ordinary transverse phonon.

The propagating tensor sector is formulated as a self-equilibrated directional-tension redistribution of the active Soft Floor. Its leading gapless long-wavelength closure is governed by spatial gradients of the collective tensor rather than by a local affine shear energy. Within this closure, the tensor-source normalization is fixed by the independently established weak-field static gravitational response, while free propagation remains governed solely by the State-I mechanical carrier. The resulting collective response is therefore spectral: the effective gravitational-wave stiffness and equivalent continuum inertia depend on wave number or frequency rather than representing universal equilibrium material constants.

This construction yields a derived microscopic-to-collective response ratio $\zeta_{\mathrm{GW}}(k)$, replacing its previous role as an unexplained numerical scale comparison. The same tensor normalization produces the far-zone quadrupole strain, gravitational-wave energy flux, total quadrupole luminosity, and leading circular-binary chirp relation. GW150914 consequently enters as an observational consistency check on the derived response rather than as the calibration used to define it.

Static gravity and gravitational radiation remain distinct dynamical sectors of the same State-I mechanical architecture: static gravity is an equilibrated restorative tension configuration, whereas gravitational radiation is a propagating transverse tensor redistribution of that configuration. The

remaining microscopic completion is the derivation of the collective directional-tension action from the full finite-wave-number FCC contact, phase, rotational, condensate, and Tension-Column dynamics, together with the corresponding strong-field source projection for the evolving FCC/SC phase boundary.

N.1 Microscopic Scaffold Baseline and Scale Hierarchy

Appendix D establishes the gravity-independent microscopic FCC scaffold that supplies the local transverse mechanical carrier of the active State-I vacuum. Under the leading isotropic contact closure,

$$\kappa_{\mathrm{n}} = \kappa_{\mathrm{t}}, \tag{N.1}$$

the primitive-cell scaffold inertia normalization is

$$\rho_{\mathrm{sh}}^{(\mathrm{micro},0)} = \beta_{\mathrm{geo}}\rho_{\mathrm{D}}, \tag{N.2}$$

and the corresponding primitive-cell tangent shear coefficient is

$$K_{\mathrm{sh}}^{(\mathrm{micro},0)} = \rho_{\mathrm{sh}}^{(\mathrm{micro},0)}c_{\mathrm{E}}^2 = \beta_{\mathrm{geo}}\rho_{\mathrm{D}}c_{\mathrm{E}}^2. \tag{N.3}$$

Here ρ_{D} is the intrinsic density assigned to the solid nodal phase, whereas $\rho_{\mathrm{sh}}^{(\mathrm{micro},0)}$ is the nodal mass averaged over the complete FCC primitive-cell volume. The factor

$$\beta_{\mathrm{geo}} = \frac{\pi}{3\sqrt{2}} \tag{N.4}$$

is therefore the FCC solid-volume fraction entering the primitive-cell averaging and does not represent a reduction of the intrinsic nodal density.

The coefficient $K_{\mathrm{sh}}^{(\mathrm{micro},0)}$ is the unstrained primitive-cell tangent shear modulus of the FCC scaffold. Equivalently, Appendix D gives

$$K_{\mathrm{sh}}^{(\mathrm{micro},0)} = \frac{A_{\mathrm{ct}}^{(\mathrm{modal})}}{V_{\mathrm{p}}}\tau_{\mathrm{D}}, \tag{N.5}$$

where

$$A_{\mathrm{ct}}^{(\mathrm{modal})} = 2\pi\ell_{\mathrm{S}}^2, \tag{N.6}$$

and

$$V_{\mathrm{p}} = 4\sqrt{2}\, r_{\mathrm{D}}^3. \tag{N.7}$$

The area $A_{\mathrm{ct}}^{(\mathrm{modal})}$ is the modal surface-to-cell normalization of the reduced transverse scaffold coordinate; it is not interpreted as a literal microscopic contact patch. These relations are already established by the FCC homogenization and will be used below without further microscopic normalization.

The underlying State-I interface coefficients occupy a different dimensional level. The baseline surface tension and surface inertia are

$$\tau_{\mathrm{D}} = \frac{F_{\mathrm{S}}}{r_{\mathrm{D}}} = \frac{c_{\mathrm{E}}^4}{Gr_{\mathrm{D}}}, \tag{N.8}$$

and

$$\mu_{\mathrm{D}} = \frac{\tau_{\mathrm{D}}}{c_{\mathrm{E}}^2} = \frac{c_{\mathrm{E}}^2}{Gr_{\mathrm{D}}}, \tag{N.9}$$

so that

$$\frac{\tau_{\mathrm{D}}}{\mu_{\mathrm{D}}} = c_{\mathrm{E}}^2. \tag{N.10}$$

These quantities are the established two-dimensional Soft-Floor interface coefficients inherited from the structural force scale $F_{\mathrm{S}} = c_{\mathrm{E}}^4/G$ at the duality scale r_{D}. They are not re-derived in this appendix. Their role here is to provide the baseline surface stiffness–inertia pair from which the primitive-cell FCC contact action and its continuum coefficients are constructed.

The corresponding scale hierarchy is therefore

$$F_{\mathrm{S}} \longrightarrow \{\tau_{\mathrm{D}}, \mu_{\mathrm{D}}\} \longrightarrow \left\{K_{\mathrm{sh}}^{(\mathrm{micro},0)}, \rho_{\mathrm{sh}}^{(\mathrm{micro},0)}\right\}. \tag{N.11}$$

The first quantity is a force scale, the second pair consists of surface coefficients, and the final pair consists of primitive-cell volumetric coefficients. They describe related levels of the same State-I mechanical construction but are not interchangeable constitutive quantities.

In particular, $K_{\mathrm{sh}}^{(\mathrm{micro},0)}$ is neither a static gravitational stress nor the macroscopic gravitational-wave response coefficient. It measures the local affine tangent response of the microscopic FCC scaffold. The gravitational-wave tensor developed below is a collective directional-tension coordinate assembled across the FCC network, and its effective response must therefore be obtained by a separate long-wavelength projection rather than by identifying it directly with the primitive-cell affine shear modulus.

This distinction is essential. An ordinary affine transverse-traceless deformation of the FCC scaffold would retain the full microscopic coefficient $K_{\mathrm{sh}}^{(\mathrm{micro},0)}$. The observed gravitational-wave sector instead requires a collective tensor coordinate whose spatial transfer is resolved at a different constitutive level. The derivation of that distinction begins with the FCC bond geometry in the following sections.

Gravitational preloading is independently characterized by the dimensionless structural coupling $\alpha_{\mathrm{G}}(\mathbf{x})$, which specifies the locally realized static loading of the active Soft Floor. The endpoint-transfer construction of Appendix J gives the corresponding local propagation capacity

$$c_{\mathrm{P}}(\mathbf{x}) = c_{\mathrm{E}}\left[1 - \alpha_{\mathrm{G}}(\mathbf{x})\right]^2. \tag{N.12}$$

Thus α_{G} is a local environmental state variable and must remain distinct from the microscopic-to-collective response ratio derived later in this appendix. In the gravity-neutral reference limit, $\alpha_{\mathrm{G}} \to 0$, the underlying State-I carrier recovers $c_{\mathrm{P}} \to c_{\mathrm{E}}$.

All finite-frequency gravitational-wave propagation considered here occurs in the active State-I Soft Floor. The phase-locked Hard Floor supplies the underlying structural reference and record used elsewhere in the theory, but it is not assigned an independently additive propagating stiffness or inertia in the gravitational-wave carrier.

N.2 The Coherent State-I Carrier

Appendix E establishes the conservative coherent kinematics of the dual-phase State-I vacuum. Let $\mathbf{u}(\mathbf{x}, t)$ denote the homogenized FCC scaffold displacement and $\mathbf{v}_{\mathrm{IC}}$ the interstitial-condensate velocity. Their relative velocity is

$$\mathbf{v}_{\mathrm{rel}} = \mathbf{v}_{\mathrm{IC}} - \dot{\mathbf{u}}. \tag{N.13}$$

For the coherent branch, $\mathbf{v}_{\mathrm{rel}} = \mathbf{0}$. The condensate is therefore not stationary while the scaffold propagates through it. At the retained conservative order, it is entrained with the FCC scaffold, so the two phases share the coherent translational motion without relative condensate flow.

This entrainment is a kinematic condition. It does not by itself establish an independently additive condensate inertia for the coherent coordinate. At the primitive-cell microscopic scale used in Appendix D, the selected translational carrier is normalized by the scaffold coefficient $\rho_{\mathrm{sh}}^{(\mathrm{micro},0)}$, while the corresponding restoring coefficient is $K_{\mathrm{sh}}^{(\mathrm{micro},0)}$. Their baseline relation is

$$\frac{K_{\mathrm{sh}}^{(\mathrm{micro},0)}}{\rho_{\mathrm{sh}}^{(\mathrm{micro},0)}} = c_{\mathrm{E}}^2. \tag{N.14}$$

The interstitial condensate supplies the incremental pressure constraint of the coherent branch. In the selected low-energy reduction, $\nabla \cdot \mathbf{u} = 0$. The associated long-wavelength primitive-cell equation may therefore be written

$$\rho_{\mathrm{sh}}^{(\mathrm{micro},0)} \ddot{\mathbf{u}} = K_{\mathrm{sh}}^{(\mathrm{micro},0)} \nabla^2 \mathbf{u} - \nabla \delta p_{\mathrm{IC}}, \tag{N.15}$$

subject to $\nabla \cdot \mathbf{u} = 0$. Here δp_{IC} acts as the work-conjugate pressure enforcing the incremental volume constraint. The condition does not imply that the active vacuum is incapable of sustaining finite background gravitational loading or undergoing nonlinear FCC-to-SC conversion; it applies to the selected coherent perturbative branch about a fixed State-I background.

For a transverse plane-wave perturbation,

$$\mathbf{u} = u_0 \mathbf{e}_{\mathrm{T}} e^{i(\mathbf{k}\cdot\mathbf{x} - \omega t)}, \tag{N.16}$$

with $\mathbf{k} \cdot \mathbf{e}_{\mathrm{T}} = 0$, the pressure term has no transverse projection. The carrier dispersion is therefore

$$\omega_{\mathrm{T}}^2 = \frac{K_{\mathrm{sh}}^{(\mathrm{micro},0)}}{\rho_{\mathrm{sh}}^{(\mathrm{micro},0)}} k^2 = c_{\mathrm{E}}^2 k^2. \tag{N.17}$$

Thus, the gravity-neutral coherent translational carrier possesses two degenerate transverse polarizations and propagates at the baseline State-I speed c_{E}.

In a gravitationally preloaded region, the endpoint-transfer construction of Appendix J acts on this baseline carrier and gives the locally completed propagation speed

$$c_{\mathrm{P}}(\mathbf{x}) = c_{\mathrm{E}} \left[1 - \alpha_{\mathrm{G}}(\mathbf{x})\right]^2. \tag{N.18}$$

The background loading α_{G} is quasistatic on the timescale of the local perturbation and is not itself identified with the propagating wave amplitude.

The restriction $\nabla \cdot \mathbf{u} = 0$ removes the ordinary finite-frequency volumetric polarization from this selected translational sector. It does not remove rotational, torsional, phase, chiral, or localized relative-flow branches from the complete microscopic FCC spectrum.

Most importantly, the two transverse displacement polarizations of $\mathbf{u}$ are the kinematic carrier, not yet the macroscopic gravitational-wave tensor. A vector displacement field and a transverse-traceless rank-two field are different mechanical objects. The collective tensor response must therefore arise from a correlated projection of the FCC directional structure rather than from identifying an ordinary transverse phonon directly with a spin-2 gravitational wave.

The next section constructs that projection from the nearest-neighbor FCC bond dyads and shows that the two gravitational-wave tensor bases are already contained in the microscopic lattice geometry.

N.3 FCC Bond-Dyad Origin of the Tensor Polarization Basis

The coherent displacement field developed in the preceding section supplies two transverse vector carrier modes. A gravitational-wave response, however, is represented by a symmetric transverse-traceless rank-two field. The required tensor structure is already contained in the directional geometry of the FCC nearest-neighbor network.

Using the six undirected nearest-neighbor bond directions established in Appendix D, define

$$\mathbf{n}_1 = \frac{1}{\sqrt{2}}(1,1,0), \qquad \mathbf{n}_2 = \frac{1}{\sqrt{2}}(1,-1,0), \tag{N.19}$$

$$\mathbf{n}_3 = \frac{1}{\sqrt{2}}(1,0,1), \qquad \mathbf{n}_4 = \frac{1}{\sqrt{2}}(1,0,-1), \tag{N.20}$$

$$\mathbf{n}_5 = \frac{1}{\sqrt{2}}(0,1,1), \qquad \mathbf{n}_6 = \frac{1}{\sqrt{2}}(0,1,-1). \tag{N.21}$$

Each undirected bond family defines the symmetric rank-two directional dyad

$$\mathbf{P}_a \equiv \mathbf{n}_a \otimes \mathbf{n}_a. \tag{N.22}$$

The six dyads satisfy the exact FCC second-moment identity

$$\sum_{a=1}^{6} \mathbf{P}_a = 2\mathbf{I}. \tag{N.23}$$

This relation expresses the isotropic second moment of the nearest-neighbor FCC bond set. The individual bond families are directionally discrete, but their complete primitive-cell sum is proportional to the identity tensor.

For a wave whose propagation direction is selected as the z-axis, consider first the two bond families lying in the xy-plane. Their dyadic difference is

$$\mathbf{P}_1 - \mathbf{P}_2 = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}. \tag{N.24}$$

This is precisely the cross-polarization basis tensor,

$$\mathbf{E}_\times = \mathbf{P}_1 - \mathbf{P}_2. \tag{N.25}$$

Next compare the two xz-plane bond families with the two yz-plane bond families:

$$\mathbf{P}_3 + \mathbf{P}_4 - \mathbf{P}_5 - \mathbf{P}_6 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix}. \tag{N.26}$$

This gives the plus-polarization basis tensor,

$$\mathbf{E}_+ = \mathbf{P}_3 + \mathbf{P}_4 - \mathbf{P}_5 - \mathbf{P}_6. \tag{N.27}$$

The two polarization tensors therefore arise as exact correlated imbalances among the FCC bond-family dyads:

$$\mathbf{E}_+ = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \qquad \mathbf{E}_\times = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}. \tag{N.28}$$

They satisfy $\mathbf{E}_A : \mathbf{E}_B = 2\delta_{AB}$ for $A, B \in \{+, \times\}$, together with

$$(\mathbf{E}_A)_{ij} = (\mathbf{E}_A)_{ji}, \qquad (\mathbf{E}_A)_{ii} = 0, \qquad \hat{z}^i(\mathbf{E}_A)_{ij} = 0. \tag{N.29}$$

Thus both bond-derived tensors are symmetric, traceless, transverse to the selected propagation direction, mutually orthogonal, and equally normalized.

A collective transverse-traceless response can consequently be expanded as

$$\mathsf{H}_{ij}^{(\mathrm{GW})} = \frac{1}{2}\left[h_+(\mathbf{E}_+)_{ij} + h_\times(\mathbf{E}_\times)_{ij}\right]. \tag{N.30}$$

The normalization gives

$$\mathsf{H}_{ij}^{(\mathrm{GW})}\mathsf{H}_{ij}^{(\mathrm{GW})} = \frac{1}{2}\left(h_+^2 + h_\times^2\right). \tag{N.31}$$

For the pure plus mode,

$$\mathsf{H}_{xx}^{(\mathrm{GW})} = \frac{h_+}{2}, \qquad \mathsf{H}_{yy}^{(\mathrm{GW})} = -\frac{h_+}{2}, \tag{N.32}$$

and therefore

$$\mathsf{H}_{xx}^{(\mathrm{GW})} - \mathsf{H}_{yy}^{(\mathrm{GW})} = h_+. \tag{N.33}$$

The amplitudes h_+ and $h_\times$ are consequently normalized directly to the differential transverse strain represented by the collective tensor.

Because the microscopic basis is constructed from directional dyads rather than vectors, a rotation of the transverse axes through an angle ψ closes within the same two-dimensional tensor subspace:

$$\mathbf{E}'_+ = \cos(2\psi)\mathbf{E}_+ + \sin(2\psi)\mathbf{E}_\times, \tag{N.34}$$

$$\mathbf{E}'_\times = -\sin(2\psi)\mathbf{E}_+ + \cos(2\psi)\mathbf{E}_\times. \tag{N.35}$$

The doubled angular dependence is therefore already encoded in the rank-two FCC bond geometry. It does not arise from treating either transverse displacement polarization as an independent scalar amplitude.

N.3.1 Energetic Degeneracy of the Two FCC Tensor Patterns

The bond construction also determines the microscopic affine energy associated with the two tensor patterns. Let

$$\boldsymbol{\varepsilon}^{(\mathrm{TT})} = \frac{1}{2}\left(h_+\mathbf{E}_+ + h_\times\mathbf{E}_\times\right) \tag{N.36}$$

be an affine symmetric transverse-traceless strain imposed on one FCC primitive cell.

For bond family a, the affine relative displacement is

$$\Delta\mathbf{u}_a = d_{\mathrm{nn}}\boldsymbol{\varepsilon}^{(\mathrm{TT})}\mathbf{n}_a. \tag{N.37}$$

Its normal component is determined by

$$\delta_{\mathrm{n}}^{(a)} = d_{\mathrm{nn}} \mathbf{n}_a \cdot \boldsymbol{\varepsilon}^{(\mathrm{TT})} \mathbf{n}_a, \tag{N.38}$$

while the remaining part is tangential to the bond.

For a pure plus pattern, the six-bond sums give

$$\sum_{a=1}^{6} \left(\delta_{\mathrm{n}}^{(a)} \right)^2 = \frac{d_{\mathrm{nn}}^2}{4} h_+^2, \tag{N.39}$$

and

$$\sum_{a=1}^{6} \left| \boldsymbol{\delta}_{\mathrm{t}}^{(a)} \right|^2 = \frac{3 d_{\mathrm{nn}}^2}{4} h_+^2. \tag{N.40}$$

The corresponding primitive-cell energy density is therefore

$$W_+^{(\mathrm{aff})} = \frac{A_{\mathrm{ct}}^{(\mathrm{modal})} d_{\mathrm{nn}}^2}{8 V_{\mathrm{p}}} \left(\kappa_{\mathrm{n}} + 3\kappa_{\mathrm{t}} \right) h_+^2. \tag{N.41}$$

For a pure cross pattern,

$$\sum_{a=1}^{6} \left(\delta_{\mathrm{n}}^{(a)} \right)^2 = \frac{d_{\mathrm{nn}}^2}{2} h_\times^2, \tag{N.42}$$

and

$$\sum_{a=1}^{6} \left| \boldsymbol{\delta}_{\mathrm{t}}^{(a)} \right|^2 = \frac{d_{\mathrm{nn}}^2}{2} h_\times^2. \tag{N.43}$$

Hence

$$W_\times^{(\mathrm{aff})} = \frac{A_{\mathrm{ct}}^{(\mathrm{modal})} d_{\mathrm{nn}}^2}{4 V_{\mathrm{p}}} \left(\kappa_{\mathrm{n}} + \kappa_{\mathrm{t}} \right) h_\times^2. \tag{N.44}$$

Before the isotropic contact closure is imposed, the two tensor patterns generally have different affine energetic weights. Under the Appendix D condition $\kappa_{\mathrm{n}} = \kappa_{\mathrm{t}} \equiv \kappa_{\mathrm{c}}$, both expressions reduce to

$$W_+^{(\mathrm{aff})} = \frac{1}{2} K_{\mathrm{sh}}^{(\mathrm{micro},0)} h_+^2, \tag{N.45}$$

and

$$W_\times^{(\mathrm{aff})} = \frac{1}{2} K_{\mathrm{sh}}^{(\mathrm{micro},0)} h_\times^2, \tag{N.46}$$

where

$$K_{\mathrm{sh}}^{(\mathrm{micro},0)} = \frac{A_{\mathrm{ct}}^{(\mathrm{modal})} \kappa_{\mathrm{c}} d_{\mathrm{nn}}^2}{V_{\mathrm{p}}}. \tag{N.47}$$

For a general affine combination,

$$W_{\mathrm{TT}}^{(\mathrm{aff})} = \frac{K_{\mathrm{sh}}^{(\mathrm{micro},0)}}{2} \left(h_+^2 + h_\times^2 \right). \tag{N.48}$$

The same contact condition that produces the leading isotropic FCC continuum therefore makes the plus and cross tensor patterns exactly degenerate at the primitive-cell affine level.

This calculation establishes two results. First, the FCC nearest-neighbor geometry contains the complete transverse-traceless polarization basis required by the macroscopic gravitational-wave tensor. Second, ordinary affine realization of that basis engages the full primitive-cell scaffold coefficient $K_{\mathrm{sh}}^{(\mathrm{micro},0)}$. The much smaller macroscopic gravitational-wave response therefore cannot be obtained by identifying $\mathsf{H}_{ij}^{(\mathrm{GW})}$ directly with an ordinary affine Cauchy strain.

N.4 The Collective Directional-Tension Tensor

The FCC bond dyads derived in the preceding section provide a complete basis for symmetric rank-two states. They do not, by themselves, determine which microscopic coordinate carries the gravitational-wave response. A distinction must therefore be made between an affine deformation of the node positions and a correlated redistribution of the directional tension carried by the FCC contact network.

Let $\lambda_a(\mathbf{x}, t)$ for $a = 1, \ldots, 6$ denote dimensionless perturbations of the completed directional transfer associated with the six undirected FCC bond families. Each undirected family represents the opposite pair $+\mathbf{n}_a$ and $-\mathbf{n}_a$. The corresponding symmetric directional-transfer tensor is

$$\mathsf{A}_{ij} = \sum_{a=1}^{6} \lambda_a (\mathbf{P}_a)_{ij}, \tag{N.49}$$

where

$$\mathbf{P}_a = \mathbf{n}_a \otimes \mathbf{n}_a. \tag{N.50}$$

Both λ_a and A_{ij} are dimensionless:

$$[\lambda_a] = 1, \qquad [\mathsf{A}_{ij}] = 1. \tag{N.51}$$

Because $\operatorname{tr} \mathbf{P}_a = 1$, the trace of the directional-transfer tensor is

$$\mathsf{A}_{ii} = \sum_{a=1}^{6} \lambda_a. \tag{N.52}$$

Define the mean directional loading by

$$\overline{\lambda} = \frac{1}{6} \sum_{a=1}^{6} \lambda_a, \tag{N.53}$$

and the trace-free directional coefficients by

$$\lambda_a^\circ = \lambda_a - \overline{\lambda}. \tag{N.54}$$

They satisfy $\sum_{a=1}^{6} \lambda_a^\circ = 0$.

Using the FCC second-moment identity $\sum_{a=1}^{6} \mathbf{P}_a = 2\mathbf{I}$, the full directional-transfer tensor decomposes as

$$\mathsf{A}_{ij} = 2\overline{\lambda}\, \delta_{ij} + \mathsf{A}^\circ_{ij}, \tag{N.55}$$

where

$$\mathsf{A}^\circ_{ij} = \sum_{a=1}^{6} \lambda_a^\circ (\mathbf{P}_a)_{ij}, \tag{N.56}$$

and $\mathsf{A}^\circ_{ii} = 0$.

The first term is the scalar directional average. It belongs to the local isotropic-loading sector and may couple to the background structural loading characterized by α_{G}. The second term is a traceless redistribution of directional transfer at fixed first-order scalar capacity.

For a selected propagation direction represented by the unit vector $\mathbf{s}$, introduce the transverse projector

$$\mathcal{P}_{ij}(\mathbf{s}) = \delta_{ij} - s_i s_j, \tag{N.57}$$

and the transverse-traceless rank-four projector

$$\Lambda^{(\mathrm{TT})}_{ij,kl}(\mathbf{s}) = \frac{1}{2}\left[\mathcal{P}_{ik}\mathcal{P}_{jl} + \mathcal{P}_{il}\mathcal{P}_{jk} - \mathcal{P}_{ij}\mathcal{P}_{kl}\right]. \tag{N.58}$$

The collective gravitational-wave tensor is defined by

$$\mathsf{H}^{(\mathrm{GW})}_{ij} = \Lambda^{(\mathrm{TT})}_{ij,kl}(\mathbf{s})\mathsf{A}^{\circ}_{kl}. \tag{N.59}$$

It satisfies

$$\mathsf{H}^{(\mathrm{GW})}_{ij} = \mathsf{H}^{(\mathrm{GW})}_{ji}, \qquad s^i\mathsf{H}^{(\mathrm{GW})}_{ij} = 0, \qquad \mathsf{H}^{(\mathrm{GW})}_{ii} = 0. \tag{N.60}$$

When A°_{ij} already lies entirely within the transverse-traceless subspace selected by $\mathbf{s}$, the projector acts as the identity and $\mathsf{H}^{(\mathrm{GW})}_{ij} = \mathsf{A}^{\circ}_{ij}$. The explicit projector form is retained because the complete trace-free directional-transfer space contains five independent components, whereas the transverse-traceless radiative sector contains only two.

N.4.1 Directional Representation of the Two Polarizations

For propagation along the z-axis, $\mathbf{s} = \hat{\mathbf{z}}$, the directional coefficients required to construct the two tensor polarizations are

$$\begin{pmatrix} \lambda^{\circ}_1 \\ \lambda^{\circ}_2 \\ \lambda^{\circ}_3 \\ \lambda^{\circ}_4 \\ \lambda^{\circ}_5 \\ \lambda^{\circ}_6 \end{pmatrix} = \frac{1}{2}\begin{pmatrix} h_\times \\ -h_\times \\ h_+ \\ h_+ \\ -h_+ \\ -h_+ \end{pmatrix}. \tag{N.61}$$

Their sum vanishes: $\sum_{a=1}^{6}\lambda^{\circ}_a = 0$. Substitution into the FCC dyadic expansion gives

$$\begin{aligned} \mathsf{A}^{\circ}_{ij} = {} & \frac{h_\times}{2}\left[(\mathbf{P}_1)_{ij} - (\mathbf{P}_2)_{ij}\right] \\ & + \frac{h_+}{2}\left[(\mathbf{P}_3)_{ij} + (\mathbf{P}_4)_{ij} - (\mathbf{P}_5)_{ij} - (\mathbf{P}_6)_{ij}\right]. \end{aligned} \tag{N.62}$$

Using the bond-dyad identities of Section N.3,

$$\mathsf{A}^{\circ}_{ij} = \frac{1}{2}\left[h_+(\mathbf{E}_+)_{ij} + h_\times(\mathbf{E}_\times)_{ij}\right]. \tag{N.63}$$

This tensor is already transverse to $\hat{\mathbf{z}}$, so the transverse-traceless projector leaves it unchanged:

$$\mathsf{H}^{(\mathrm{GW})}_{ij} = \frac{1}{2}\left[h_+(\mathbf{E}_+)_{ij} + h_\times(\mathbf{E}_\times)_{ij}\right]. \tag{N.64}$$

The observed + and × responses are therefore represented as two specific traceless redistributions among the six FCC directional-transfer channels.

The six FCC bond dyads span the six-dimensional space of symmetric rank-two tensors. Their common scalar combination supplies one trace degree of freedom, while the trace-free combinations span the five-dimensional symmetric-traceless sector. Selection of a propagation direction and application of the transverse-traceless projector reduce this space to the two-dimensional radiative subspace represented by h_+ and $h_\times$.

N.4.2 Local Mechanical Balance

Each coefficient λ_a belongs to an opposite FCC bond pair. For a locally uniform pair perturbation, equal changes on the $+\mathbf{n}_a$ and $-\mathbf{n}_a$ contacts produce no cell-centered first-order resultant:

$$\delta\mathbf{f}_a^{(+)} + \delta\mathbf{f}_a^{(-)} \propto \lambda_a\mathbf{n}_a + \lambda_a(-\mathbf{n}_a) = \mathbf{0}. \tag{N.65}$$

The additional trace-free condition $\sum_{a=1}^{6} \lambda_a^\circ = 0$ ensures that the tensor mode also produces no first-order change in the scalar directional capacity.

The collective gravitational-wave state is therefore self-equilibrated in two distinct local senses:

- **opposite-bond pair balance** $\Longrightarrow$ zero cell-centered resultant, and
- **trace-free redistribution** $\Longrightarrow$ zero first-order scalar-capacity change.

These local balance statements do not imply the absence of propagation forces when the tensor state varies spatially. A uniform directional redistribution satisfies $\partial_k \mathsf{H}_{ij}^{(\mathrm{GW})} = 0$ and produces no intercell mismatch at the retained order. A nonuniform state satisfies $\partial_k \mathsf{H}_{ij}^{(\mathrm{GW})} \neq 0$, so neighboring cells possess different directional-transfer configurations. The resulting intercell mismatch supplies the restoring action developed in Section N.5.

A gravitational wave may consequently exist on a locally gravity-neutral State-I background. The static environmental loading may satisfy $\alpha_{\mathrm{G}} = 0$, while the directional tensor perturbation remains nonzero: $\mathsf{H}_{ij}^{(\mathrm{GW})} \neq 0$. The background variable α_{G} and the dynamic tensor amplitudes h_+ and $h_\times$ therefore describe different mechanical sectors. The former determines the locally available Soft-Floor transfer capacity; the latter describes a time-dependent traceless redistribution of that capacity.

N.4.3 Distinction from Affine FCC Strain

The same bond-dyad basis also appears in an ordinary affine transverse-traceless strain,

$$\varepsilon_{ij}^{(u),\mathrm{TT}} = \frac{1}{2}\left[h_+(\mathbf{E}_+)_{ij} + h_\times(\mathbf{E}_\times)_{ij}\right]. \tag{N.66}$$

Equality of tensor form does not imply equality of constitutive coordinate.

As established in Section N.3, an affine realization engages the full primitive-cell scaffold modulus:

$$W_{\mathrm{TT}}^{(\mathrm{aff})} = \frac{K_{\mathrm{sh}}^{(\mathrm{micro},0)}}{2}\left(h_+^2 + h_\times^2\right). \tag{N.67}$$

If the collective gravitational-wave tensor were identified directly with this affine Cauchy strain, its effective response would necessarily satisfy $K_{\mathrm{GW}}^{(\mathrm{eff})} = K_{\mathrm{sh}}^{(\mathrm{micro},0)}$, and the microscopic-to-collective ratio would be $\zeta_{\mathrm{GW}} = 1$. That identification would describe an ordinary affine FCC shear mode rather than a distinct long-wavelength gravitational-wave branch.

The collective tensor is therefore assigned to the projected directional-transfer coordinate,

$$\mathsf{H}_{ij}^{(\mathrm{GW})} = \Lambda_{ij,kl}^{(\mathrm{TT})}(\mathbf{s}) \sum_{a=1}^{6} \lambda_a^\circ (\mathbf{P}_a)_{kl}, \tag{N.68}$$

rather than to the local displacement gradient:

$$\mathsf{H}_{ij}^{(\mathrm{GW})} \neq \varepsilon_{ij}^{(u),\mathrm{TT}} \tag{N.69}$$

as a constitutive identity.

The two fields may be dynamically coupled, and a propagating collective state may generate small microscopic scaffold displacements. Their work-conjugate response coefficients and energy functionals, however, belong to different levels of the mechanical hierarchy.

The construction above establishes the collective tensor kinematics but does not yet determine its propagation energy. The next section introduces the leading gapless long-wavelength closure by coupling neighboring cell-centered directional-tension tensors through their spatial mismatch.

N.5 Long-Wavelength Tensor-Gradient Dynamics

The directional-tension tensor constructed in Section N.4 is a dimensionless, cell-centered collective coordinate, $\mathsf{H}_{ij}^{(\mathrm{GW})}(\mathbf{R},t)$, defined on the FCC primitive cells labeled by $\mathbf{R}$. Its two independent transverse-traceless components describe correlated redistributions among the six FCC directional-transfer channels.

The bond geometry determines the tensor basis, but it does not by itself determine the energy required to transfer that tensor state between neighboring cells. A separate collective closure is therefore required.

N.5.1 Gapless Long-Wavelength Selection

A propagating gravitational-wave branch must satisfy

$$\omega(k) \to 0 \qquad \text{as} \qquad k \to 0. \tag{N.70}$$

A local quadratic term of the form $\frac{1}{2}K_0\mathsf{H}_{ij}^{(\mathrm{GW})}\mathsf{H}_{ij}^{(\mathrm{GW})}$ would instead produce a finite zero-wavenumber frequency,

$$\omega^2(0) = \frac{K_0}{I_{\mathrm{TT}}}, \tag{N.71}$$

where I_{TT} denotes the corresponding tensor-coordinate inertia. Such a term would describe a gapped local internal mode rather than the required long-wavelength radiative branch.

The selected gravitational-wave sector is therefore the gapless collective sector in which the leading restoring energy depends on the mismatch between neighboring tensor states. A spatially uniform tensor configuration produces no intercell transfer mismatch at the retained order.

This is a constitutive selection of the long-wavelength radiative branch. The complete microscopic parent action may contain additional gapped directional, rotational, phase, or internal tensor modes, but those modes are not identified with the gravitational-wave sector developed here.

N.5.2 Discrete FCC Tensor-Transfer Action

For each of the six undirected nearest-neighbor FCC links, define the tensor difference

$$\Delta_a\mathsf{H}_{ij}(\mathbf{R}) = \mathsf{H}_{ij}\left(\mathbf{R} + d_{\mathrm{nn}}\mathbf{n}_a\right) - \mathsf{H}_{ij}(\mathbf{R}). \tag{N.72}$$

The minimal quadratic cell action for the symmetric transverse-traceless tensor state is

$$\begin{aligned} S_{\mathrm{TT}}^{(\mathrm{disc})} = \int dt \sum_{\mathbf{R}} \Bigg[& \frac{1}{2} I_{\mathrm{TT}}^{(\mathrm{cell})} \dot{\mathsf{H}}_{ij}(\mathbf{R}) \dot{\mathsf{H}}_{ij}(\mathbf{R}) \\ & - \frac{1}{2} K_{\mathrm{TT}}^{(\mathrm{link})} \sum_{a=1}^{6} \Delta_a\mathsf{H}_{ij}(\mathbf{R}) \Delta_a\mathsf{H}_{ij}(\mathbf{R}) \Bigg]. \end{aligned} \tag{N.73}$$

Here $[I_{\mathrm{TT}}^{(\mathrm{cell})}] = \mathrm{kg\,m^2}$ and $[K_{\mathrm{TT}}^{(\mathrm{link})}] = \mathrm{J}$. These are collective coefficients of the cell-centered directional-tension coordinate. They are not replacements for the microscopic interface coefficients τ_{D} and μ_{D}, nor are they identical to the primitive-cell affine coefficients $K_{\mathrm{sh}}^{(\mathrm{micro},0)}$ and $\rho_{\mathrm{sh}}^{(\mathrm{micro},0)}$.

Variation with respect to $\mathsf{H}_{ij}(\mathbf{R})$ gives

$$I_{\mathrm{TT}}^{(\mathrm{cell})}\ddot{\mathsf{H}}_{ij}(\mathbf{R}) = K_{\mathrm{TT}}^{(\mathrm{link})}\sum_{a=1}^{6}\Big[\mathsf{H}_{ij}\left(\mathbf{R}+d_{\mathrm{nn}}\mathbf{n}_a\right) + \mathsf{H}_{ij}\left(\mathbf{R}-d_{\mathrm{nn}}\mathbf{n}_a\right) - 2\mathsf{H}_{ij}(\mathbf{R})\Big]. \tag{N.74}$$

For the Bloch form

$$\mathsf{H}_{ij}(\mathbf{R},t) = \mathsf{H}_{ij}^{(0)}e^{i(\mathbf{k}\cdot\mathbf{R}-\omega t)}, \tag{N.75}$$

the minimal collective tensor-transfer closure gives the lattice dispersion

$$\omega^2(\mathbf{k}) = \frac{2K_{\mathrm{TT}}^{(\mathrm{link})}}{I_{\mathrm{TT}}^{(\mathrm{cell})}}\sum_{a=1}^{6}\left[1-\cos\left(d_{\mathrm{nn}}\mathbf{k}\cdot\mathbf{n}_a\right)\right]. \tag{N.76}$$

Equivalently,

$$\omega^2(\mathbf{k}) = \frac{4K_{\mathrm{TT}}^{(\mathrm{link})}}{I_{\mathrm{TT}}^{(\mathrm{cell})}}\sum_{a=1}^{6}\sin^2\left(\frac{1}{2}d_{\mathrm{nn}}\mathbf{k}\cdot\mathbf{n}_a\right). \tag{N.77}$$

This dispersion is exact for the minimal collective link action introduced above. It is not asserted to be the complete finite-wave-number spectrum of the full FCC node, contact, phase, rotational, condensate, and Tension-Column parent dynamics.

The selected collective branch is gapless because $\omega(0) = 0$.

N.5.3 Long-Wavelength FCC Limit

For $kd_{\mathrm{nn}} \ll 1$, the lattice dispersion becomes

$$\omega^2(\mathbf{k}) = \frac{K_{\mathrm{TT}}^{(\mathrm{link})}d_{\mathrm{nn}}^2}{I_{\mathrm{TT}}^{(\mathrm{cell})}}\sum_{a=1}^{6}(\mathbf{k}\cdot\mathbf{n}_a)^2 + \mathcal{O}\left(k^4d_{\mathrm{nn}}^4\right). \tag{N.78}$$

Using the exact FCC second-moment identity $\sum_{a=1}^{6} n_a^i n_a^j = 2\delta^{ij}$, one obtains

$$\sum_{a=1}^{6}(\mathbf{k}\cdot\mathbf{n}_a)^2 = 2k^2. \tag{N.79}$$

Therefore,

$$\omega^2 = \frac{2K_{\mathrm{TT}}^{(\mathrm{link})}d_{\mathrm{nn}}^2}{I_{\mathrm{TT}}^{(\mathrm{cell})}}k^2 + \mathcal{O}\left(k^4d_{\mathrm{nn}}^4\right). \tag{N.80}$$

The gravity-neutral collective tensor speed is consequently

$$c_{\mathrm{TT}}^2 = \frac{2K_{\mathrm{TT}}^{(\mathrm{link})}d_{\mathrm{nn}}^2}{I_{\mathrm{TT}}^{(\mathrm{cell})}}. \tag{N.81}$$

The collective branch is selected as a long-wavelength tensor sector of the same active State-I causal carrier established in Section N.2. Its gravity-neutral propagation condition is therefore $c_{\mathrm{TT}} = c_{\mathrm{E}}$, which imposes the coefficient relation

$$\frac{2K_{\mathrm{TT}}^{(\mathrm{link})} d_{\mathrm{nn}}^2}{I_{\mathrm{TT}}^{(\mathrm{cell})}} = c_{\mathrm{E}}^2. \tag{N.82}$$

This relation fixes the ratio of the collective link coefficient to the collective cell inertia. It does not yet fix their common absolute normalization.

N.5.4 Continuum Tensor-Gradient Action

Introduce the continuum coefficients

$$M_{\mathrm{TT}}^{(0)} \equiv \frac{I_{\mathrm{TT}}^{(\mathrm{cell})}}{V_{\mathrm{p}}}, \qquad \text{and} \qquad \mathcal{T}_{\mathrm{TT}}^{(0)} \equiv \frac{2K_{\mathrm{TT}}^{(\mathrm{link})} d_{\mathrm{nn}}^2}{V_{\mathrm{p}}}. \tag{N.83}$$

Their dimensions are $[M_{\mathrm{TT}}^{(0)}] = \mathrm{kg\,m^{-1}}$ and $[\mathcal{T}_{\mathrm{TT}}^{(0)}] = \mathrm{N}$. The long-wavelength coefficient relation becomes

$$\frac{\mathcal{T}_{\mathrm{TT}}^{(0)}}{M_{\mathrm{TT}}^{(0)}} = c_{\mathrm{E}}^2. \tag{N.84}$$

The corresponding continuum action is

$$S_{\mathrm{TT}}^{(2)} = \frac{1}{2} \int \left[M_{\mathrm{TT}}^{(0)} \dot{\mathsf{H}}_{ij} \dot{\mathsf{H}}_{ij} - \mathcal{T}_{\mathrm{TT}}^{(0)} \partial_k \mathsf{H}_{ij} \partial_k \mathsf{H}_{ij} \right] d^3x\, dt. \tag{N.85}$$

Using $M_{\mathrm{TT}}^{(0)} = \mathcal{T}_{\mathrm{TT}}^{(0)} / c_{\mathrm{E}}^2$, this may be written

$$S_{\mathrm{TT}}^{(2)} = \frac{\mathcal{T}_{\mathrm{TT}}^{(0)}}{2} \int \left[\frac{1}{c_{\mathrm{E}}^2} \dot{\mathsf{H}}_{ij} \dot{\mathsf{H}}_{ij} - \partial_k \mathsf{H}_{ij} \partial_k \mathsf{H}_{ij} \right] d^3x\, dt. \tag{N.86}$$

The action is restricted to the symmetric transverse-traceless sector:

$$\mathsf{H}_{ij} = \mathsf{H}_{ji}, \qquad \partial_i \mathsf{H}_{ij} = 0, \qquad \mathsf{H}_{ii} = 0. \tag{N.87}$$

Variation gives the source-free collective wave equation

$$\frac{1}{c_{\mathrm{E}}^2} \ddot{\mathsf{H}}_{ij} - \nabla^2 \mathsf{H}_{ij} = 0. \tag{N.88}$$

The two amplitudes h_+ and $h_\times$ therefore obey the same gravity-neutral dispersion, $\omega^2 = c_{\mathrm{E}}^2 k^2$, at leading long wavelength.

The coefficient $\mathcal{T}_{\mathrm{TT}}^{(0)}$ is a force-dimensioned collective tensor-gradient coefficient. It is not the microscopic surface tension τ_{D}, the primitive-cell affine modulus $K_{\mathrm{sh}}^{(\mathrm{micro},0)}$, or the transverse-traceless source stress tensor introduced later in this appendix.

N.5.5 Propagation Through a Gravitationally Loaded Background

The coefficients above refer to the gravity-neutral State-I background. Let

$$C(\mathbf{x}) = [1 - \alpha_{\mathrm{G}}(\mathbf{x})]^2 \tag{N.89}$$

be the completed endpoint-transfer factor established in Appendix J.

The endpoint-transfer construction is established there for the selected coherent State-I transfer coordinate. Conditional on the collective transverse-traceless coordinate inheriting the same completed-transfer Jacobian, its referred collective line inertia becomes

$$M_{\mathrm{TT}}(\alpha_{\mathrm{G}}) = \frac{M_{\mathrm{TT}}^{(0)}}{C^2} = \frac{M_{\mathrm{TT}}^{(0)}}{(1-\alpha_{\mathrm{G}})^4}. \tag{N.90}$$

At this constitutive order, the local tensor-gradient coefficient retains its gravity-neutral restoring normalization:

$$\mathcal{T}_{\mathrm{TT}}(\alpha_{\mathrm{G}}) = \mathcal{T}_{\mathrm{TT}}^{(0)}. \tag{N.91}$$

The locally completed propagation speed is then

$$c_{\mathrm{GW}}^2 = \frac{\mathcal{T}_{\mathrm{TT}}^{(0)}}{M_{\mathrm{TT}}(\alpha_{\mathrm{G}})} = c_{\mathrm{E}}^2 C^2, \tag{N.92}$$

and therefore

$$c_{\mathrm{GW}}(\mathbf{x}) = c_{\mathrm{E}}\left[1 - \alpha_{\mathrm{G}}(\mathbf{x})\right]^2. \tag{N.93}$$

This loaded-background relation is the selected endpoint-inheritance closure for the collective tensor branch. Its derivation directly from the full directional-tension parent action remains a microscopic completion requirement.

In the gravity-neutral limit, $\alpha_{\mathrm{G}} \to 0$, the nonzero tensor perturbation propagates at $c_{\mathrm{GW}} \to c_{\mathrm{E}}$. The condition $\alpha_{\mathrm{G}} = 0$ refers to the absence of static background gravitational loading; it does not require $\mathsf{H}_{ij}^{(\mathrm{GW})} = 0$.

N.5.6 Role of the Hard Floor

The phase-locked Hard Floor supplies the structural reference and record associated with the State-I configuration, but it does not provide the finite propagating energy of the tensor branch.

A fixed local coupling between the collective tensor and an immobile Hard-Floor value would generate a term proportional to $\mathsf{H}_{ij}\mathsf{H}_{ij}$, and would therefore produce a gapped rather than gapless spectrum. In the ideal record limit, the Hard-Floor state follows the completed structural configuration as an auxiliary constraint record without contributing an independently additive finite tensor inertia or tensor-gradient stiffness.

Accordingly:

- **Hard Floor** = reference and record.
- **State-I Soft Floor** = finite-speed tensor carrier.

The coefficient $\mathcal{T}_{\mathrm{TT}}^{(0)}$ introduced here is therefore a collective State-I tensor-gradient coefficient. Its absolute value has not been calibrated from gravitational-wave data and has not been identified with an 8π propagation geometry. The following section fixes its long-wavelength normalization from the independently established weak-field static-to-tensor projection of TFT.

N.6 Static-to-Tensor Projection Normalization

Section N.5 establishes the form of the gapless collective tensor-gradient action and fixes the ratio

$$\frac{\mathcal{T}^{(0)}_{\mathrm{TT}}}{M^{(0)}_{\mathrm{TT}}} = c_{\mathrm{E}}^2. \tag{N.94}$$

That result determines the gravity-neutral propagation speed but does not determine the common absolute normalization of the collective tensor stiffness and inertia.

The normalization must not be obtained from a gravitational-wave event, because doing so would use an observed source model to define the vacuum response that is subsequently invoked to interpret the same event. It must instead follow from an independently established sector of TFT.

The required normalization is supplied by the weak-field static gravitational response. The static sector fixes the scalar source strength through spherical tension-flux conservation, while the effective temporal response fixes the conversion from the scalar potential to the dimensionless symmetric tensor coordinate. The resulting tensor projection coefficient is then inherited by the transverse-traceless sector under the minimal single-tensor-sector closure stated below.

N.6.1 Weak-Field Static Source Normalization

The specific tension potential of the active Soft Floor is denoted by $\Phi_\tau(\mathbf{x})$, with dimensions $[\Phi_\tau] = \mathrm{m}^2\,\mathrm{s}^{-2}$. For a localized static source, the independently established tension-flux law is

$$\oint_{\partial V} \nabla\Phi_\tau \cdot d\mathbf{A} = 4\pi G M(V), \tag{N.95}$$

where

$$M(V) = \int_V \rho(\mathbf{x})\, d^3x. \tag{N.96}$$

Applying the divergence theorem to Equation (N.95) gives

$$\int_V \nabla^2\Phi_\tau\, d^3x = 4\pi G \int_V \rho\, d^3x. \tag{N.97}$$

Because the volume is arbitrary, the local weak-field static equation is

$$\nabla^2\Phi_\tau = 4\pi G\rho. \tag{N.98}$$

The factor 4π in Equation (N.98) has an unambiguous geometric origin. It is the spherical flux normalization of a localized three-dimensional source. It is not a constitutive coefficient of free wave propagation.

For an isolated point source,

$$\Phi_\tau(R) = -\frac{GM}{R}, \tag{N.99}$$

and the structural gravitational coupling is

$$\alpha_{\mathrm{G}} = \frac{GM}{Rc_{\mathrm{E}}^2} = -\frac{\Phi_\tau}{c_{\mathrm{E}}^2}. \tag{N.100}$$

Equation (N.98) is therefore the local differential representation of the same restorative tension field that produces the inverse-square acceleration law. It is established independently of the gravitational-wave construction.

N.6.2 Dimensionless Temporal Tensor Response

The effective temporal response of the gravitationally loaded State-I vacuum is represented by

$$g_{tt}^{(\tau)} = -\left(1-\alpha_{\mathrm{G}}\right)^2 c_{\mathrm{E}}^2. \tag{N.101}$$

The gravity-neutral reference value is $g_{tt}^{(0)} = -c_{\mathrm{E}}^2$.

Define the dimensionless temporal departure from the gravity-neutral State-I reference by

$$\mathsf{H}_{00}^{(\tau)} \equiv \frac{g_{tt}^{(\tau)} - g_{tt}^{(0)}}{c_{\mathrm{E}}^2}. \tag{N.102}$$

Using Equation (N.101),

$$\mathsf{H}_{00}^{(\tau)} = 1 - \left(1-\alpha_{\mathrm{G}}\right)^2, \tag{N.103}$$

and therefore

$$\mathsf{H}_{00}^{(\tau)} = 2\alpha_{\mathrm{G}} - \alpha_{\mathrm{G}}^2. \tag{N.104}$$

In the weak-field limit, $\alpha_{\mathrm{G}} \ll 1$, the leading response is

$$\mathsf{H}_{00}^{(\tau)} = 2\alpha_{\mathrm{G}} + \mathcal{O}\left(\alpha_{\mathrm{G}}^2\right). \tag{N.105}$$

Using Equation (N.100),

$$\mathsf{H}_{00}^{(\tau)} = -\frac{2\Phi_\tau}{c_{\mathrm{E}}^2} + \mathcal{O}\left(\frac{\Phi_\tau^2}{c_{\mathrm{E}}^4}\right). \tag{N.106}$$

The factor 2 in Equation (N.106) is not introduced through spherical geometry. It arises from the two-endpoint temporal response $(1-\alpha_{\mathrm{G}})^2$ of the loaded State-I transfer coordinate.

Applying the static wave operator to Equation (N.106) gives

$$-\nabla^2 \mathsf{H}_{00}^{(\tau)} = \frac{2}{c_{\mathrm{E}}^2}\nabla^2\Phi_\tau. \tag{N.107}$$

Using Equation (N.98),

$$-\nabla^2 \mathsf{H}_{00}^{(\tau)} = \frac{8\pi G}{c_{\mathrm{E}}^2}\rho. \tag{N.108}$$

In the local weak-field source frame, $T_{00}^{(\mathrm{src})} \simeq \rho c_{\mathrm{E}}^2$. Hence,

$$-\nabla^2 \mathsf{H}_{00}^{(\tau)} = \frac{8\pi G}{c_{\mathrm{E}}^4} T_{00}^{(\mathrm{src})}. \tag{N.109}$$

Introducing the State-I wave operator

$$\Box_{\mathrm{E}} \equiv \frac{1}{c_{\mathrm{E}}^2}\frac{\partial^2}{\partial t^2} - \nabla^2, \tag{N.110}$$

the static result may be written

$$\Box_{\mathrm{E}} \mathsf{H}_{00}^{(\tau)} = \frac{8\pi G}{c_{\mathrm{E}}^4} T_{00}^{(\mathrm{src})} \tag{N.111}$$

when the temporal derivatives vanish.

The transverse-traceless tensor-source normalization is therefore

$$\kappa_{\mathrm{TT}} \equiv \kappa|_{\mathrm{TT}} = 8\pi. \tag{N.112}$$

This result has the mechanical decomposition

$$8\pi = \underbrace{4\pi}_{\text{spherical scalar-flux normalization}} \times \underbrace{2}_{\text{dimensionless temporal tensor response}} . \tag{N.113}$$

The quantity 8π is therefore not interpreted as the area, solid angle, or physical shape of the propagating vacuum. It is the source-to-tensor normalization produced when the scalar restorative potential is represented as a dimensionless symmetric response of the State-I continuum.

N.6.3 Minimal Single-Tensor-Sector Closure

Equation (N.109) fixes the temporal component of the weak-field symmetric response. The spatial transverse-traceless field developed in Sections N.3–N.5 is a different projection of the same long-wavelength State-I directional-tension architecture.

The minimal constitutive unification adopted here is that the temporal weak-field response and the spatial transverse-traceless response share one long-wavelength symmetric tensor-source normalization:

$$\kappa_{\mathrm{TT}} = 8\pi. \tag{N.114}$$

Under this closure, the static temporal sector and the dynamic radiative sector are not treated as unrelated effective fields having independently adjustable source coefficients.

This is a long-wavelength constitutive identification. It does not yet constitute a derivation of the complete symmetric tensor action from the full finite-wave-number FCC node, contact, rotational, phase, condensate, and Tension-Column parent action. That microscopic derivation remains a completion requirement.

The same value is also developed through the topological tensor-projection construction of Appendix P. The present derivation does not import the value 8π from that appendix as an assumption. Instead, it obtains the normalization independently from the static tension-flux law and the weak-field temporal response. Agreement with Appendix P therefore provides a cross-sector consistency check.

N.6.4 Absolute Tensor-Gradient Normalization

The absolute TFT structural-force scale is

$$F_{\mathrm{S}} = \frac{c_{\mathrm{E}}^4}{G}. \tag{N.115}$$

Define the transverse-traceless source-projection coefficient by

$$\frac{1}{\mathcal{T}_{\mathrm{TT}}^{(0)}} \equiv \frac{\kappa_{\mathrm{TT}}}{F_{\mathrm{S}}}. \tag{N.116}$$

Using $\kappa_{\mathrm{TT}} = 8\pi$, one obtains

$$\mathcal{T}_{\mathrm{TT}}^{(0)} = \frac{F_{\mathrm{S}}}{8\pi} = \frac{c_{\mathrm{E}}^4}{8\pi G}. \tag{N.117}$$

The corresponding collective line inertia is fixed by the gravity-neutral propagation relation derived in Section N.5:

$$M_{\mathrm{TT}}^{(0)} = \frac{\mathcal{T}_{\mathrm{TT}}^{(0)}}{c_{\mathrm{E}}^2}. \tag{N.118}$$

Therefore,

$$M_{\mathrm{TT}}^{(0)} = \frac{c_{\mathrm{E}}^2}{8\pi G}. \tag{N.119}$$

The dimensions are $[\mathcal{T}_{\mathrm{TT}}^{(0)}] = \mathrm{N}$ and $[M_{\mathrm{TT}}^{(0)}] = \mathrm{kg\,m^{-1}}$. Their ratio remains $\mathcal{T}_{\mathrm{TT}}^{(0)}/M_{\mathrm{TT}}^{(0)} = c_{\mathrm{E}}^2$.

The normalization in Equation (N.117) must not be reversed. The collective tensor-gradient coefficient is $\mathcal{T}_{\mathrm{TT}}^{(0)} = F_{\mathrm{S}}/(8\pi)$, not $8\pi F_{\mathrm{S}}$. The inverse coefficient is what multiplies the source:

$$\frac{1}{\mathcal{T}_{\mathrm{TT}}^{(0)}} = \frac{8\pi G}{c_{\mathrm{E}}^4}. \tag{N.120}$$

N.6.5 Normalized Source-Coupled Tensor Action

Let

$$T_{ij}^{(\mathrm{TT})} = \Lambda_{ij,kl}^{(\mathrm{TT})} T_{kl}^{(\mathrm{src})} \tag{N.121}$$

denote the transverse-traceless projection of the source stress tensor for the selected radiation direction.

Because the observable tensor strain is normalized by $h_{ij}^{(\mathrm{TT})} = 2\mathsf{H}_{ij}^{(\mathrm{GW})}$, the standard symmetric work-conjugate interaction $\frac{1}{2} h_{ij}^{(\mathrm{TT})} T_{ij}^{(\mathrm{TT})}$ is equivalently $\mathsf{H}_{ij}^{(\mathrm{GW})} T_{ij}^{(\mathrm{TT})}$. No additional dimensionless source-coupling constant is required.

The normalized long-wavelength source-coupled action is therefore

$$\begin{aligned} S_{\mathrm{TT}}^{(2,\mathrm{src})} = \int \Bigg\{ & \frac{c_{\mathrm{E}}^4}{16\pi G} \left[\frac{1}{c_{\mathrm{E}}^2} \dot{\mathsf{H}}_{ij} \dot{\mathsf{H}}_{ij} - \partial_k \mathsf{H}_{ij} \partial_k \mathsf{H}_{ij} \right] \\ & + \mathsf{H}_{ij} T_{ij}^{(\mathrm{TT})} \Bigg\} d^3x\, dt. \end{aligned} \tag{N.122}$$

Variation with respect to the transverse-traceless field gives

$$\frac{1}{c_{\mathrm{E}}^2} \ddot{\mathsf{H}}_{ij} - \nabla^2 \mathsf{H}_{ij} = \frac{8\pi G}{c_{\mathrm{E}}^4} T_{ij}^{(\mathrm{TT})}. \tag{N.123}$$

The overall sign of the source term may equivalently be reversed by adopting the opposite sign convention for the interaction term or for the definition of the source stress. The physical normalization is the magnitude $8\pi G/c_{\mathrm{E}}^4$.

In a source-free region, $T_{ij}^{(\mathrm{TT})} = 0$, and Equation (N.123) reduces to

$$\frac{1}{c_{\mathrm{E}}^2} \ddot{\mathsf{H}}_{ij} - \nabla^2 \mathsf{H}_{ij} = 0. \tag{N.124}$$

Thus the factor 8π fixes the source-to-tensor conversion but does not appear as a geometry, index, or additional impedance in free propagation. Once the tensor state has left the source region, its gravity-neutral speed remains determined solely by $\mathcal{T}_{\mathrm{TT}}^{(0)}/M_{\mathrm{TT}}^{(0)} = c_{\mathrm{E}}^2$.

N.6.6 Constitutive Status of the Normalization

The normalization established in this section follows the chain:

- static tension-flux conservation $\longrightarrow 4\pi G\rho$,

- two-endpoint temporal response $\longrightarrow -\frac{2\Phi_T}{c_{\mathrm{E}}^2}$,
- and therefore long-wavelength TT source projection $\longrightarrow \frac{8\pi G}{c_{\mathrm{E}}^4}$.

Consequently,

$$\mathcal{T}_{\mathrm{TT}}^{(0)} = \frac{c_{\mathrm{E}}^4}{8\pi G}, \qquad M_{\mathrm{TT}}^{(0)} = \frac{c_{\mathrm{E}}^2}{8\pi G}. \tag{N.125}$$

No gravitational-wave event has been used to determine either coefficient. The normalization is inherited from the independently established static weak-field sector under the minimal single-tensor-sector closure.

The remaining microscopic problem is not the numerical value of the long-wavelength normalization. It is the derivation of the collective directional-tension action itself from the complete FCC contact, phase, rotational, condensate, and Tension-Column parent dynamics, together with demonstration that the resulting microscopic eigenbranch reduces to Equation (N.123) in the long-wavelength limit.

With the absolute tensor-gradient normalization fixed, the next section derives the wavelength- and frequency-dependent effective gravitational-wave response and the microscopic-to-collective spectral ratio $\zeta_{\mathrm{GW}}(k)$.

N.7 Spectral Gravitational-Wave Response and the Derived Cross-Scale Ratio

Section N.6 fixes the absolute gravity-neutral tensor-gradient coefficient and its conjugate collective line inertia:

$$\mathcal{T}_{\mathrm{TT}}^{(0)} = \frac{c_{\mathrm{E}}^4}{8\pi G}, \qquad \text{and} \qquad M_{\mathrm{TT}}^{(0)} = \frac{c_{\mathrm{E}}^2}{8\pi G}. \tag{N.126}$$

Their ratio gives $\mathcal{T}_{\mathrm{TT}}^{(0)}/M_{\mathrm{TT}}^{(0)} = c_{\mathrm{E}}^2$, while their common normalization is inherited from the independently established weak-field static-to-tensor projection.

The collective gravitational-wave response is not governed by a local Hookean term proportional to $\mathsf{H}_{ij}^{(\mathrm{GW})}\mathsf{H}_{ij}^{(\mathrm{GW})}$. Its leading restoring energy is instead governed by the tensor gradient. Consequently, any pressure-dimensioned coefficient assigned to a Fourier component of the gravitational-wave field must depend on wave number. It is a spectral representation of the tensor-gradient action rather than a universal equilibrium modulus of the vacuum.

N.7.1 Fourier-Mode Tensor Response

Consider a gravity-neutral transverse-traceless Fourier mode, $\mathsf{H}_{ij}^{(\mathrm{GW})} = \widetilde{\mathsf{H}}_{ij} e^{i(\mathbf{k}\cdot\mathbf{x}-\omega t)}$, with $k^i\widetilde{\mathsf{H}}_{ij} = 0$, and $\widetilde{\mathsf{H}}_{ii} = 0$. The source-free field equation derived in Section N.6 gives

$$\omega^2 = c_{\mathrm{E}}^2 k^2. \tag{N.127}$$

Using the polarization normalization established in Section N.3,

$$\widetilde{\mathsf{H}}_{ij} = \frac{1}{2}\left[\widetilde{h}_+(\mathbf{E}_+)_{ij} + \widetilde{h}_\times(\mathbf{E}_\times)_{ij}\right], \tag{N.128}$$

one has

$$\widetilde{\mathsf{H}}_{ij}^*\widetilde{\mathsf{H}}_{ij} = \frac{1}{2}\left(|\widetilde{h}_+|^2 + |\widetilde{h}_\times|^2\right). \tag{N.129}$$

For a Fourier component, the tensor-gradient contribution to the quadratic energy density is

$$u_{\nabla}(k) = \frac{1}{2}\mathcal{T}^{(0)}_{\mathrm{TT}} k^2 \widetilde{\mathsf{H}}^{*}_{ij} \widetilde{\mathsf{H}}_{ij}. \tag{N.130}$$

Using Equation (N.129),

$$u_{\nabla}(k) = \frac{1}{4}\mathcal{T}^{(0)}_{\mathrm{TT}} k^2 \left(|\widetilde{h}_{+}|^2 + |\widetilde{h}_{\times}|^2 \right). \tag{N.131}$$

Define the effective spectral gravitational-wave stiffness by the work-conjugate quadratic convention

$$u_{\nabla}(k) \equiv \frac{1}{2} K^{(\mathrm{eff})}_{\mathrm{GW}}(k) \left(|\widetilde{h}_{+}|^2 + |\widetilde{h}_{\times}|^2 \right). \tag{N.132}$$

Comparison with Equation (N.131) gives

$$K^{(\mathrm{eff})}_{\mathrm{GW}}(k) = \frac{1}{2}\mathcal{T}^{(0)}_{\mathrm{TT}} k^2. \tag{N.133}$$

Substituting the absolute tensor-gradient normalization, $\mathcal{T}^{(0)}_{\mathrm{TT}} = c_{\mathrm{E}}^4/(8\pi G)$, yields

$$K^{(\mathrm{eff})}_{\mathrm{GW}}(k) = \frac{c_{\mathrm{E}}^4 k^2}{16\pi G}. \tag{N.134}$$

The dimensions are $[K^{(\mathrm{eff})}_{\mathrm{GW}}] = \mathrm{Pa}$. This pressure dimension does not make $K^{(\mathrm{eff})}_{\mathrm{GW}}(k)$ an intrinsic local material modulus. It is the pressure-equivalent spectral coefficient obtained when the force-dimensioned tensor-gradient action is evaluated on a mode of wave number k.

N.7.2 Frequency-Domain Form

In the gravity-neutral State-I background, $k = \omega/c_{\mathrm{E}}$, so Equation (N.134) becomes

$$K^{(\mathrm{eff})}_{\mathrm{GW}}(\omega) = \frac{c_{\mathrm{E}}^2 \omega^2}{16\pi G}. \tag{N.135}$$

Using $\omega = 2\pi f$, the cyclic-frequency representation is

$$K^{(\mathrm{eff})}_{\mathrm{GW}}(f) = \frac{\pi c_{\mathrm{E}}^2 f^2}{4G}. \tag{N.136}$$

The quadratic frequency dependence, $K^{(\mathrm{eff})}_{\mathrm{GW}} \propto \omega^2 \propto f^2$, is a direct consequence of the gradient-controlled collective action. It does not represent ordinary material dispersion introduced phenomenologically. It follows because the effective pressure-dimensioned response is obtained from $\partial_k \mathsf{H}_{ij} \partial_k \mathsf{H}_{ij} \longrightarrow k^2 \mathsf{H}_{ij} \mathsf{H}_{ij}$ for a Fourier mode.

N.7.3 Equivalent Continuum Inertia and Impedance

A pressure-dimensioned stiffness may be represented in the equivalent ordinary-wave form $K^{(\mathrm{eff})}_{\mathrm{GW}} = \rho^{(\mathrm{eff})}_{\mathrm{GW}} c_{\mathrm{E}}^2$. This defines the spectral equivalent continuum inertia density

$$\rho^{(\mathrm{eff})}_{\mathrm{GW}}(k) \equiv \frac{K^{(\mathrm{eff})}_{\mathrm{GW}}(k)}{c_{\mathrm{E}}^2}. \tag{N.137}$$

Using Equation (N.134),

$$\rho_{\mathrm{GW}}^{(\mathrm{eff})}(k) = \frac{c_{\mathrm{E}}^2 k^2}{16\pi G}. \tag{N.138}$$

Equivalently,

$$\rho_{\mathrm{GW}}^{(\mathrm{eff})}(\omega) = \frac{\omega^2}{16\pi G}. \tag{N.139}$$

In terms of cyclic frequency,

$$\rho_{\mathrm{GW}}^{(\mathrm{eff})}(f) = \frac{\pi f^2}{4G}. \tag{N.140}$$

The corresponding spectral impedance is defined by $Z_{\mathrm{GW}}^{(\mathrm{eff})} \equiv \sqrt{K_{\mathrm{GW}}^{(\mathrm{eff})} \rho_{\mathrm{GW}}^{(\mathrm{eff})}}$. Because $K_{\mathrm{GW}}^{(\mathrm{eff})} = \rho_{\mathrm{GW}}^{(\mathrm{eff})} c_{\mathrm{E}}^2$, one obtains $Z_{\mathrm{GW}}^{(\mathrm{eff})}(k) = K_{\mathrm{GW}}^{(\mathrm{eff})}(k)/c_{\mathrm{E}}$. Therefore,

$$Z_{\mathrm{GW}}^{(\mathrm{eff})}(k) = \frac{c_{\mathrm{E}}^3 k^2}{16\pi G}. \tag{N.141}$$

Equivalently,

$$Z_{\mathrm{GW}}^{(\mathrm{eff})}(\omega) = \frac{c_{\mathrm{E}} \omega^2}{16\pi G}, \tag{N.142}$$

and

$$Z_{\mathrm{GW}}^{(\mathrm{eff})}(f) = \frac{\pi c_{\mathrm{E}} f^2}{4G}. \tag{N.143}$$

The dimensions are $[\rho_{\mathrm{GW}}^{(\mathrm{eff})}] = \mathrm{kg\,m^{-3}}$, and $[Z_{\mathrm{GW}}^{(\mathrm{eff})}] = \mathrm{kg\,m^{-2}\,s^{-1}}$.

The quantity $\rho_{\mathrm{GW}}^{(\mathrm{eff})}(k)$ must remain distinct from both $\rho_{\mathrm{sh}}^{(\mathrm{micro},0)}$ and $M_{\mathrm{TT}}^{(0)}$. The first is the primitive-cell-averaged density of the microscopic FCC scaffold, the second is the force-conjugate collective line inertia appearing directly in the tensor action, and the third is a pressure-equivalent spectral density inferred from the Fourier-mode response. They have different dimensional and constitutive meanings.

N.7.4 Derived Microscopic-to-Collective Response Ratio

The microscopic scaffold coefficient established in Appendix D and summarized in Section N.1 is

$$K_{\mathrm{sh}}^{(\mathrm{micro},0)} = \frac{A_{\mathrm{ct}}^{(\mathrm{modal})}}{V_{\mathrm{p}}} \tau_{\mathrm{D}}, \tag{N.144}$$

with $A_{\mathrm{ct}}^{(\mathrm{modal})} = 2\pi \ell_{\mathrm{S}}^2$, $V_{\mathrm{p}} = 4\sqrt{2}\, r_{\mathrm{D}}^3$, and $\tau_{\mathrm{D}} = F_{\mathrm{S}}/r_{\mathrm{D}}$. Substitution gives

$$K_{\mathrm{sh}}^{(\mathrm{micro},0)} = \frac{2\pi \ell_{\mathrm{S}}^2}{4\sqrt{2}\, r_{\mathrm{D}}^3} \frac{F_{\mathrm{S}}}{r_{\mathrm{D}}}, \tag{N.145}$$

and therefore

$$K_{\mathrm{sh}}^{(\mathrm{micro},0)} = \frac{\pi}{2\sqrt{2}} F_{\mathrm{S}} \frac{\ell_{\mathrm{S}}^2}{r_{\mathrm{D}}^4}. \tag{N.146}$$

Using $F_{\mathrm{S}} = c_{\mathrm{E}}^4/G$, the spectral gravitational-wave coefficient may be written

$$K_{\mathrm{GW}}^{(\mathrm{eff})}(k) = \frac{F_{\mathrm{S}} k^2}{16\pi}. \tag{N.147}$$

Define the microscopic-to-collective response ratio by

$$\zeta_{\mathrm{GW}}(k) \equiv \frac{K_{\mathrm{GW}}^{(\mathrm{eff})}(k)}{K_{\mathrm{sh}}^{(\mathrm{micro},0)}}. \tag{N.148}$$

Substituting Equations (N.146) and (N.147) gives

$$\zeta_{\mathrm{GW}}(k) = \frac{F_{\mathrm{S}} k^2}{16\pi} \left[\frac{2\sqrt{2}}{\pi F_{\mathrm{S}}} \frac{r_{\mathrm{D}}^4}{\ell_{\mathrm{S}}^2} \right]. \tag{N.149}$$

The structural force scale cancels exactly, leaving

$$\zeta_{\mathrm{GW}}(k) = \frac{\sqrt{2}}{8\pi^2} \frac{r_{\mathrm{D}}^4 k^2}{\ell_{\mathrm{S}}^2}. \tag{N.150}$$

Equivalently,

$$\zeta_{\mathrm{GW}}(k) = \frac{\sqrt{2}}{8\pi^2} \left(\frac{r_{\mathrm{D}}}{\ell_{\mathrm{S}}} \right)^2 (k r_{\mathrm{D}})^2. \tag{N.151}$$

The corresponding angular-frequency representation is

$$\zeta_{\mathrm{GW}}(\omega) = \frac{\sqrt{2}}{8\pi^2} \left(\frac{r_{\mathrm{D}}}{\ell_{\mathrm{S}}} \right)^2 \left(\frac{\omega r_{\mathrm{D}}}{c_{\mathrm{E}}} \right)^2. \tag{N.152}$$

Using $\omega = 2\pi f$, this reduces to

$$\zeta_{\mathrm{GW}}(f) = \frac{1}{\sqrt{2}} \left(\frac{r_{\mathrm{D}}}{\ell_{\mathrm{S}}} \right)^2 \left(\frac{f r_{\mathrm{D}}}{c_{\mathrm{E}}} \right)^2. \tag{N.153}$$

The ratio is therefore spectral: $\zeta_{\mathrm{GW}} \propto k^2 \propto \omega^2 \propto f^2$.

N.7.5 Representative Long-Wavelength Scale

To expose the magnitude of the derived hierarchy, consider the representative frequency $f = 150\,\mathrm{Hz}$. This frequency is used only to evaluate the derived spectral response. It is not used to calibrate any coefficient.

The corresponding angular frequency and gravity-neutral wave number are $\omega = 2\pi f$, and $k = 2\pi f / c_{\mathrm{E}} \simeq 3.14 \times 10^{-6}\,\mathrm{m}^{-1}$. Using $r_{\mathrm{D}} \simeq 7.45 \times 10^{-27}\,\mathrm{m}$ and $\ell_{\mathrm{S}} \simeq 1.6163 \times 10^{-35}\,\mathrm{m}$, one finds $k r_{\mathrm{D}} \simeq 2.34 \times 10^{-32}$, and therefore

$$\zeta_{\mathrm{GW}} \simeq 2.1 \times 10^{-48}. \tag{N.154}$$

At the same frequency, the derived spectral stiffness, equivalent continuum inertia density, and spectral impedance are:

$$K_{\mathrm{GW}}^{(\mathrm{eff})} \simeq 2.38 \times 10^{31}\,\mathrm{Pa}, \tag{N.155}$$

$$\rho_{\mathrm{GW}}^{(\mathrm{eff})} \simeq 2.65 \times 10^{14}\,\mathrm{kg\,m^{-3}}, \tag{N.156}$$

$$Z_{\mathrm{GW}}^{(\mathrm{eff})} \simeq 7.94 \times 10^{22}\,\mathrm{kg\,m^{-2}\,s^{-1}}. \tag{N.157}$$

For the established microscopic scaffold scale $K_{\mathrm{sh}}^{(\mathrm{micro},0)} \simeq 1.14 \times 10^{79}\,\mathrm{Pa}$, the same ratio is recovered directly: $K_{\mathrm{GW}}^{(\mathrm{eff})} / K_{\mathrm{sh}}^{(\mathrm{micro},0)} \simeq 2.1 \times 10^{-48}$.

The numerical hierarchy therefore follows from the previously established microscopic scales, the independently normalized collective tensor action, and the selected Fourier wavelength. No gravitational-wave event amplitude or inferred source flux has entered the calculation.

N.7.6 Physical Interpretation of the Spectral Ratio

The quantity $\zeta_{\mathrm{GW}}(k)$ is not a universal vacuum constant. It is also not interpreted as:

- a material volume fraction,
- a probability,
- an attenuation coefficient,
- a microscopic defect-loading fraction, or
- the fraction of FCC nodes physically present in the wave.

It is a dimensionless comparison between two pressure-dimensioned responses belonging to different constitutive levels:

- $K_{\mathrm{sh}}^{(\mathrm{micro},0)}$ = local affine primitive-cell scaffold response, whereas
- $K_{\mathrm{GW}}^{(\mathrm{eff})}(k)$ = spectral pressure-equivalent response of the collective tensor-gradient mode.

The factor $(kr_{\mathrm{D}})^2$ measures the long-wavelength intercell mismatch of the collective tensor state. For a wavelength vastly larger than the FCC scale, neighboring cells differ only infinitesimally, even though the underlying scaffold itself possesses an extremely large local affine stiffness.

The limit $\lim_{k\to 0}\zeta_{\mathrm{GW}}(k) = 0$ does not mean that the State-I carrier disappears or that its microscopic stiffness vanishes. It means that a spatially uniform tensor redistribution produces no tensor-gradient mismatch at the retained order: $k \to 0 \Longrightarrow \partial_k \mathsf{H}_{ij} \to 0$.

The previously unexplained hierarchy near 10^{-48} is therefore not assigned to an arbitrarily small microscopic participation coefficient. It emerges primarily from the enormous separation between the gravitational-wave wavelength and the duality scale, together with the established Hard-Floor/Soft-Floor scale ratio contained in $(r_{\mathrm{D}}/\ell_{\mathrm{S}})^2$.

N.7.7 Scope in a Gravitationally Loaded Background

Equations (N.135)–(N.153) use the gravity-neutral dispersion $\omega = c_{\mathrm{E}}k$. In a quasistatic gravitationally loaded background, the selected endpoint-inheritance closure of Section N.5 gives $\omega = c_{\mathrm{GW}}(\mathbf{x})k$, with $c_{\mathrm{GW}}(\mathbf{x}) = c_{\mathrm{E}}\left[1-\alpha_{\mathrm{G}}(\mathbf{x})\right]^2$.

The wave-number representation $K_{\mathrm{GW}}^{(\mathrm{eff})}(k) = \frac{1}{2}\mathcal{T}_{\mathrm{TT}}^{(0)}k^2$ remains the direct constitutive representation of the tensor-gradient energy under that closure. A local frequency representation must instead use $k = \omega/c_{\mathrm{GW}}(\mathbf{x})$. Therefore,

$$K_{\mathrm{GW}}^{(\mathrm{eff})}\left(\omega,\alpha_{\mathrm{G}}\right) = \frac{\mathcal{T}_{\mathrm{TT}}^{(0)}}{2c_{\mathrm{GW}}^2(\mathbf{x})}\omega^2. \tag{N.158}$$

The gravity-neutral expressions derived above are the appropriate far-zone State-I reference relations used in the subsequent radiation calculation. The next section applies the normalized sourced tensor equation to a localized conserved source and derives the retarded far-zone quadrupole field.

N.8 Source Coupling and the Far-Zone Quadrupole Field

Section N.6 establishes the normalized source-coupled tensor equation

$$\frac{1}{c_{\mathrm{E}}^2}\ddot{\mathsf{H}}_{ij}^{(\mathrm{GW})} - \nabla^2 \mathsf{H}_{ij}^{(\mathrm{GW})} = \frac{8\pi G}{c_{\mathrm{E}}^4} T_{ij}^{(\mathrm{TT})}. \tag{N.159}$$

The source tensor is the transverse-traceless projection of the mechanical stress-energy flux associated with a localized, time-dependent source. The present section derives the retarded solution of Equation (N.159) and reduces it, under the leading long-wavelength source approximation, to the far-zone quadrupole field.

No gravitational-wave observation is used to set the amplitude normalization. The coefficient in Equation (N.159) has already been fixed by the independently established static-to-tensor projection of Section N.6.

N.8.1 Retarded Solution of the Tensor Wave Equation

Introduce the gravity-neutral State-I wave operator

$$\Box_{\mathrm{E}} \equiv \frac{1}{c_{\mathrm{E}}^2}\frac{\partial^2}{\partial t^2} - \nabla^2. \tag{N.160}$$

Equation (N.159) may then be written

$$\Box_{\mathrm{E}} \mathsf{H}_{ij}^{(\mathrm{GW})} = \frac{8\pi G}{c_{\mathrm{E}}^4} T_{ij}^{(\mathrm{TT})}. \tag{N.161}$$

The retarded Green function of $\Box_{\mathrm{E}}$ in three spatial dimensions is

$$G_{\mathrm{ret}}\left(\mathbf{x}, t; \mathbf{x}', t'\right) = \frac{\delta\left[t - t' - |\mathbf{x} - \mathbf{x}'|/c_{\mathrm{E}}\right]}{4\pi|\mathbf{x} - \mathbf{x}'|}. \tag{N.162}$$

It satisfies $\Box_{\mathrm{E}} G_{\mathrm{ret}}\left(\mathbf{x}, t; \mathbf{x}', t'\right) = \delta(t - t')\delta^{(3)}\left(\mathbf{x} - \mathbf{x}'\right)$.

The retarded solution of Equation (N.161) is therefore

$$\begin{aligned} \mathsf{H}_{ij}^{(\mathrm{GW})}(\mathbf{x}, t) &= \frac{8\pi G}{c_{\mathrm{E}}^4} \int G_{\mathrm{ret}}\left(\mathbf{x}, t; \mathbf{x}', t'\right) T_{ij}^{(\mathrm{TT})}(\mathbf{x}', t')\, d^3x'\, dt' \\ &= \frac{2G}{c_{\mathrm{E}}^4} \int \frac{T_{ij}^{(\mathrm{TT})}\left(\mathbf{x}', t - |\mathbf{x} - \mathbf{x}'|/c_{\mathrm{E}}\right)}{|\mathbf{x} - \mathbf{x}'|}\, d^3x'. \end{aligned} \tag{N.163}$$

The factor 4π appearing in the denominator of the three-dimensional Green function combines with the source normalization $8\pi G/c_{\mathrm{E}}^4$ to give the coefficient $2G/c_{\mathrm{E}}^4$ in Equation (N.163). This is ordinary three-dimensional retarded spreading and does not introduce an additional material or projection coefficient.

N.8.2 Radiation-Zone Approximation

Let the source occupy a compact region of characteristic size L, and let the observation point satisfy $R \equiv |\mathbf{x}| \gg L$. Define the radiation direction $\mathbf{n} \equiv \mathbf{x}/R$, and the leading retarded time

$$t_{\mathrm{R}} \equiv t - \frac{R}{c_{\mathrm{E}}}. \tag{N.164}$$

For $|\mathbf{x}'| \lesssim L$, the source-to-observer distance is $|\mathbf{x} - \mathbf{x}'| = R - \mathbf{n} \cdot \mathbf{x}' + \mathcal{O}\left(L^2/R\right)$. At leading radiation-zone order, $1/|\mathbf{x} - \mathbf{x}'| = 1/R + \mathcal{O}\left(L/R^2\right)$.

The leading quadrupole reduction additionally assumes that the source is long-wavelength relative to its own size:

$$\frac{\omega L}{c_{\mathrm{E}}} \ll 1. \tag{N.165}$$

Under this condition, the variation of the retarded phase across the source is subleading at the retained order.

For the selected observation direction $\mathbf{n}$, define the transverse projector $\mathcal{P}_{ij}(\mathbf{n}) = \delta_{ij} - n_i n_j$, and the transverse-traceless projector

$$\Lambda_{ij,kl}(\mathbf{n}) = \frac{1}{2}\left[\mathcal{P}_{ik}\mathcal{P}_{jl} + \mathcal{P}_{il}\mathcal{P}_{jk} - \mathcal{P}_{ij}\mathcal{P}_{kl}\right]. \tag{N.166}$$

Within the far-zone approximation, this projector is constant across the compact source and may be applied after the source integration: $T_{ij}^{(\mathrm{TT})} = \Lambda_{ij,kl}(\mathbf{n}) T_{kl}^{(\mathrm{src})}$. Equation (N.163) then becomes

$$\mathsf{H}_{ij}^{(\mathrm{GW})}(\mathbf{x}, t) = \frac{2G}{c_{\mathrm{E}}^4 R} \Lambda_{ij,kl}(\mathbf{n}) \int T_{kl}^{(\mathrm{src})}\left(\mathbf{x}', t_{\mathrm{R}}\right) d^3x' \tag{N.167}$$

to leading order in L/R and $\omega L/c_{\mathrm{E}}$.

The transverse-traceless projection in Equation (N.167) is direction-dependent and belongs to the mapping from the localized source into the outgoing radiative channel. It is not an additional modification of the source-free propagation law.

N.8.3 Source-Conservation Identity

Let $\rho(\mathbf{x}, t)$ denote the effective mass density of the localized source, $j_i(\mathbf{x}, t)$ its momentum density, and $T_{ij}^{(\mathrm{src})}(\mathbf{x}, t)$ its mechanical momentum-flux tensor.

At the retained weak-field source order, local mass and momentum conservation are

$$\frac{\partial \rho}{\partial t} + \partial_k j_k = 0, \tag{N.168}$$

and

$$\frac{\partial j_i}{\partial t} + \partial_k T_{ik}^{(\mathrm{src})} = 0. \tag{N.169}$$

Define the mass second moment

$$I_{ij}(t) \equiv \int \rho(\mathbf{x}, t) x_i x_j \, d^3x. \tag{N.170}$$

Differentiating once and using Equation (N.168) gives

$$\begin{aligned} \dot{I}_{ij} &= -\int \partial_k j_k x_i x_j \, d^3x \\ &= \int \left(j_i x_j + j_j x_i\right) d^3x, \end{aligned} \tag{N.171}$$

where the boundary term vanishes for a spatially localized source.

Differentiating again and applying Equation (N.169),

$$\begin{aligned}\ddot{I}_{ij} &= -\int \left[\partial_k T^{(\mathrm{src})}_{ik} x_j + \partial_k T^{(\mathrm{src})}_{jk} x_i\right] d^3x \\ &= \int \left[T^{(\mathrm{src})}_{ij} + T^{(\mathrm{src})}_{ji}\right] d^3x.\end{aligned} \tag{N.172}$$

For the symmetric mechanical source tensor, $T^{(\mathrm{src})}_{ij} = T^{(\mathrm{src})}_{ji}$, one obtains the exact localized-source identity

$$\int T^{(\mathrm{src})}_{ij}\, d^3x = \frac{1}{2}\ddot{I}_{ij}. \tag{N.173}$$

This identity follows from local conservation and spatial localization. It does not require geometric spacetime curvature.

N.8.4 Symmetric Trace-Free Mass Quadrupole

Define the symmetric trace-free mass quadrupole by

$$Q_{ij} \equiv I_{ij} - \frac{1}{3}\delta_{ij} I_{kk}. \tag{N.174}$$

Equivalently,

$$Q_{ij}(t) = \int \rho(\mathbf{x}, t)\left(x_i x_j - \frac{1}{3}\delta_{ij} r^2\right) d^3x. \tag{N.175}$$

It satisfies $Q_{ij} = Q_{ji}$ and $Q_{ii} = 0$.

The TT projector annihilates a pure trace: $\Lambda_{ij,kl}(\mathbf{n})\delta_{kl} = 0$. Consequently,

$$\Lambda_{ij,kl}\ddot{I}_{kl} = \Lambda_{ij,kl}\ddot{Q}_{kl}. \tag{N.176}$$

Substituting Equation (N.173) into Equation (N.167) and using Equation (N.176) gives

$$\mathsf{H}^{(\mathrm{GW})}_{ij}(\mathbf{x}, t) = \frac{G}{c_{\mathrm{E}}^4 R}\Lambda_{ij,kl}(\mathbf{n})\ddot{Q}_{kl}\left(t_{\mathrm{R}}\right). \tag{N.177}$$

The observable transverse-traceless strain is normalized by $h^{(\mathrm{TT})}_{ij} = 2\mathsf{H}^{(\mathrm{GW})}_{ij}$. Therefore,

$$h^{(\mathrm{TT})}_{ij}(\mathbf{x}, t) = \frac{2G}{c_{\mathrm{E}}^4 R}\Lambda_{ij,kl}(\mathbf{n})\ddot{Q}_{kl}\left(t_{\mathrm{R}}\right). \tag{N.178}$$

Equation (N.178) is the leading far-zone quadrupole field of the normalized State-I tensor sector. Its coefficient follows from the tensor-gradient normalization derived in Section N.6; it has not been fitted to a binary event.

N.8.5 Polarization Amplitudes

For the selected radiation direction $\mathbf{n}$, let $(\mathbf{E}_+)_{ij}$ and $(\mathbf{E}_\times)_{ij}$ be the normalized transverse tensor bases satisfying $\mathbf{E}_A : \mathbf{E}_B = 2\delta_{AB}$. The observable strain decomposes as

$$h^{(\mathrm{TT})}_{ij} = h_+(\mathbf{E}_+)_{ij} + h_\times(\mathbf{E}_\times)_{ij}. \tag{N.179}$$

The individual amplitudes are extracted by $h_A = \frac{1}{2}(\mathbf{E}_A)_{ij} h_{ij}^{(\mathrm{TT})}$ for $A \in \{+, \times\}$. Using Equation (N.178),

$$h_A(\mathbf{x}, t) = \frac{G}{c_{\mathrm{E}}^4 R}(\mathbf{E}_A)_{ij} \ddot{Q}_{ij}\left(t_{\mathrm{R}}\right), \qquad A \in \{+, \times\}. \tag{N.180}$$

Because the polarization tensors already lie in the transverse-traceless subspace, the TT projector acts as the identity when contracted with them.

The two polarization amplitudes are therefore different directional projections of the same conserved source quadrupole. Their common propagation speed and common normalization follow from the degenerate FCC tensor basis derived in Section N.3 and the normalized collective action derived in Sections N.5 and N.6.

N.8.6 Absence of Monopole and Dipole Radiation

The leading radiative source is quadrupolar because the lower multipole moments are constrained by conservation.

The total source mass is $M = \int \rho \, d^3x$. Equation (N.168) gives $\dot{M} = 0$ for an isolated source. The monopole moment therefore cannot provide a time-dependent radiative degree of freedom at the retained order.

The mass dipole is $D_i = \int \rho x_i \, d^3x$. Its first derivative is the total momentum, $\dot{D}_i = P_i$, and isolation gives $\dot{P}_i = 0$. Hence, $\ddot{D}_i = 0$. The dipole therefore represents uniform center-of-mass motion rather than an outgoing radiative tensor source.

The first nontrivial time-dependent conserved source moment is consequently the symmetric trace-free quadrupole Q_{ij}.

N.8.7 Mechanical Interpretation and Scope

The derivation in this section establishes the sequence

$$T_{ij}^{(\mathrm{src})} \longrightarrow \Lambda_{ij,kl} T_{kl}^{(\mathrm{src})} \longrightarrow \mathsf{H}_{ij}^{(\mathrm{GW})} \longrightarrow h_{ij}^{(\mathrm{TT})}, \tag{N.181}$$

with

$$h_{ij}^{(\mathrm{TT})} = \frac{2G}{c_{\mathrm{E}}^4 R} \Lambda_{ij,kl} \ddot{Q}_{kl}. \tag{N.182}$$

The localized source excites the collective directional-tension tensor through the TT projection of its mechanical momentum flux. Once generated, the tensor state propagates through the source-free State-I Soft Floor according to

$$\frac{1}{c_{\mathrm{E}}^2} \ddot{\mathsf{H}}_{ij}^{(\mathrm{GW})} - \nabla^2 \mathsf{H}_{ij}^{(\mathrm{GW})} = 0. \tag{N.183}$$

The factor 8π therefore belongs to source-to-tensor normalization, while the outgoing free field is governed by the ratio $\mathcal{T}_{\mathrm{TT}}^{(0)} / M_{\mathrm{TT}}^{(0)} = c_{\mathrm{E}}^2$.

The present reduction assumes:

1. a weak-field State-I exterior;
2. a spatially localized source;
3. local mass and momentum conservation;
4. an observation distance satisfying $R \gg L$;

5. a leading long-wavelength source limit satisfying $\omega L/c_{\mathrm{E}} \ll 1$; and

6. propagation through the gravity-neutral far-zone reference medium.

Within these conditions, no additional source-normalization coefficient, microscopic participation fraction, or event-dependent stiffness is required.

The effective source quadrupole Q_{ij} is the long-wavelength source moment seen by the exterior tensor field. Deriving this moment directly from the evolving microscopic FCC/SC live boundary during strong-field merger and ringdown remains a separate completion problem. In particular, the full map from the microscopic phase-boundary variables and Tension-Column transfer state to the effective far-zone quadrupole is not claimed to be closed here.

The next section derives the conserved mechanical energy flux of the outgoing tensor field, performs the complete transverse-traceless angular projection over the radiation sphere, and obtains the total quadrupole luminosity.

N.9 Tensor Energy Flux and Total Quadrupole Luminosity

The normalized tensor-gradient action derived in Section N.6 determines not only the sourced field amplitude but also the mechanical energy carried by the outgoing transverse-traceless tensor state. The present section derives the local tensor-energy balance, obtains the far-zone gravitational-wave intensity, performs the complete angular transverse-traceless projection, and recovers the total quadrupole luminosity.

The calculation is performed in the source-free gravity-neutral State-I exterior, where

$$\frac{1}{c_{\mathrm{E}}^2}\ddot{\mathsf{H}}_{ij}^{(\mathrm{GW})} - \nabla^2 \mathsf{H}_{ij}^{(\mathrm{GW})} = 0. \tag{N.184}$$

The source enters only through the outgoing boundary data established in Section N.8.

N.9.1 Local Tensor-Energy Balance

The source-coupled tensor Lagrangian density is

$$\mathcal{L}_{\mathrm{TT}} = \frac{\mathcal{T}_{\mathrm{TT}}^{(0)}}{2}\left[\frac{1}{c_{\mathrm{E}}^2}\dot{\mathsf{H}}_{ij}\dot{\mathsf{H}}_{ij} - \partial_k \mathsf{H}_{ij}\partial_k \mathsf{H}_{ij}\right] + \mathsf{H}_{ij} T_{ij}^{(\mathrm{TT})}, \tag{N.185}$$

where

$$\mathcal{T}_{\mathrm{TT}}^{(0)} = \frac{c_{\mathrm{E}}^4}{8\pi G}. \tag{N.186}$$

The corresponding tensor-field energy density is

$$u_{\mathrm{GW}} = \frac{\mathcal{T}_{\mathrm{TT}}^{(0)}}{2c_{\mathrm{E}}^2}\dot{\mathsf{H}}_{ij}\dot{\mathsf{H}}_{ij} + \frac{\mathcal{T}_{\mathrm{TT}}^{(0)}}{2}\partial_k \mathsf{H}_{ij}\partial_k \mathsf{H}_{ij}. \tag{N.187}$$

The associated mechanical energy-flux vector is

$$\mathcal{F}_k^{(\mathrm{GW})} = -\mathcal{T}_{\mathrm{TT}}^{(0)}\dot{\mathsf{H}}_{ij}\partial_k \mathsf{H}_{ij}. \tag{N.188}$$

To verify the local balance law, multiply the sourced field equation

$$\frac{1}{c_{\mathrm{E}}^2}\ddot{\mathsf{H}}_{ij} - \nabla^2 \mathsf{H}_{ij} = \frac{1}{\mathcal{T}_{\mathrm{TT}}^{(0)}} T_{ij}^{(\mathrm{TT})} \tag{N.189}$$

by $\mathcal{T}_{\mathrm{TT}}^{(0)}\dot{\mathsf{H}}_{ij}$. Using the identity

$$-\dot{\mathsf{H}}_{ij}\nabla^2\mathsf{H}_{ij} = -\partial_k\left(\dot{\mathsf{H}}_{ij}\partial_k\mathsf{H}_{ij}\right) + \frac{1}{2}\frac{\partial}{\partial t}\left(\partial_k\mathsf{H}_{ij}\partial_k\mathsf{H}_{ij}\right), \tag{N.190}$$

one obtains

$$\frac{\partial u_{\mathrm{GW}}}{\partial t} + \partial_k\mathcal{F}_k^{(\mathrm{GW})} = \dot{\mathsf{H}}_{ij}T_{ij}^{(\mathrm{TT})}. \tag{N.191}$$

The right-hand side is the mechanical power density transferred from the localized source into the collective tensor field. Outside the source region, $T_{ij}^{(\mathrm{TT})} = 0$, and Equation (N.191) reduces to

$$\frac{\partial u_{\mathrm{GW}}}{\partial t} + \partial_k\mathcal{F}_k^{(\mathrm{GW})} = 0. \tag{N.192}$$

The tensor-gradient action therefore carries a locally conserved positive quadratic energy in the source-free State-I exterior.

N.9.2 Outgoing Far-Zone Intensity

For an outgoing radiation field,

$$\mathsf{H}_{ij}^{(\mathrm{GW})} = \frac{1}{R}\mathsf{A}_{ij}\left(t - \frac{R}{c_{\mathrm{E}}}, \mathbf{n}\right) + \mathcal{O}\left(\frac{1}{R^2}\right), \tag{N.193}$$

where $\mathbf{n} = \mathbf{x}/R$.

In the radiation zone, $kR \gg 1$, the leading radial derivative is

$$\partial_R\mathsf{H}_{ij}^{(\mathrm{GW})} = -\frac{1}{c_{\mathrm{E}}}\dot{\mathsf{H}}_{ij}^{(\mathrm{GW})} + \mathcal{O}\left(\frac{1}{kR^2}\right). \tag{N.194}$$

The outward radial intensity is $I_{\mathrm{GW}} \equiv n_k\mathcal{F}_k^{(\mathrm{GW})}$. Using Equations (N.188) and (N.194),

$$I_{\mathrm{GW}} = \frac{\mathcal{T}_{\mathrm{TT}}^{(0)}}{c_{\mathrm{E}}}\dot{\mathsf{H}}_{ij}^{(\mathrm{GW})}\dot{\mathsf{H}}_{ij}^{(\mathrm{GW})}. \tag{N.195}$$

Substituting $\mathcal{T}_{\mathrm{TT}}^{(0)} = c_{\mathrm{E}}^4/(8\pi G)$ gives

$$I_{\mathrm{GW}} = \frac{c_{\mathrm{E}}^3}{8\pi G}\dot{\mathsf{H}}_{ij}^{(\mathrm{GW})}\dot{\mathsf{H}}_{ij}^{(\mathrm{GW})}. \tag{N.196}$$

The observable transverse-traceless strain is $h_{ij}^{(\mathrm{TT})} = 2\mathsf{H}_{ij}^{(\mathrm{GW})}$. Therefore,

$$I_{\mathrm{GW}} = \frac{c_{\mathrm{E}}^3}{32\pi G}\dot{h}_{ij}^{(\mathrm{TT})}\dot{h}_{ij}^{(\mathrm{TT})}. \tag{N.197}$$

For the polarization decomposition

$$h_{ij}^{(\mathrm{TT})} = h_+(\mathbf{E}_+)_{ij} + h_\times(\mathbf{E}_\times)_{ij}, \tag{N.198}$$

with $\mathbf{E}_A : \mathbf{E}_B = 2\delta_{AB}$, one has $\dot{h}_{ij}^{(\mathrm{TT})}\dot{h}_{ij}^{(\mathrm{TT})} = 2\left(\dot{h}_+^2 + \dot{h}_\times^2\right)$. Hence,

$$I_{\mathrm{GW}} = \frac{c_{\mathrm{E}}^3}{16\pi G}\left(\dot{h}_+^2 + \dot{h}_\times^2\right). \tag{N.199}$$

For periodic radiation, the measured intensity is the time average

$$\langle I_{\mathrm{GW}}\rangle = \frac{c_{\mathrm{E}}^3}{16\pi G}\left\langle\dot{h}_+^2 + \dot{h}_\times^2\right\rangle. \tag{N.200}$$

N.9.3 Consistency with the Spectral Response

Consider monochromatic polarization amplitudes

$$h_A(t) = h_A^{(0)} \cos\left(\omega t + \varphi_A\right), \qquad A \in \{+, \times\}. \tag{N.201}$$

Their averaged squared time derivatives are $\left\langle \dot{h}_A^2 \right\rangle = \frac{1}{2}\omega^2 \left(h_A^{(0)}\right)^2$.

Define $h_{\text{eff}}^2 \equiv \left(h_+^{(0)}\right)^2 + \left(h_\times^{(0)}\right)^2$. Equation (N.200) becomes

$$\langle I_{\text{GW}} \rangle = \frac{c_{\text{E}}^3 \omega^2}{32\pi G} h_{\text{eff}}^2. \tag{N.202}$$

Section N.7 gives $K_{\text{GW}}^{(\text{eff})}(\omega) = c_{\text{E}}^2 \omega^2/(16\pi G)$. Therefore,

$$\langle I_{\text{GW}} \rangle = \frac{1}{2} K_{\text{GW}}^{(\text{eff})}(\omega) c_{\text{E}} h_{\text{eff}}^2. \tag{N.203}$$

The effective spectral stiffness derived in Section N.7 is thus exactly the pressure-equivalent coefficient inferred from the tensor energy flux. It is not an independently fitted modulus.

N.9.4 Angular Radiation Pattern

The far-zone quadrupole strain derived in Section N.8 is

$$h_{ij}^{(\text{TT})} = \frac{2G}{c_{\text{E}}^4 R} \Lambda_{ij,kl}(\mathbf{n}) \ddot{Q}_{kl}\left(t_{\text{R}}\right). \tag{N.204}$$

Differentiation gives

$$\dot{h}_{ij}^{(\text{TT})} = \frac{2G}{c_{\text{E}}^4 R} \Lambda_{ij,kl}(\mathbf{n}) \dddot{Q}_{kl}\left(t_{\text{R}}\right). \tag{N.205}$$

Define

$$A_{ij} \equiv \dddot{Q}_{ij}\left(t_{\text{R}}\right). \tag{N.206}$$

Because Q_{ij} is symmetric and trace-free, $A_{ij} = A_{ji}$ and $A_{ii} = 0$. Its transverse-traceless projection is

$$A_{ij}^{(\text{TT})} \equiv \Lambda_{ij,kl}(\mathbf{n}) A_{kl}. \tag{N.207}$$

Equation (N.205) becomes

$$\dot{h}_{ij}^{(\text{TT})} = \frac{2G}{c_{\text{E}}^4 R} A_{ij}^{(\text{TT})}. \tag{N.208}$$

Substituting into Equation (N.197) gives the angular intensity

$$I_{\text{GW}}(\mathbf{n}) = \frac{G}{8\pi c_{\text{E}}^5 R^2} A_{ij}^{(\text{TT})} A_{ij}^{(\text{TT})}. \tag{N.209}$$

For periodic or quasiperiodic radiation,

$$\langle I_{\text{GW}}(\mathbf{n}) \rangle = \frac{G}{8\pi c_{\text{E}}^5 R^2} \left\langle A_{ij}^{(\text{TT})} A_{ij}^{(\text{TT})} \right\rangle. \tag{N.210}$$

The radiated power per unit solid angle is therefore

$$\frac{dP_{\text{GW}}}{d\Omega} = \frac{G}{8\pi c_{\text{E}}^5} \left\langle A_{ij}^{(\text{TT})} A_{ij}^{(\text{TT})} \right\rangle. \tag{N.211}$$

N.9.5 Complete Angular TT Projection

The TT projector is

$$\Lambda_{ij,kl}(\mathbf{n}) = \frac{1}{2}\left[\mathcal{P}_{ik}\mathcal{P}_{jl} + \mathcal{P}_{il}\mathcal{P}_{jk} - \mathcal{P}_{ij}\mathcal{P}_{kl}\right], \tag{N.212}$$

where $\mathcal{P}_{ij} = \delta_{ij} - n_i n_j$. For a symmetric trace-free tensor A_{ij}, direct contraction gives

$$A_{ij}^{(\mathrm{TT})} A_{ij}^{(\mathrm{TT})} = A_{ij}A_{ij} - 2\left(A_{ij}n_j\right)\left(A_{ik}n_k\right) + \frac{1}{2}\left(A_{ij}n_i n_j\right)^2. \tag{N.213}$$

The required angular identities over the unit sphere are $\int d\Omega = 4\pi$,

$$\int n_i n_j \, d\Omega = \frac{4\pi}{3}\delta_{ij}, \tag{N.214}$$

and

$$\int n_i n_j n_k n_l \, d\Omega = \frac{4\pi}{15}\left(\delta_{ij}\delta_{kl} + \delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk}\right). \tag{N.215}$$

The first term of Equation (N.213) gives

$$\int A_{ij}A_{ij} \, d\Omega = 4\pi A_{ij}A_{ij}. \tag{N.216}$$

For the second term,

$$\begin{aligned}\int \left(A_{ij}n_j\right)\left(A_{ik}n_k\right) d\Omega &= A_{ij}A_{ik}\int n_j n_k \, d\Omega \\ &= \frac{4\pi}{3}A_{ij}A_{ij}.\end{aligned} \tag{N.217}$$

For the final term,

$$\begin{aligned}\int \left(A_{ij}n_i n_j\right)^2 d\Omega &= A_{ij}A_{kl}\int n_i n_j n_k n_l \, d\Omega \\ &= \frac{4\pi}{15}A_{ij}A_{kl}\left(\delta_{ij}\delta_{kl} + \delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk}\right).\end{aligned} \tag{N.218}$$

Because $A_{ii} = 0$ and $A_{ij} = A_{ji}$, this reduces to

$$\int \left(A_{ij}n_i n_j\right)^2 d\Omega = \frac{8\pi}{15}A_{ij}A_{ij}. \tag{N.219}$$

Substitution into Equation (N.213) gives

$$\begin{aligned}\int A_{ij}^{(\mathrm{TT})}A_{ij}^{(\mathrm{TT})} d\Omega &= 4\pi A_{ij}A_{ij} - \frac{8\pi}{3}A_{ij}A_{ij} + \frac{4\pi}{15}A_{ij}A_{ij} \\ &= \frac{8\pi}{5}A_{ij}A_{ij}.\end{aligned} \tag{N.220}$$

Therefore,

$$\int A_{ij}^{(\mathrm{TT})}A_{ij}^{(\mathrm{TT})} d\Omega = \frac{8\pi}{5}A_{ij}A_{ij}. \tag{N.221}$$

The factor $8\pi/5$ is a genuine angular result obtained by integrating the physical transverse-traceless radiation pattern over the complete sphere. It is conceptually distinct from the source normalization $\kappa_{\mathrm{TT}} = 8\pi$ derived in Section N.6.

N.9.6 Total Quadrupole Luminosity

The total radiated power is $P_{\mathrm{GW}} = \int \frac{dP_{\mathrm{GW}}}{d\Omega}\, d\Omega$. Using Equations (N.211) and (N.221),

$$\begin{aligned} P_{\mathrm{GW}} &= \frac{G}{8\pi c_{\mathrm{E}}^5} \left\langle \int A_{ij}^{(\mathrm{TT})} A_{ij}^{(\mathrm{TT})} d\Omega \right\rangle \\ &= \frac{G}{8\pi c_{\mathrm{E}}^5} \frac{8\pi}{5} \left\langle A_{ij} A_{ij} \right\rangle . \end{aligned} \tag{N.222}$$

Hence,

$$P_{\mathrm{GW}} = \frac{G}{5c_{\mathrm{E}}^5} \left\langle \dddot{Q}_{ij}\, \dddot{Q}_{ij} \right\rangle . \tag{N.223}$$

The source loses mechanical energy at the corresponding rate:

$$\frac{dE_{\mathrm{src}}}{dt} = -P_{\mathrm{GW}}. \tag{N.224}$$

Equation (N.223) is positive definite and contains no adjustable microscopic participation factor, event-specific stiffness, or additional angular coefficient. The tensor-source normalization, far-zone field amplitude, local wave intensity, and complete angular projection close into a single quadrupole luminosity.

N.9.7 Mechanical Interpretation and Scope

The energy carried by a gravitational wave is the finite mechanical energy of the propagating State-I directional-tension tensor. It is stored in two conjugate forms:

$$\text{collective tensor-transfer inertia} \quad \longleftrightarrow \quad \dot{\mathsf{H}}_{ij}\dot{\mathsf{H}}_{ij}, \tag{N.225}$$

and

$$\text{intercell directional-tension mismatch} \quad \longleftrightarrow \quad \partial_k \mathsf{H}_{ij} \partial_k \mathsf{H}_{ij}. \tag{N.226}$$

For a freely propagating far-zone wave, the time-averaged kinetic and gradient contributions are equal:

$$\left\langle \frac{\mathcal{T}_{\mathrm{TT}}^{(0)}}{2c_{\mathrm{E}}^2} \dot{\mathsf{H}}_{ij} \dot{\mathsf{H}}_{ij} \right\rangle = \left\langle \frac{\mathcal{T}_{\mathrm{TT}}^{(0)}}{2} \partial_k \mathsf{H}_{ij} \partial_k \mathsf{H}_{ij} \right\rangle . \tag{N.227}$$

The Hard Floor remains the phase-locked reference and record of the completed structural state. It is not assigned an additional propagating tensor-energy term. The finite radiative energy resides in the active State-I Soft-Floor tensor carrier.

The derivation in this section assumes:

1. the normalized long-wavelength tensor-gradient action of Section N.6;
2. a weak-field source-free State-I exterior;
3. an outgoing radiation-zone field satisfying $kR \gg 1$;
4. the far-zone quadrupole field derived in Section N.8; and
5. a localized source for which the boundary terms used in the conservation identities vanish.

Within these conditions, the complete leading-order radiation chain is

$$T_{ij}^{(\mathrm{src})} \longrightarrow Q_{ij} \longrightarrow h_{ij}^{(\mathrm{TT})} \longrightarrow I_{\mathrm{GW}} \longrightarrow P_{\mathrm{GW}}. \tag{N.228}$$

The next section applies Equation (N.223) to a weak-field circular binary and derives the corresponding orbital power loss and leading gravitational-wave chirp relation.

N.10 Circular-Binary Radiation and the Leading Chirp Relation

The total quadrupole luminosity derived in Section N.9 is

$$P_{\mathrm{GW}} = \frac{G}{5c_{\mathrm{E}}^5} \left\langle \dddot{Q}_{ij} \ddot{Q}_{ij} \right\rangle . \tag{N.229}$$

The present section applies this result to two compact masses in a weak-field, slowly evolving circular orbit. The calculation derives the leading orbital-energy loss, separation decay, gravitational-wave frequency evolution, and chirp-mass relation without introducing any additional tensor-response coefficient.

The derivation assumes that the orbital motion remains within the weak-field State-I regime and that the orbital evolution is adiabatic:

$$\left| \frac{\dot{\Omega}}{\Omega^2} \right| \ll 1. \tag{N.230}$$

The orbit may therefore be treated as circular over each individual radiation cycle while its separation and frequency evolve slowly through gravitational-wave energy loss.

N.10.1 Center-of-Mass Binary Kinematics

Let the two source masses be m_1 and m_2. Define the total mass

$$M \equiv m_1 + m_2, \tag{N.231}$$

and the reduced mass

$$\mu \equiv \frac{m_1 m_2}{M}. \tag{N.232}$$

In the center-of-mass frame, $m_1\mathbf{x}_1 + m_2\mathbf{x}_2 = \mathbf{0}$. Let the relative separation vector be $\mathbf{r} \equiv \mathbf{x}_1 - \mathbf{x}_2$. For a circular orbit in the xy-plane,

$$\mathbf{r}(t) = r \begin{pmatrix} \cos \Omega t \\ \sin \Omega t \\ 0 \end{pmatrix}, \tag{N.233}$$

where r is the instantaneous binary separation and Ω is the orbital angular frequency.

The center-of-mass positions are $\mathbf{x}_1 = \frac{m_2}{M}\mathbf{r}$ and $\mathbf{x}_2 = -\frac{m_1}{M}\mathbf{r}$.

For two pointlike source masses, the symmetric trace-free mass quadrupole defined in Section N.8 reduces to

$$Q_{ij} = \mu \left(r_i r_j - \frac{1}{3}\delta_{ij} r^2 \right). \tag{N.234}$$

The weak-field circular-orbit balance supplied by the static restorative gravitational sector is

$$\Omega^2 = \frac{GM}{r^3}. \tag{N.235}$$

This relation determines the conservative orbital motion. The tensor-radiation sector then determines the slow secular loss of orbital energy.

N.10.2 Time-Dependent Binary Quadrupole

Using Equation (N.233), the nonzero quadrupole components are

$$Q_{xx} = \mu r^2 \left[\frac{1}{6} + \frac{1}{2}\cos(2\Omega t)\right], \tag{N.236}$$

$$Q_{yy} = \mu r^2 \left[\frac{1}{6} - \frac{1}{2}\cos(2\Omega t)\right], \tag{N.237}$$

$$Q_{xy} = Q_{yx} = \frac{1}{2}\mu r^2 \sin(2\Omega t), \tag{N.238}$$

and

$$Q_{zz} = -\frac{1}{3}\mu r^2. \tag{N.239}$$

The trace vanishes: $Q_{xx} + Q_{yy} + Q_{zz} = 0$.

At leading adiabatic order, r and Ω are treated as constant during differentiation over one orbital cycle. The third derivatives of the time-dependent components are then

$$\dddot{Q}_{xx} = 4\mu r^2 \Omega^3 \sin(2\Omega t), \tag{N.240}$$

$$\dddot{Q}_{yy} = -4\mu r^2 \Omega^3 \sin(2\Omega t), \tag{N.241}$$

$$\dddot{Q}_{xy} = \dddot{Q}_{yx} = -4\mu r^2 \Omega^3 \cos(2\Omega t). \tag{N.242}$$

The component Q_{zz} is constant at this order and therefore gives $\dddot{Q}_{zz} = 0$.

The complete contraction is

$$\begin{aligned} \dddot{Q}_{ij}\,\ddot{Q}_{ij} &= \left(\dddot{Q}_{xx}\right)^2 + \left(\dddot{Q}_{yy}\right)^2 + 2\left(\dddot{Q}_{xy}\right)^2 \\ &= 32\mu^2 r^4 \Omega^6. \end{aligned} \tag{N.243}$$

Therefore,

$$\left\langle \dddot{Q}_{ij}\,\ddot{Q}_{ij} \right\rangle = 32\mu^2 r^4 \Omega^6. \tag{N.244}$$

For an exactly circular orbit at the retained order, this contraction is already time independent, so the cycle average does not alter its value.

N.10.3 Circular-Binary Gravitational-Wave Power

Substitution of Equation (N.244) into the general luminosity Equation (N.229) gives

$$P_{\mathrm{GW}} = \frac{32}{5}\frac{G\mu^2 r^4 \Omega^6}{c_{\mathrm{E}}^5}. \tag{N.245}$$

Using the weak-field orbital relation $\Omega^2 = GM/r^3$, one obtains $r^4\Omega^6 = G^3M^3/r^5$. Hence,

$$P_{\mathrm{GW}} = \frac{32}{5}\frac{G^4\mu^2 M^3}{c_{\mathrm{E}}^5 r^5}. \tag{N.246}$$

The radiation power may also be expressed directly in terms of orbital angular frequency. From Equation (N.235), $r = \left(GM/\Omega^2\right)^{1/3}$. Substitution into Equation (N.245) gives

$$P_{\mathrm{GW}} = \frac{32}{5}\frac{G^{7/3}\mu^2 M^{4/3}}{c_{\mathrm{E}}^5}\Omega^{10/3}. \tag{N.247}$$

No new tensor-projection coefficient appears in any of these forms. The normalization is inherited entirely from the collective tensor action and angular quadrupole calculation completed in Sections N.6–N.9.

N.10.4 Orbital Energy and Separation Decay

The conservative mechanical energy of the circular binary is

$$E_{\rm orb} = \frac{1}{2}\mu r^2\Omega^2 - \frac{GM\mu}{r}. \tag{N.248}$$

Using the circular-orbit relation $r^2\Omega^2 = GM/r$, the orbital energy becomes

$$E_{\rm orb} = -\frac{GM\mu}{2r}. \tag{N.249}$$

The local tensor-energy balance derived in Section N.9 requires

$$\frac{dE_{\rm orb}}{dt} = -P_{\rm GW}. \tag{N.250}$$

Differentiating Equation (N.249), we find $\frac{dE_{\rm orb}}{dt} = \frac{GM\mu}{2r^2}\dot{r}$. Using Equation (N.246), $\frac{GM\mu}{2r^2}\dot{r} = -\frac{32}{5}\frac{G^4\mu^2M^3}{c_{\rm E}^5 r^5}$. Therefore,

$$\dot{r} = -\frac{64}{5}\frac{G^3\mu M^2}{c_{\rm E}^5 r^3}. \tag{N.251}$$

The negative sign indicates a secular decrease in binary separation. The radiated tensor energy is supplied by the mechanical binding energy of the source, so the orbit contracts as the outgoing State-I tensor field carries positive energy away from the system.

N.10.5 Frequency Evolution and Chirp Mass

Differentiating the circular-orbit relation

$$\Omega^2 = \frac{GM}{r^3}, \tag{N.252}$$

with M constant gives $2\frac{\dot{\Omega}}{\Omega} = -3\frac{\dot{r}}{r}$. Thus, $\dot{\Omega} = -\frac{3}{2}\Omega\frac{\dot{r}}{r}$. Using Equation (N.251),

$$\dot{\Omega} = \frac{96}{5}\frac{G^3\mu M^2}{c_{\rm E}^5 r^4}\Omega. \tag{N.253}$$

Eliminating r through $r = \left(GM/\Omega^2\right)^{1/3}$ gives

$$\dot{\Omega} = \frac{96}{5}\frac{G^{5/3}\mu M^{2/3}}{c_{\rm E}^5}\Omega^{11/3}. \tag{N.254}$$

Define the chirp mass by

$$\mathcal{M} \equiv \mu^{3/5}M^{2/5}. \tag{N.255}$$

This definition gives $\mathcal{M}^{5/3} = \mu M^{2/3}$. Equation (N.254) therefore becomes

$$\dot{\Omega} = \frac{96}{5}\frac{(G\mathcal{M})^{5/3}}{c_{\rm E}^5}\Omega^{11/3}. \tag{N.256}$$

The dominant quadrupole radiation oscillates at twice the orbital angular frequency: $\omega_{\rm GW} = 2\Omega$. The corresponding gravitational-wave cyclic frequency is

$$f_{\rm GW} = \frac{\omega_{\rm GW}}{2\pi} = \frac{\Omega}{\pi}. \tag{N.257}$$

For the remainder of this section, define $f \equiv f_{\mathrm{GW}}$. Then $\Omega = \pi f$, and $\dot{\Omega} = \pi \dot{f}$. Substitution into Equation (N.256) gives

$$\dot{f} = \frac{96}{5}\pi^{8/3}\frac{(G\mathcal{M})^{5/3}}{c_{\mathrm{E}}^{5}} f^{11/3}. \tag{N.258}$$

Equation (N.258) is the leading circular-binary chirp relation. The increasing frequency follows mechanically from the sequence:

positive outgoing tensor-energy flux $\longrightarrow$ loss of orbital binding energy $\longrightarrow$ decreasing separation $\longrightarrow$ increasing or (N.259)

The mass combination controlling this frequency evolution is the chirp mass $\mathcal{M}$, not the total mass or reduced mass separately.

N.10.6 Time Remaining in the Leading Adiabatic Limit

Equation (N.258) may be written

$$\frac{df}{dt} = \mathcal{A} f^{11/3}, \tag{N.260}$$

where $\mathcal{A} \equiv \frac{96}{5}\pi^{8/3}\left(G\mathcal{M}\right)^{5/3}/c_{\mathrm{E}}^{5}$. Separating variables gives $dt = \frac{1}{\mathcal{A}} f^{-11/3} df$. Integration from the instantaneous frequency f to the formal endpoint of the leading adiabatic approximation gives $t_{\mathrm{c}} - t = \frac{3}{8\mathcal{A}} f^{-8/3}$. Therefore,

$$t_{\mathrm{c}} - t = \frac{5}{256}\frac{c_{\mathrm{E}}^{5}}{\pi^{8/3}\left(G\mathcal{M}\right)^{5/3}} f^{-8/3}. \tag{N.261}$$

Equivalently,

$$t_{\mathrm{c}} - t = \frac{5}{256}\left(\frac{G\mathcal{M}}{c_{\mathrm{E}}^{3}}\right)^{-5/3}\left(\pi f\right)^{-8/3}. \tag{N.262}$$

The quantity t_{c} is the formal endpoint obtained by extrapolating the leading weak-field adiabatic law. It is not identified with the exact microscopic time of FCC-to-SC contact, merger, saturation, or ringdown. Those regimes require the nonlinear live-boundary dynamics excluded from the present approximation.

N.10.7 Frequency-Domain Power

Using the chirp mass identity $\mu^2 M^{4/3} = \mathcal{M}^{10/3}$, Equation (N.247) becomes

$$P_{\mathrm{GW}} = \frac{32}{5}\frac{G^{7/3}\mathcal{M}^{10/3}}{c_{\mathrm{E}}^{5}}\Omega^{10/3}. \tag{N.263}$$

Using $\Omega = \pi f$, one obtains

$$P_{\mathrm{GW}}(f) = \frac{32}{5}\frac{G^{7/3}\mathcal{M}^{10/3}}{c_{\mathrm{E}}^{5}}\left(\pi f\right)^{10/3}. \tag{N.264}$$

Equivalently,

$$P_{\mathrm{GW}}(f) = \frac{32}{5}\frac{c_{\mathrm{E}}^{5}}{G}\left(\frac{\pi G\mathcal{M} f}{c_{\mathrm{E}}^{3}}\right)^{10/3}. \tag{N.265}$$

The natural luminosity scale is therefore c_{E}^{5}/G, multiplied by the dimensionless orbital-frequency factor $\left(\pi G\mathcal{M} f/c_{\mathrm{E}}^{3}\right)^{10/3}$.

N.10.8 Mechanical Interpretation

The leading circular-binary result closes the following mechanical chain:

$$\text{restorative static orbital binding} \longrightarrow Q_{ij}(t) \longrightarrow \mathsf{H}_{ij}^{(\mathrm{GW})} \longrightarrow P_{\mathrm{GW}} \longrightarrow \dot{r} < 0, \quad \dot{f} > 0. \tag{N.266}$$

The conservative orbital relation and the radiative tensor relation occupy distinct but coupled sectors. The static tension field determines the instantaneous orbital binding, while the dynamic transverse-traceless State-I tensor carries energy away from the source. Their common dependence on G follows from the single static-to-tensor normalization established in Section N.6.

No additional dark-sector component, phenomenological radiation-reaction coefficient, microscopic participation factor, or event-calibrated vacuum stiffness is inserted into the leading chirp relation.

N.10.9 Domain of Validity and Completion Boundary

The results of this section apply under the following conditions:

1. the binary is spatially localized relative to the emitted wavelength;
2. the exterior remains in the weak-field State-I phase;
3. the source motion is nonrelativistic at the retained order;
4. the orbit is circular or has negligible eccentricity over the evaluated interval;
5. the radiation reaction is adiabatic;
6. the masses may be represented by an effective conserved source density; and
7. the strong-field FCC-to-SC live-boundary dynamics have not yet become dominant.

The formulas

$$P_{\mathrm{GW}} = \frac{32}{5}\frac{G^4\mu^2M^3}{c_{\mathrm{E}}^5 r^5}, \qquad \text{and} \qquad \dot{f} = \frac{96}{5}\pi^{8/3}\frac{(G\mathcal{M})^{5/3}}{c_{\mathrm{E}}^5} f^{11/3} \tag{N.267}$$

are therefore the leading weak-field circular-binary limit of the TFT tensor sector.

They do not by themselves describe the nonlinear merger, FCC-to-SC phase conversion, evolving saturation boundary, or ringdown spectrum. Completing those regimes requires deriving the effective quadrupole and its higher-order corrections directly from the evolving microscopic live-boundary variables.

The next section uses the independently derived spectral response, quadrupole strain, energy flux, and chirp relation to evaluate GW150914 as an observational consistency check rather than as a calibration input.

N.11 GW150914 as an Observational Consistency Check

The preceding sections determine the gravity-neutral tensor-gradient normalization, spectral response, far-zone quadrupole strain, tensor-energy flux, total quadrupole luminosity, and leading circular-binary chirp relation without using a gravitational-wave event to define any constitutive

coefficient. GW150914 may therefore be used as an observational consistency check rather than as a calibration of the State-I vacuum.

The logical direction of the comparison is

$$\{c_{\mathrm{E}}, G, r_{\mathrm{D}}, \ell_{\mathrm{S}}, f\} \longrightarrow \left\{K_{\mathrm{GW}}^{(\mathrm{eff})}, \rho_{\mathrm{GW}}^{(\mathrm{eff})}, Z_{\mathrm{GW}}^{(\mathrm{eff})}, \zeta_{\mathrm{GW}}\right\} \longrightarrow \text{event-band comparison.} \tag{N.268}$$

It is not

$$\text{event strain and inferred flux} \longrightarrow \text{definition of the vacuum response.} \tag{N.269}$$

The event therefore tests the scale and leading form of quantities derived independently from the TFT tensor action. It does not define those quantities.

N.11.1 Representative Event-Band Spectral Response

Consider the representative gravitational-wave frequency $f_{\mathrm{ref}} = 150\,\mathrm{Hz}$. This value is used as a representative frequency within the event band. It is not interpreted as a unique monochromatic frequency of the complete transient waveform.

The corresponding angular frequency and gravity-neutral wave number are $\omega_{\mathrm{ref}} = 2\pi f_{\mathrm{ref}}$, and $k_{\mathrm{ref}} = 2\pi f_{\mathrm{ref}}/c_{\mathrm{E}} \simeq 3.14 \times 10^{-6}\,\mathrm{m}^{-1}$.

Section N.7 gives the frequency-domain spectral coefficients:

$$K_{\mathrm{GW}}^{(\mathrm{eff})}(f) = \frac{\pi c_{\mathrm{E}}^2 f^2}{4G}, \tag{N.270}$$

$$\rho_{\mathrm{GW}}^{(\mathrm{eff})}(f) = \frac{\pi f^2}{4G}, \tag{N.271}$$

$$Z_{\mathrm{GW}}^{(\mathrm{eff})}(f) = \frac{\pi c_{\mathrm{E}} f^2}{4G}. \tag{N.272}$$

The microscopic-to-collective response ratio is

$$\zeta_{\mathrm{GW}}(f) = \frac{1}{\sqrt{2}} \left(\frac{r_{\mathrm{D}}}{\ell_{\mathrm{S}}}\right)^2 \left(\frac{f r_{\mathrm{D}}}{c_{\mathrm{E}}}\right)^2. \tag{N.273}$$

Using $r_{\mathrm{D}} \simeq 7.45 \times 10^{-27}\,\mathrm{m}$ and $\ell_{\mathrm{S}} \simeq 1.6163 \times 10^{-35}\,\mathrm{m}$, the resulting representative values are summarized in Table N.1.

Table N.1: Derived State-I tensor-response quantities at the representative frequency $f_{\mathrm{ref}} = 150\,\mathrm{Hz}$. The values follow from the independently normalized TFT tensor-gradient action and are not fitted to GW150914.

Quantity	**Derived expression**	**Representative value**
k_{ref}	$2\pi f_{\mathrm{ref}}/c_{\mathrm{E}}$	$3.14 \times 10^{-6}\,\mathrm{m}^{-1}$
$K_{\mathrm{GW}}^{(\mathrm{eff})}$	$\pi c_{\mathrm{E}}^2 f_{\mathrm{ref}}^2/(4G)$	$2.38 \times 10^{31}\,\mathrm{Pa}$
$\rho_{\mathrm{GW}}^{(\mathrm{eff})}$	$\pi f_{\mathrm{ref}}^2/(4G)$	$2.65 \times 10^{14}\,\mathrm{kg\,m^{-3}}$
$Z_{\mathrm{GW}}^{(\mathrm{eff})}$	$\pi c_{\mathrm{E}} f_{\mathrm{ref}}^2/(4G)$	$7.94 \times 10^{22}\,\mathrm{kg\,m^{-2}\,s^{-1}}$
ζ_{GW}	Equation (N.273)	2.1×10^{-48}

For the established microscopic affine scaffold scale $K_{\mathrm{sh}}^{(\mathrm{micro},0)} \simeq 1.14 \times 10^{79}\,\mathrm{Pa}$, the same hierarchy is recovered directly:

$$\frac{K_{\mathrm{GW}}^{(\mathrm{eff})}\,(f_{\mathrm{ref}})}{K_{\mathrm{sh}}^{(\mathrm{micro},0)}} \simeq 2.1 \times 10^{-48}. \tag{N.274}$$

The large pressure- and density-dimensioned quantities in Table N.1 are not universal equilibrium properties of the vacuum. They are spectral equivalents of the force-dimensioned tensor-gradient action evaluated at the selected frequency.

The extremely small value of ζ_{GW} does not imply that only a corresponding fraction of the FCC scaffold physically exists or participates in the wave. It measures the ratio between the pressure-equivalent response of a long-wavelength collective tensor-gradient mode and the local affine primitive-cell scaffold response.

N.11.2 Representative Strain–Flux Scale

For a locally monochromatic tensor wave, define the total peak polarization amplitude by

$$h_{\mathrm{eff}}^2 \equiv \left(h_+^{(0)}\right)^2 + \left(h_\times^{(0)}\right)^2. \tag{N.275}$$

Section N.9 gives the cycle-averaged intensity

$$\langle I_{\mathrm{GW}} \rangle = \frac{1}{2} K_{\mathrm{GW}}^{(\mathrm{eff})}(f) c_{\mathrm{E}} h_{\mathrm{eff}}^2. \tag{N.276}$$

For the representative total polarization amplitude $h_{\mathrm{eff}} = 10^{-21}$ at $f = 150\,\mathrm{Hz}$, the independently derived tensor response gives

$$\langle I_{\mathrm{GW}} \rangle_{\mathrm{ref}} \simeq 3.57 \times 10^{-3}\,\mathrm{W\,m^{-2}}. \tag{N.277}$$

This value establishes a representative terrestrial flux scale associated with a total polarization amplitude of order 10^{-21} in the selected frequency band. It is not a direct reconstruction of GW150914 because an interferometer measures the detector-projected strain

$$h_{\mathrm{det}}(t) = F_+ h_+(t) + F_\times h_\times(t), \tag{N.278}$$

where F_+ and $F_\times$ are antenna-response factors determined by the source direction, detector orientation, and polarization basis.

In general, $h_{\mathrm{det}} \neq h_{\mathrm{eff}}$. A detector-level strain–flux comparison must additionally include the source inclination, the relative polarization phase, the time-dependent waveform amplitude, the luminosity-distance inference, and the distinction among instantaneous, cycle-averaged, and band-integrated flux.

Equation (N.277) is therefore an order-of-magnitude constitutive check rather than a substitute for a full detector-response analysis.

N.11.3 Relation to the Earlier Event-Derived Estimate

An earlier event-based estimate used during the development of this appendix adopted the representative flux proxy $I_{\mathrm{proxy}} \simeq 1.41 \times 10^{-3}\,\mathrm{W\,m^{-2}}$, together with $h_{\mathrm{rep}} \simeq 10^{-21}$, and the monochromatic relation $I = \frac{1}{2} K_{\mathrm{GW}}^{(\mathrm{eff})} c_{\mathrm{E}} h^2$. Solving for the pressure-equivalent coefficient gave

$$K_{\mathrm{GW}}^{(\mathrm{event})} = \frac{2 I_{\mathrm{proxy}}}{c_{\mathrm{E}} h_{\mathrm{rep}}^2} \simeq 9.4 \times 10^{30}\,\mathrm{Pa}. \tag{N.279}$$

The independently derived spectral value at the representative frequency is $K_{\mathrm{GW}}^{(\mathrm{eff})}(150\,\mathrm{Hz}) \simeq 2.38 \times 10^{31}\,\mathrm{Pa}$. Their ratio is

$$\frac{K_{\mathrm{GW}}^{(\mathrm{eff})}(150\,\mathrm{Hz})}{K_{\mathrm{GW}}^{(\mathrm{event})}} \simeq 2.53. \tag{N.280}$$

The two estimates therefore occupy the same order of magnitude: $K_{\mathrm{GW}}^{(\mathrm{eff})} \sim 10^{31}\,\mathrm{Pa}$. The remaining numerical difference is not diagnostically significant because the earlier construction combined a detector-projected strain, a representative event frequency, and an inferred flux proxy as though they were the total polarization amplitude, monochromatic frequency, and cycle-averaged intensity of one matched Fourier component.

Those quantities are not generally equivalent. In particular, the detector strain is filtered through Equation (N.278), whereas the flux proxy is inferred from a source luminosity and distance model rather than measured independently as a local tensor-energy flux.

The value $K_{\mathrm{GW}}^{(\mathrm{event})} \simeq 9.4 \times 10^{30}\,\mathrm{Pa}$ is therefore retained only as a retrospective order-of-magnitude comparison. It no longer defines $K_{\mathrm{GW}}^{(\mathrm{eff})}$.

N.11.4 Consistency of the Leading Chirp Structure

Section N.10 derives the leading weak-field frequency evolution

$$\dot{f} = \frac{96}{5}\pi^{8/3}\frac{(G\mathcal{M})^{5/3}}{c_{\mathrm{E}}^{5}} f^{11/3}. \tag{N.281}$$

The relation predicts $\dot{f} > 0$ for a bound circular binary that loses positive mechanical energy through the outgoing tensor field.

Equation (N.281) may be inverted to infer the chirp mass from a weak-field frequency track:

$$\mathcal{M}_{\mathrm{chirp}} = \frac{1}{G}\left[\frac{5}{96}\pi^{-8/3} c_{\mathrm{E}}^{5}\dot{f} f^{-11/3}\right]^{3/5}. \tag{N.282}$$

Within the leading adiabatic regime, a consistent compact-binary inspiral should yield an approximately constant value of $\mathcal{M}$ when Equation (N.282) is evaluated over the weak-field portion of the waveform.

The rising-frequency character of GW150914 is compatible with the mechanical sequence:

$$P_{\mathrm{GW}} > 0 \longrightarrow \dot{E}_{\mathrm{orb}} < 0 \longrightarrow \dot{r} < 0 \longrightarrow \dot{f} > 0. \tag{N.283}$$

A numerical reconstruction of the event parameters requires the detector data, waveform conditioning, source orientation, cosmological redshift treatment, and higher-order orbital and strong-field corrections. The present comparison is restricted to the leading functional structure

$$\dot{f} \propto \mathcal{M}^{5/3} f^{11/3}. \tag{N.284}$$

N.11.5 Observational Status and Limits

The comparison with GW150914 supports a limited consistency statement. The independently normalized TFT tensor sector produces:

1. a positive far-zone tensor-energy flux;

2. a representative strain–flux scale compatible in order of magnitude with a compact-binary event in the selected frequency band; and

3. the leading circular-binary dependence $\dot{f} \propto \mathcal{M}^{5/3} f^{11/3}$.

The event does not directly measure $K_{\mathrm{GW}}^{(\mathrm{eff})}$, $\rho_{\mathrm{GW}}^{(\mathrm{eff})}$, $Z_{\mathrm{GW}}^{(\mathrm{eff})}$, or ζ_{GW}. These are TFT spectral representations derived from the normalized tensor-gradient action and evaluated using the representative event-band frequency.

The comparison also does not independently establish the microscopic FCC bond-dyad origin of the tensor basis, the directional-transfer interpretation of $\mathsf{H}_{ij}^{(\mathrm{GW})}$, the complete finite-wave-number FCC tensor eigenbranch, the loaded-background endpoint inheritance, the Hard-Floor record mechanism, the microscopic live-boundary map to Q_{ij}, or the nonlinear merger and ringdown dynamics.

The defensible conclusion is therefore

$$\begin{gathered}\text{the independently derived TFT tensor response is consistent} \\ \text{in representative scale and leading inspiral form with GW150914}.\end{gathered} \tag{N.285}$$

The event is not used to prove the microscopic FCC mechanism, and the proposed microscopic mechanism is not presented as a complete detector-level reanalysis of the event.

The following section closes the appendix by separating static gravitational loading from dynamic tensor radiation, consolidating the roles of the Soft Floor, interstitial condensate, Hard Floor, and Tension-Column architecture, and stating the remaining microscopic and strong-field completion requirements once.

N.12 Sector Synthesis, Scope, and Conclusion

The preceding sections establish static gravitational loading and gravitational radiation as distinct dynamical sectors of the same active State-I mechanical architecture. They share the FCC Soft-Floor carrier, the interstitial-condensate constraint, the structural force scale F_{S}, and the weak-field source normalization. They are not, however, the same constitutive coordinate.

Static gravity is an equilibrated scalar loading of the active vacuum. Gravitational radiation is a propagating transverse-traceless redistribution of directional transfer within that vacuum. Their separation follows from the directional-tensor decomposition introduced in Section N.4.

N.12.1 Scalar and Tensor Directional Sectors

The six FCC directional-transfer amplitudes decompose as $\lambda_a = \overline{\lambda} + \lambda_a^{\circ}$, where $\overline{\lambda} = \frac{1}{6}\sum_{a=1}^{6} \lambda_a$ and $\sum_{a=1}^{6} \lambda_a^{\circ} = 0$.

The corresponding directional-transfer tensor is $\mathsf{A}_{ij} = \sum_{a=1}^{6} \lambda_a (\mathbf{P}_a)_{ij}$. Using the identity $\sum_{a=1}^{6} \mathbf{P}_a = 2\mathbf{I}$, one obtains

$$\mathsf{A}_{ij} = 2\overline{\lambda}\,\delta_{ij} + \mathsf{A}_{ij}^{\circ}, \tag{N.286}$$

where $\mathsf{A}_{ij}^{\circ} = \sum_{a=1}^{6} \lambda_a^{\circ} (\mathbf{P}_a)_{ij}$ and $\mathsf{A}_{ii}^{\circ} = 0$.

The scalar term $2\overline{\lambda}\,\delta_{ij}$ changes the common directional loading and therefore belongs to the isotropic structural sector. The trace-free term A_{ij}° redistributes directional transfer while preserving the first-order scalar capacity.

For a selected propagation direction $\mathbf{s}$, the radiative tensor is

$$\mathsf{H}_{ij}^{(\mathrm{GW})} = \Lambda_{ij,kl}^{(\mathrm{TT})}(\mathbf{s}) \mathsf{A}_{kl}^{\circ}. \tag{N.287}$$

It satisfies

$$\mathsf{H}_{ij}^{(\mathrm{GW})} = \mathsf{H}_{ji}^{(\mathrm{GW})}, \qquad s^i \mathsf{H}_{ij}^{(\mathrm{GW})} = 0, \qquad \mathsf{H}_{ii}^{(\mathrm{GW})} = 0. \tag{N.288}$$

The structural distinction may therefore be summarized as:

- **static gravitational loading** $\longleftrightarrow$ scalar directional sector
- **gravitational radiation** $\longleftrightarrow$ transverse-traceless directional redistribution

N.12.2 Static Restorative Gravity

The static gravitational sector is described by the specific tension potential $\Phi_\tau(\mathbf{x})$, which satisfies the weak-field source equation

$$\nabla^2 \Phi_\tau = 4\pi G \rho. \tag{N.289}$$

The corresponding dimensionless structural loading is

$$\alpha_{\mathrm{G}} = -\frac{\Phi_\tau}{c_{\mathrm{E}}^2}. \tag{N.290}$$

For an isolated point source, $\alpha_{\mathrm{G}}(R) = GM/(Rc_{\mathrm{E}}^2)$.

The static configuration is an equilibrated restorative state. It determines the local loading, propagation capacity, and effective optical response of the active State-I medium. In the endpoint-transfer construction of Appendix J, the corresponding completed local propagation capacity is

$$c_{\mathrm{P}}(\mathbf{x}) = c_{\mathrm{E}} \left[1 - \alpha_{\mathrm{G}}(\mathbf{x})\right]^2. \tag{N.291}$$

A static gravitational configuration may be nonzero without containing an outgoing gravitational wave: $\alpha_{\mathrm{G}} \neq 0$ and $\mathsf{H}_{ij}^{(\mathrm{GW})} = 0$. A time-independent monopole field therefore represents an equilibrated structural loading rather than a radiative tensor state.

N.12.3 Dynamic Tensor Radiation

The radiative sector is governed by the normalized collective equation

$$\frac{1}{c_{\mathrm{E}}^2} \ddot{\mathsf{H}}_{ij}^{(\mathrm{GW})} - \nabla^2 \mathsf{H}_{ij}^{(\mathrm{GW})} = \frac{8\pi G}{c_{\mathrm{E}}^4} T_{ij}^{(\mathrm{TT})}. \tag{N.292}$$

The source term is the transverse-traceless projection of the localized mechanical momentum-flux tensor. Once the tensor state leaves the source region, $T_{ij}^{(\mathrm{TT})} = 0$, and the propagation equation becomes

$$\frac{1}{c_{\mathrm{E}}^2} \ddot{\mathsf{H}}_{ij}^{(\mathrm{GW})} - \nabla^2 \mathsf{H}_{ij}^{(\mathrm{GW})} = 0. \tag{N.293}$$

The factor 8π fixes the source-to-tensor normalization. It is not an additional free-propagation geometry or a local impedance inserted throughout the exterior medium.

A gravitational wave may propagate through a locally gravity-neutral State-I region: $\alpha_{\mathrm{G}} = 0$ and $\mathsf{H}_{ij}^{(\mathrm{GW})} \neq 0$. The absence of static background loading does not remove the dynamic directional-tension perturbation.

Conversely, a nonzero static field does not automatically radiate. Radiation requires a time-dependent transverse-traceless source moment. At leading weak-field order,

$$h_{ij}^{(\mathrm{TT})}(\mathbf{x}, t) = \frac{2G}{c_{\mathrm{E}}^4 R} \Lambda_{ij,kl}(\mathbf{n}) \ddot{Q}_{kl} \left(t - \frac{R}{c_{\mathrm{E}}} \right), \tag{N.294}$$

so a time-independent source quadrupole produces no outgoing tensor wave.

N.12.4 Mechanical Roles of the Dual-Phase Architecture

The gravitational-wave construction assigns distinct mechanical roles to the components of the TFT vacuum architecture.

FCC Soft Floor

The FCC Soft Floor supplies the nearest-neighbor directional geometry, the local transverse scaffold carrier, the bond-dyad basis of the two tensor polarizations, the cell-centered directional-transfer coordinate, and the finite-speed tensor-gradient dynamics.

The two polarization bases arise from the six undirected FCC nearest-neighbor dyads:

$$\mathbf{E}_\times = \mathbf{P}_1 - \mathbf{P}_2, \qquad \text{and} \qquad \mathbf{E}_+ = \mathbf{P}_3 + \mathbf{P}_4 - \mathbf{P}_5 - \mathbf{P}_6. \tag{N.295}$$

The finite radiative energy resides in the active State-I carrier through the conjugate terms $\dot{\mathsf{H}}_{ij}\dot{\mathsf{H}}_{ij}$ and $\partial_k \mathsf{H}_{ij}\partial_k \mathsf{H}_{ij}$. The radiative coordinate is therefore a collective directional-transfer tensor rather than an ordinary affine deformation of the FCC scaffold.

Interstitial Condensate

The interstitial condensate supplies the coherent incremental volume constraint developed in Appendix E. For the selected conservative carrier, $\mathbf{v}_{\rm rel} = \mathbf{0}$ and $\nabla \cdot \mathbf{u} = 0$. The condensate is therefore entrained with the scaffold at the retained order and enforces the coherent incompressible branch. It is not assigned an independently additive tensor inertia after the primitive-cell carrier has already been normalized.

Hard Floor

The phase-locked Hard Floor supplies the structural reference and record of the completed State-I configuration. It is not assigned an independently propagating tensor stiffness or tensor inertia.

A fixed local Hard-Floor restoring term proportional to $\mathsf{H}_{ij}\mathsf{H}_{ij}$ would create a finite zero-wavenumber frequency and would therefore gap the selected radiative branch. Such a term is excluded from the leading long-wavelength gravitational-wave action.

Accordingly:

- **Hard Floor** = phase-locked reference and record.
- **Soft Floor** = finite-energy propagating carrier.

Tension-Column Architecture

The Tension-Column structure connects the active Soft-Floor state to the phase-locked structural reference and supplies the cross-floor transfer architecture used elsewhere in TFT.

In the present appendix, it supports the completed static endpoint-transfer response and provides the structural path through which the directional State-I configuration is referenced and recorded.

The full derivation of the collective rank-two directional-transfer action directly from the microscopic Tension-Column and contact variables remains open. The tensor-gradient action used here is the minimal long-wavelength closure consistent with gaplessness, FCC isotropy, source normalization, and the weak-field radiative sector.

N.12.5 Microscopic, Collective, and Spectral Coefficients

The appendix introduces several related but noninterchangeable mechanical quantities.

The microscopic interface pair is

$$\tau_{\mathrm{D}} = \frac{c_{\mathrm{E}}^4}{G r_{\mathrm{D}}}, \qquad \mu_{\mathrm{D}} = \frac{c_{\mathrm{E}}^2}{G r_{\mathrm{D}}}. \tag{N.296}$$

Their dimensions are $[\tau_{\mathrm{D}}] = \mathrm{N\,m^{-1}}$ and $[\mu_{\mathrm{D}}] = \mathrm{kg\,m^{-2}}$.

The primitive-cell affine coefficients are

$$K_{\mathrm{sh}}^{(\mathrm{micro},0)} = \beta_{\mathrm{geo}} \rho_{\mathrm{D}} c_{\mathrm{E}}^2, \qquad \rho_{\mathrm{sh}}^{(\mathrm{micro},0)} = \beta_{\mathrm{geo}} \rho_{\mathrm{D}}. \tag{N.297}$$

Their dimensions are $[K_{\mathrm{sh}}^{(\mathrm{micro},0)}] = \mathrm{Pa}$ and $[\rho_{\mathrm{sh}}^{(\mathrm{micro},0)}] = \mathrm{kg\,m^{-3}}$.

The collective tensor-gradient pair is

$$\mathcal{T}_{\mathrm{TT}}^{(0)} = \frac{c_{\mathrm{E}}^4}{8\pi G}, \qquad M_{\mathrm{TT}}^{(0)} = \frac{c_{\mathrm{E}}^2}{8\pi G}. \tag{N.298}$$

Their dimensions are $[\mathcal{T}_{\mathrm{TT}}^{(0)}] = \mathrm{N}$ and $[M_{\mathrm{TT}}^{(0)}] = \mathrm{kg\,m^{-1}}$. Their ratio gives $\mathcal{T}_{\mathrm{TT}}^{(0)} / M_{\mathrm{TT}}^{(0)} = c_{\mathrm{E}}^2$.

The gravity-neutral collective action is

$$S_{\mathrm{TT}}^{(2)} = \frac{\mathcal{T}_{\mathrm{TT}}^{(0)}}{2} \int \left[\frac{1}{c_{\mathrm{E}}^2} \dot{\mathsf{H}}_{ij} \dot{\mathsf{H}}_{ij} - \partial_k \mathsf{H}_{ij} \partial_k \mathsf{H}_{ij} \right] d^3x\, dt. \tag{N.299}$$

The pressure-equivalent Fourier-mode coefficients are

$$K_{\mathrm{GW}}^{(\mathrm{eff})}(k) = \frac{c_{\mathrm{E}}^4 k^2}{16\pi G}, \qquad \rho_{\mathrm{GW}}^{(\mathrm{eff})}(k) = \frac{c_{\mathrm{E}}^2 k^2}{16\pi G}, \qquad Z_{\mathrm{GW}}^{(\mathrm{eff})}(k) = \frac{c_{\mathrm{E}}^3 k^2}{16\pi G}. \tag{N.300}$$

The corresponding microscopic-to-collective response ratio is

$$\zeta_{\mathrm{GW}}(k) = \frac{\sqrt{2}}{8\pi^2} \left(\frac{r_{\mathrm{D}}}{\ell_{\mathrm{S}}} \right)^2 (k r_{\mathrm{D}})^2 . \tag{N.301}$$

The constitutive hierarchy is therefore

$$\{\tau_{\mathrm{D}}, \mu_{\mathrm{D}}\} \longrightarrow \left\{ K_{\mathrm{sh}}^{(\mathrm{micro},0)}, \rho_{\mathrm{sh}}^{(\mathrm{micro},0)} \right\} \longrightarrow \left\{ \mathcal{T}_{\mathrm{TT}}^{(0)}, M_{\mathrm{TT}}^{(0)} \right\} \longrightarrow \left\{ K_{\mathrm{GW}}^{(\mathrm{eff})}(k), \rho_{\mathrm{GW}}^{(\mathrm{eff})}(k), Z_{\mathrm{GW}}^{(\mathrm{eff})}(k) \right\}. \tag{N.302}$$

No member of this sequence should be substituted for another solely because their ratios reproduce the same propagation speed.

N.12.6 Closed Long-Wavelength Relations

The central long-wavelength relations obtained in this appendix may be collected without repeating their derivations.

The absolute source normalization is $\kappa_{\mathrm{TT}} = 8\pi$, which fixes $\mathcal{T}_{\mathrm{TT}}^{(0)} = c_{\mathrm{E}}^4/(8\pi G)$.

The source-free gravity-neutral dispersion is $\omega^2 = c_{\mathrm{E}}^2 k^2$.

For a localized conserved source, the far-zone strain is

$$h_{ij}^{(\mathrm{TT})}(\mathbf{x}, t) = \frac{2G}{c_{\mathrm{E}}^4 R} \Lambda_{ij,kl}(\mathbf{n}) \ddot{Q}_{kl} \left(t - \frac{R}{c_{\mathrm{E}}} \right). \tag{N.303}$$

The corresponding cycle-averaged intensity is

$$\langle I_{\mathrm{GW}} \rangle = \frac{c_{\mathrm{E}}^3}{32\pi G} \left\langle \dot{h}_{ij}^{(\mathrm{TT})} \dot{h}_{ij}^{(\mathrm{TT})} \right\rangle . \tag{N.304}$$

Complete angular TT projection gives the total quadrupole luminosity

$$P_{\mathrm{GW}} = \frac{G}{5c_{\mathrm{E}}^5} \left\langle \dddot{Q}_{ij} \dddot{Q}_{ij} \right\rangle . \tag{N.305}$$

For a weak-field circular binary, $P_{\mathrm{GW}} = \frac{32}{5} \frac{G^4 \mu^2 M^3}{c_{\mathrm{E}}^5 r^5}$, and the leading chirp relation is

$$\dot{f} = \frac{96}{5} \pi^{8/3} \frac{(G\mathcal{M})^{5/3}}{c_{\mathrm{E}}^5} f^{11/3}. \tag{N.306}$$

These relations follow from the FCC directional basis, the collective tensor-gradient action, the independently fixed static-to-tensor normalization, source conservation, and conservative weak-field orbital binding. No gravitational-wave event is used to determine the vacuum coefficient.

N.12.7 Status of the Loaded-Background Propagation Law

For the gravity-neutral collective branch, $c_{\mathrm{GW}} = c_{\mathrm{E}}$.

Conditional on the collective transverse-traceless coordinate inheriting the same completed endpoint-transfer Jacobian as the coherent State-I carrier, Section N.5 gives

$$c_{\mathrm{GW}}(\mathbf{x}) = c_{\mathrm{E}} \left[1 - \alpha_{\mathrm{G}}(\mathbf{x})\right]^2 . \tag{N.307}$$

This relation is consistent with the endpoint-transfer architecture but remains a constitutive inheritance condition rather than a separately derived eigenvalue of the complete rank-two microscopic parent system.

A complete derivation must show that the directional-tension tensor coordinate acquires the referred inertia

$$M_{\mathrm{TT}}(\alpha_{\mathrm{G}}) = \frac{M_{\mathrm{TT}}^{(0)}}{(1 - \alpha_{\mathrm{G}})^4}, \tag{N.308}$$

while retaining the corresponding local tensor-gradient normalization at the retained order.

Until that parent-action derivation is completed, Equation (N.307) should be interpreted as the selected loaded-background closure rather than as an independently closed microscopic theorem.

N.12.8 Falsifiable Long-Wavelength Consequences

The long-wavelength construction produces several consequences that may be tested independently of the unresolved microscopic completion.

The pressure-equivalent response satisfies $K_{\mathrm{GW}}^{(\mathrm{eff})} \propto f^2$. The equivalent continuum inertia and impedance obey the same quadratic spectral scaling:

$$\rho_{\mathrm{GW}}^{(\mathrm{eff})} \propto f^2, \qquad Z_{\mathrm{GW}}^{(\mathrm{eff})} \propto f^2. \tag{N.309}$$

The microscopic-to-collective response ratio also satisfies $\zeta_{\mathrm{GW}} \propto f^2$, and is therefore not a frequency-independent participation constant.

The weak-field radiative sector contains two degenerate tensor polarizations constructed from the FCC bond-dyad basis. Source conservation excludes leading monopole and dipole tensor radiation, leaving the quadrupole as the first nontrivial radiative source moment.

Under the loaded-background endpoint-inheritance closure, $c_{\mathrm{GW}} = c_{\mathrm{E}}\,(1-\alpha_{\mathrm{G}})^2$. A direct microscopic derivation or observational failure of this relation would test the proposed connection between static loading and dynamic tensor propagation.

N.12.9 Remaining Microscopic and Strong-Field Completion

The leading weak-field, long-wavelength exterior sector is closed at the level developed in this appendix. The remaining completion requirements concern the microscopic origin of the collective action, its finite-wave-number extension, and the nonlinear strong-field source.

Full Parent Directional-Tension Action

The tensor-gradient action must ultimately be derived by integrating out or projecting the complete microscopic FCC contact, rotational, phase, condensate, and Tension-Column variables. That derivation must identify the microscopic work-conjugate coordinate corresponding to λ_a°, and show explicitly how $\mathcal{T}_{\mathrm{TT}}^{(0)} = c_{\mathrm{E}}^4/(8\pi G)$ emerges from the parent action.

Complete Finite-Wave-Number Eigenbranch

Section N.5 derives the exact dispersion of the minimal collective link closure. The complete first-Brillouin-zone spectrum of the full FCC parent system remains to be calculated. That analysis must determine:

1. whether the long-wavelength TT branch remains isolated from the phase, rotational, and relative-flow branches;
2. the leading cubic-anisotropy corrections beyond the isotropic k^2 limit;
3. the locations of avoided crossings or mode conversions;
4. the ultraviolet termination or transition of the collective tensor branch; and
5. the relation between the collective cell-centered tensor and the microscopic nodal eigenvectors.

Loaded-Background Tensor Inheritance

The relation $c_{\mathrm{GW}} = c_{\mathrm{E}}\,(1-\alpha_{\mathrm{G}})^2$ must be derived directly for the rank-two collective coordinate rather than inherited by constitutive analogy from the coherent carrier. This requires establishing the loaded-background transformation of both M_{TT} and $\mathcal{T}_{\mathrm{TT}}$ from the complete directional-transfer Jacobian.

Microscopic Source-to-Quadrupole Map

The weak-field exterior field depends on the effective STF source quadrupole Q_{ij}. For compact strong-field objects in TFT, the source is an evolving FCC/SC live boundary rather than an abstract point singularity. The remaining source problem is therefore:

$$\text{FCC/SC live-boundary variables} \longrightarrow T_{ij}^{(\mathrm{src})} \longrightarrow Q_{ij}. \tag{N.310}$$

This map must incorporate the evolving phase-boundary shape, boundary tension and rotational loading, redistribution of State-I directional capacity, Tension-Column transfer at the moving boundary, strong-field retardation across the source, nonlinear multipole corrections, and the transition from inspiral to merger and ringdown.

Merger and Ringdown

The leading chirp relation applies only while the binary remains weak-field and adiabatic. Merger and ringdown require the eigenmodes of the final saturated or partially saturated FCC/SC structure. A complete TFT ringdown calculation must derive the frequencies, damping rates, and polarization content from the mechanical relaxation spectrum of the final live-boundary configuration. These quantities are not determined by the exterior quadrupole law alone.

N.12.10 Conclusion

Static gravity and gravitational radiation are neither unrelated phenomena nor identical field configurations. They are complementary scalar and tensor sectors of the same active State-I mechanical substrate:

- **static gravity** = equilibrated scalar restorative loading
- **gravitational radiation** = propagating transverse-traceless directional-tension redistribution

The FCC Soft Floor supplies the active carrier and directional geometry. The interstitial condensate enforces the coherent incremental constraint. The Hard Floor supplies the phase-locked reference and record. The Tension-Column architecture supplies the cross-floor transfer structure and the static endpoint-response framework.

Within the stated weak-field and long-wavelength domain, the appendix establishes a mechanically normalized progression from FCC directional geometry to a gapless collective tensor field, a conserved positive energy flux, the far-zone quadrupole strain, the total quadrupole luminosity, and the leading compact-binary chirp.

The remaining work is confined to deriving the collective tensor sector from the complete microscopic parent action, extending it through the full finite-wave-number spectrum, closing the loaded-background tensor inheritance, and constructing the nonlinear live-boundary source dynamics required for merger and ringdown.

Appendix P

The Topological Projection Operator and the Mechanical Origin of 8π

Abstract: In standard General Relativity, the coupling constant $\kappa = 8\pi$ is derived algebraically to ensure the tensor equations reduce to Newtonian gravity in the weak-field limit. However, a pure geometric shape with an 8π solid angle is impossible to visualize in 3D space, leaving the constant without a direct physical ontology. Tension Field Theory (TFT) resolves this by reframing the metric tensor not as curved empty geometry, but as the Cauchy stress tensor of a continuous solid. We demonstrate that 8π is not a mathematical artifact, but the exact geometric footprint of Newton's Third Law applied to a continuous phase boundary in absolute static equilibrium, verified by both structural statics and thermodynamic boundary expansion.

P.1 The Topological Projection Operator (κ)

Because TFT dictates that inertial mass physically transitions from a 3D volumetric distribution to a 2D holographic surface defect upon saturation, the parameter κ acts as a Topological Projection Operator. It adapts the dimensionless geometric factor to the specific spatial domain of the interaction:

- **Volumetric Projection ($\kappa = \frac{4\pi}{3}$):** Used for calculating the 3D interior mass distribution of pre-collapse localized matter on the Soft Floor.
- **Areal/Boundary Projection ($\kappa = 4\pi$):** Used for calculating the 2D surface mass segregation at the Event Horizon boundary limit.
- **Tensor Field Projection ($\kappa = 8\pi$):** Used for projecting the scalar strain into the relativistic metric tensor ($G_{\mu\nu}$). Mechanically, this operator encodes the absolute bi-directional stress equilibrium of the continuous lattice. Because lattice tension is restorative in all directions, defining the complete state of stress at any coordinate requires summing the geometric projection of the tension pulling from the outside-in (4π) and the equal-and-opposite tension pulling from the inside-out (4π).

P.2 The Historical Derivation (The Algebraic Artifact)

To understand why 8π exists in standard physics, we must review how Einstein derived it. Einstein required his tensor equation ($G_{\mu\nu} = \kappa T_{\mu\nu}$) to perfectly match Poisson's equation for Newtonian

scalar gravity ($\nabla^2\Phi_{\mathrm{N}} = 4\pi G\rho$) in the weak-field, non-relativistic limit.

- **The Metric Perturbation:** In a weak field, the temporal component of the metric deviates slightly from flat space: $g_{00} \approx -\left(1 + \frac{2\Phi_{\mathrm{N}}}{c_{\mathrm{E}}^2}\right)$.
- **The Ricci Tensor:** The corresponding curvature component simplifies to the Laplacian of the potential: $R_{00} \approx \frac{1}{c_{\mathrm{E}}^2}\nabla^2\Phi_{\mathrm{N}}$.
- **The Stress-Energy Tensor:** For a static dust fluid, only the rest-mass density matters: $T_{00} \approx \rho c_{\mathrm{E}}^2$.

Einstein substituted these into the trace-reversed field equation ($R_{\mu\nu} = \kappa\left(T_{\mu\nu} - \frac{1}{2}Tg_{\mu\nu}\right)$). Evaluating the 00-component yields the critical factor of $\frac{1}{2}$:

$$R_{00} \approx \frac{1}{2}\kappa\rho c_{\mathrm{E}}^2 \tag{P.1}$$

Equating this to the Newtonian Laplacian ($R_{00} \approx \frac{1}{c_{\mathrm{E}}^2}4\pi G\rho$), the factor of $\frac{1}{2}$ moves to the other side, instantly doubling the geometry:

$$\frac{1}{2}\kappa\rho c_{\mathrm{E}}^2 = \frac{4\pi G\rho}{c_{\mathrm{E}}^2} \quad \Longrightarrow \quad \kappa = \frac{8\pi G}{c_{\mathrm{E}}^4} \tag{P.2}$$

The Problem: The mathematics are flawless, but the physical ontology is empty. The multiplier of 2 is an algebraic necessity born from the trace of a Rank-2 tensor, leaving physicists with a coupling constant (8π) that corresponds to no known single geometric shape in three-dimensional space. To ground this in continuum mechanics, TFT formally maps this abstract Newtonian potential to the specific physical tension potential of the Soft Floor ($\Phi_{\mathrm{N}} \longleftrightarrow \Phi_\tau$) in the weak-field static limit.

P.3 Vectors vs. Tensors in a Continuum

TFT resolves this mystery by moving from abstract geometry to mechanical material science. The discrepancy between 4π and 8π is simply the difference between measuring a Vector field and measuring a Tensor field.

- **The Newtonian Vector (4π):** Poisson's equation describes an acceleration field ($\vec{g}$). A vector is uni-directional. It only measures the flux of lines pointing *inward* toward the center of mass. The total solid angle of a sphere encompassing this inward directional flux is exactly 4π steradians.
- **The TFT Tensor (8π):** General Relativity and TFT utilize a symmetric Rank-2 tensor. In continuum mechanics, a Rank-2 tensor measures *Stress*. Stress is not a vector; it is bi-directional. A physical medium cannot experience stress in only one direction without accelerating.

P.4 Newton's Third Law and the Double-Covering

In Tension Field Theory, the vacuum is a high-tension elastic solid (the Soft Floor). To define the exact state of mechanical equilibrium at any arbitrary infinitesimal point (or across a macroscopic Event Horizon boundary), we must apply Newton's Third Law of Motion: *For every action, there is an equal and opposite reaction.*

- **The Action (4π):** The lattice tension pulls from the outside-in upon the coordinate, attempting to compress it. Projected across 3D space, this structural force consumes a full solid angle of 4π.
- **The Reaction (4π):** To maintain static equilibrium, the coordinate must pull from the inside-out with exact, equal restorative tension against the surrounding lattice. This restorative reaction also projects across a full solid angle of 4π.

Because the Einstein Metric Tensor ($G_{\mu\nu}$) must mathematically encode the absolute, complete state of mechanical stress at that coordinate, it cannot ignore the reaction force. It must geometrically sum the total mechanical transmission across the boundary:

$$\text{Total Topological Stress} = \oint (\text{Outside-In Tension}) + \oint (\text{Inside-Out Tension}) \tag{P.3}$$

$$\kappa = 4\pi + 4\pi = 8\pi \tag{P.4}$$

P.5 Mechanical Horizon Expansion: The 8π Requirement

To prove this topological necessity thermodynamically, we analyze the mechanical work required to expand the physical phase boundary of an Event Horizon. The internal structural work rate pressing outward against the horizon surface must equal the gravitational work required to expand that boundary area.

We relate the Substrate yield tension (τ_{S}) to the change in geometric surface area ($\frac{dA}{dt} = 8\pi R_{\text{QG}} \frac{dR_{\text{QG}}}{dt}$) and the macroscopic surface gravity (g):

Step 1: The Principle of Mechanical Power

For a phase boundary to expand, the rate of internal mechanical work ($\frac{dW_{\text{in}}}{dt}$) done by the core must equal the rate of energy consumed to create new gravitational surface area ($\frac{dE_{\text{out}}}{dt}$).

Step 2: The Internal Work Rate (LHS)

Mechanical power is defined as Force multiplied by Velocity ($P = F \cdot v$).

- The total outward Force is the Substrate Tension (τ_{S}) applied across the entire spherical surface area ($A = 4\pi R_{\text{QG}}^2$). So, $F = 4\pi R_{\text{QG}}^2 \tau_{\text{S}}$.
- The Velocity of the boundary expansion is $\frac{dR_{\text{QG}}}{dt}$.

Therefore, the Left Hand Side (LHS) is:

$$P_{\text{in}} = (4\pi R_{\text{QG}}^2)\tau_{\text{S}} \frac{dR_{\text{QG}}}{dt} \tag{P.5}$$

Step 3: The Boundary Expansion Rate (RHS)

The total gravitational energy of the boundary is mathematically proportional to the surface gravity (g) and the surface area (A). In this framework, the coupling constant that converts geometric area to energy is $\frac{c_{\text{E}}^2}{8\pi G}$.

- Energy of the boundary: $E = \left(\frac{c_{\mathrm{E}}^2}{8\pi G}\right) g \cdot A$
- To find the rate of change, take the derivative with respect to time. The surface area is $A = 4\pi R_{\mathrm{QG}}^2$.
- The derivative of the area is $\frac{dA}{dt} = 8\pi R_{\mathrm{QG}} \frac{dR_{\mathrm{QG}}}{dt}$.

Therefore, the Right Hand Side (RHS) is:

$$\frac{dE_{\mathrm{out}}}{dt} = \left(\frac{c_{\mathrm{E}}^2}{8\pi G}\right) g \left(8\pi R_{\mathrm{QG}} \frac{dR_{\mathrm{QG}}}{dt}\right) \tag{P.6}$$

Step 4: Equating and Simplifying

Set the two rates equal to each other:

$$(4\pi R_{\mathrm{QG}}^2)\tau_{\mathrm{S}} \frac{dR_{\mathrm{QG}}}{dt} = \left(\frac{c_{\mathrm{E}}^2}{8\pi G}\right) g \left(8\pi R_{\mathrm{QG}} \frac{dR_{\mathrm{QG}}}{dt}\right) \tag{P.7}$$

Cancel the common kinematic expansion rate ($\frac{dR_{\mathrm{QG}}}{dt}$) from both sides:

$$(4\pi R_{\mathrm{QG}}^2)\tau_{\mathrm{S}} = \left(\frac{c_{\mathrm{E}}^2}{8\pi G}\right) g(8\pi R_{\mathrm{QG}}) \tag{P.8}$$

The generated 8π from the area derivative perfectly cancels the 8π in the tensor denominator:

$$(4\pi R_{\mathrm{QG}}^2)\tau_{\mathrm{S}} = \frac{c_{\mathrm{E}}^2}{G} g R_{\mathrm{QG}} \tag{P.9}$$

Divide both sides by the core's area ($4\pi R_{\mathrm{QG}}^2$) to isolate τ_{S}:

$$\tau_{\mathrm{S}} = \frac{c_{\mathrm{E}}^2 g R_{\mathrm{QG}}}{G(4\pi R_{\mathrm{QG}}^2)} \tag{P.10}$$

Cancel one R_{QG} from the numerator and denominator to yield the final identity:

$$\tau_{\mathrm{S}} = \frac{c_{\mathrm{E}}^2}{4\pi G R_{\mathrm{QG}}} g \tag{P.11}$$

P.6 The Cosmological Over-Extension (The Friedmann Error)

In standard cosmology, the critical density of the universe is derived by applying the Einstein field equations to the FLRW metric, yielding the Friedmann equation ($\rho_{\mathrm{c}} \propto 3H^2/8\pi G$). Tension Field Theory reveals this to be a geometric over-extension that mathematically halves the calculated closure mass.

- **The Definition of Density:** Mass density ($\rho = M/V$) is a macroscopic, global scalar. It is strictly the total mass (M) divided by the total macroscopic volume (V).
- **The Geometry of Volume:** The observable universe is a three-dimensional sphere. The absolute Euclidean volume of a 3D sphere is bounded strictly by the projection $\kappa = \frac{4\pi}{3}$. It is geometrically impossible for a physical sphere to possess a volume of $\frac{8\pi}{3} R^3$.

- **The GR Error (The Over-Extension):** Standard cosmology takes the Einstein field equations—which were designed to calculate *local differential stress* ($\kappa = 8\pi$)—and applies them to the *global macroscopic volume* of the universe via the FLRW metric. By dragging the 8π bi-directional tensor trace into a global volumetric calculation, the Friedmann equation mathematically double-counts the topological footprint of the space.
- **The Consequence:** Because GR artificially doubles the geometric volume factor in the denominator ($8\pi/3$ instead of $4\pi/3$), it artificially halves the resulting critical density calculation. Consequently, standard cosmology has been underestimating the mass required to close the universe by exactly a factor of 2 since the 1920s. TFT corrects this by restricting the definition of global density strictly to its Euclidean spatial projection ($\kappa = \frac{4\pi}{3}$).

P.7 Conclusion

The 8π coupling constant is not an abstract hyper-dimensional geometry, nor is it merely an algebraic coincidence. It is the exact topological double-covering required to describe a continuous physical medium in perfectly balanced, bi-directional static tension. Furthermore, the mechanical work derivation proves that this 8π tensor formulation is mathematically mandatory to cleanly cancel the geometric expansion rate of a spherical boundary. By proving this, Tension Field Theory grounds the mathematics of General Relativity directly into the classical mechanics of Newton's Third Law.

Appendix Q

Tensorial Cosmological Energy Budget from Continuum Mechanics

Abstract

This appendix derives the tensorial cosmological energy budget of Tension Field Theory from the continuum mechanics of the State-I active vacuum.

The active vacuum consists of an FCC nodal scaffold and a connected interstitial condensate. The nodal scaffold supplies contact stiffness, structural connectivity, and directional tensile stress. The condensate supplies coherent inertial participation, the incremental volume constraint, quasistatic pressure under gravitational loading, and conservative added inertia around localized topological defects. These constituents possess different operational densities and different constitutive responses, but they form one coupled quantum continuum.

The derivation distinguishes the operational quantities

$$\rho_{\mathrm{D}}, \qquad \tau_{\mathrm{D}}, \qquad \rho_{\mathrm{IC}}^{(\mathrm{imp})}, \tag{Q.1}$$

from the structural cosmological quantities

$$\rho_{\mathrm{G}}, \qquad \tau_{\mathrm{G}} = \rho_{\mathrm{G}} c_{\mathrm{E}}^2. \tag{Q.2}$$

The FCC fractions enter through phase-volume averaging of mechanically distinct nodal and interstitial tensors. They do not multiply identical copies of the background metric. Under the uniform TFT structural-capacity closure, the exact FCC geometric fractions become the normalized TFT structural-energy fractions,

$$\Omega_{\mathrm{D}}^{(\mathrm{TFT},0)} = \beta_{\mathrm{geo}}, \qquad \Omega_{\mathrm{IC}}^{(\mathrm{TFT},0)} = \beta_{\mathrm{IC}}. \tag{Q.3}$$

Conversion of part of the nodal structural allocation into localized baryonic defects gives the closed background ledger

$$(\beta_{\mathrm{geo}} - \beta_{\mathrm{b}}) + \beta_{\mathrm{IC}} + \beta_{\mathrm{b}} = 1. \tag{Q.4}$$

The spatial components are determined independently by nodal tension, condensate pressure and momentum transport, and defect stress. The appendix therefore replaces the GR/ΛCDM source-side budget by a phase-resolved continuum-mechanical tensor construction while leaving TFT's non-expanding cosmological kinematics as a separate sector.

Q.1 Purpose, State Domain, and Tensor Conventions

The purpose of this appendix is not merely to rewrite the FCC packing fractions in tensor notation. It is to construct the mechanical source-side energy, momentum, flux, and stress budget required for TFT cosmology.

The three TFT substrate states must remain distinct:

- **State 0: Latent Substrate.** The absolute phase-locked SC reference state. It does not possess the ordinary propagating FCC–condensate degrees of freedom used in this appendix.
- **State I: Active Vacuum.** The dual-phase FCC Soft Floor composed of the nodal scaffold and interstitial condensate. This is the dynamical continuum treated below.
- **State II: Saturated Core.** The phase-locked SC black-hole core reached after local State-I saturation. Its interior and live FCC/SC boundary require separate saturated-phase mechanics.

Accordingly, every continuum tensor derived from the FCC scaffold and interstitial condensate in this appendix is a *State-I Soft-Floor material tensor*. It is not a tensor of the State-0 Latent Substrate and is not analytically continued into the State-II saturated core.

The preferred State-I SGF coordinate is

$$x^0 = c_{\mathrm{E}} t, \tag{Q.5}$$

and the effective measurement signature is taken to be

$$(-,+,+,+). \tag{Q.6}$$

Hatted indices denote components measured in the local orthonormal State-I SGF frame. In that frame,

$$T^{\hat{0}\hat{0}} = T_{\hat{0}\hat{0}} \tag{Q.7}$$

is the mechanical energy density. The manuscript uses positive mechanical tension in the Cauchy-stress convention, so the spatial block of the energy–momentum tensor is

$$T^{\hat{i}\hat{j}} = -\sigma_{ij}. \tag{Q.8}$$

Thus, positive isotropic tensile stress appears as negative pressure in the effective tensor representation.

For the effective Soft-Floor measurement tensor, define

$$g^{(\tau)} \equiv \det\left(g^{(\tau)}_{\mu\nu}\right). \tag{Q.9}$$

The construction below tracks

$$\begin{aligned} &\text{energy density,} && \text{momentum density,} \\ &\text{energy flux,} && \text{normal and shear stress,} \end{aligned} \tag{Q.10}$$

and their redistribution among the nodal, interstitial, and defect sectors.

Three constitutive levels must remain separate.

Structural cosmological level:

$$\rho_{\mathrm{G}}, \qquad \tau_{\mathrm{G}} = \rho_{\mathrm{G}} c_{\mathrm{E}}^2. \tag{Q.11}$$

These characterize the absolute structural capacity assigned to the complete unbroken State-I active vacuum.

Operational nodal level:

$$\rho_{\mathrm{D}}, \qquad \tau_{\mathrm{D}}, \qquad K_{\mathrm{sh}}. \tag{Q.12}$$

These govern the inertia and contact mechanics of the FCC scaffold.

Operational condensate and defect level:

$$\begin{aligned} \rho_{\mathrm{IC}}^{(\mathrm{imp})} &= \mu_{\mathrm{D}} \iota_V^{(\mathrm{def})}, \\ M_{\mathrm{top}} &= \rho_{\mathrm{IC}}^{(\mathrm{imp})} V_{\mathrm{imp}} f_\varphi(\Delta\varphi). \end{aligned} \tag{Q.13}$$

These are mode-resolved quantities associated with a particular defect-induced boundary-value problem. They do not define the structural cosmological energy density of the complete interstitial geometry.

Accordingly,

$$\rho_{\mathrm{G}} \neq \rho_{\mathrm{D}}, \qquad \rho_{\mathrm{G}} \neq \rho_{\mathrm{IC}}^{(\mathrm{imp})}. \tag{Q.14}$$

The structural budget and operational dynamics are constitutively connected but are not numerically identical.

Q.2 Conservative Coherent State-I Continuum

Let $\mathbf{u}(\mathbf{x}, t)$ be the FCC scaffold displacement. The infinitesimal strain tensor is

$$\varepsilon_{ij} = \frac{1}{2} \left(\partial_i u_j + \partial_j u_i \right). \tag{Q.15}$$

The coherent State-I branch is incrementally incompressible:

$$\partial_i u_i = 0. \tag{Q.16}$$

The retained quadratic action for the coherent FCC–condensate continuum is

$$S_{\mathrm{IC}}^{(2)} = \int \left[\frac{1}{2} \rho_{\mathrm{eff}}(\alpha_{\mathrm{G}}) \dot{u}_i \dot{u}_i - K_{\mathrm{sh}} \varepsilon_{ij} \varepsilon_{ij} + \delta p_{\mathrm{IC}}\, \partial_i u_i \right] \mathrm{d}^3x\, \mathrm{d}t. \tag{Q.17}$$

Its incremental stress is

$$\delta\sigma_{ij} = 2K_{\mathrm{sh}} \varepsilon_{ij} - \delta p_{\mathrm{IC}} \delta_{ij}. \tag{Q.18}$$

The equation of motion is

$$\rho_{\mathrm{eff}}(\alpha_{\mathrm{G}}) \ddot{u}_i = \partial_j \delta\sigma_{ij}. \tag{Q.19}$$

The condensate pressure multiplier supplies the incremental volume constraint, while the FCC contact network supplies the finite transverse restoring coefficient. The coherent translational spectrum contains two transverse polarizations and no independent finite-frequency volumetric translational polarization.

The gravitational endpoint-transfer closure gives

$$\rho_{\mathrm{eff}}(\alpha_{\mathrm{G}}) = \frac{\rho_{\mathrm{eff}}^{(0)}}{(1-\alpha_{\mathrm{G}})^4}. \tag{Q.20}$$

Here $\rho_{\mathrm{eff}}^{(0)}$ is the scale-neutral continuum inertia coefficient of the selected coherent transfer coordinate; at the primitive-cell microscopic scale established in Appendix D it is identified with the scaffold-only normalization $\rho_{\mathrm{sh}}^{(\mathrm{micro},0)}$, and it must not be interpreted as an independently derived equilibrium density of the complete dual-phase vacuum.

Therefore,

$$c_{\mathrm{P}} = c_{\mathrm{E}}(1-\alpha_{\mathrm{G}})^2. \tag{Q.21}$$

Q.3 Mechanical Energy Balance

For a gravitational background that is quasistatic over the disturbance,

$$\dot{\alpha}_{\mathrm{G}} \simeq 0, \tag{Q.22}$$

the coherent mechanical energy density is

$$T_{\mathrm{coh}}^{00} = \frac{1}{2}\rho_{\mathrm{eff}}(\alpha_{\mathrm{G}})\dot{u}_i\dot{u}_i + K_{\mathrm{sh}}\varepsilon_{ij}\varepsilon_{ij}. \tag{Q.23}$$

The constraint term does not contribute independent stored energy on the coherent branch because

$$\delta p_{\mathrm{IC}}\, \partial_i u_i = 0. \tag{Q.24}$$

Multiplying the equation of motion by $\dot{u}_i$ gives

$$\rho_{\mathrm{eff}}\dot{u}_i\ddot{u}_i = \dot{u}_i\partial_j\delta\sigma_{ij}. \tag{Q.25}$$

Using

$$\dot{u}_i\partial_j\delta\sigma_{ij} = \partial_j\left(\delta\sigma_{ij}\dot{u}_i\right) - \delta\sigma_{ij}\partial_j\dot{u}_i, \tag{Q.26}$$

together with $\delta\sigma_{ij} = \delta\sigma_{ji}$, gives

$$\delta\sigma_{ij}\partial_j\dot{u}_i = 2K_{\mathrm{sh}}\varepsilon_{ij}\dot{\varepsilon}_{ij}. \tag{Q.27}$$

The pressure contribution vanishes because

$$\delta p_{\mathrm{IC}}\partial_i\dot{u}_i = 0. \tag{Q.28}$$

Therefore,

$$\frac{\partial T_{\mathrm{coh}}^{00}}{\partial t} - \partial_j\left(\delta\sigma_{ij}\dot{u}_i\right) = 0. \tag{Q.29}$$

The mechanical energy flux is represented by

$$c_{\mathrm{E}}T_{\mathrm{coh}}^{j0} = -\delta\sigma_{ij}\dot{u}_i. \tag{Q.30}$$

This is the continuum-mechanical statement that energy is transported by stress performing work on the moving State-I medium.

Q.4 Mechanical Momentum Balance

The coherent momentum density is

$$\rho_{\mathrm{eff}}\dot{u}_i. \tag{Q.31}$$

For a frozen background, the equation of motion may be written as

$$\frac{\partial}{\partial t}\left(\rho_{\mathrm{eff}}\dot{u}_i\right) - \partial_j \delta\sigma_{ij} = 0. \tag{Q.32}$$

The corresponding tensor components are

$$T^{0i}_{\mathrm{coh}} = c_{\mathrm{E}}\rho_{\mathrm{eff}}\dot{u}_i, \tag{Q.33}$$

and

$$T^{ji}_{\mathrm{coh}} = -\delta\sigma_{ij}. \tag{Q.34}$$

The complete State-I Soft-Floor material balance tensor is therefore

$$T^{\mu\nu}_{\mathrm{coh}} = \begin{pmatrix} \dfrac{1}{2}\rho_{\mathrm{eff}}\dot{u}_k\dot{u}_k + K_{\mathrm{sh}}\varepsilon_{kl}\varepsilon_{kl} & c_{\mathrm{E}}\rho_{\mathrm{eff}}\dot{u}_j \\ -\dfrac{1}{c_{\mathrm{E}}}\delta\sigma_{ik}\dot{u}_k & -\delta\sigma_{ij} \end{pmatrix}. \tag{Q.35}$$

It satisfies

$$\partial_\mu T^{\mu\nu}_{\mathrm{coh}} = 0 \tag{Q.36}$$

for an isolated coherent disturbance in a frozen State-I background. For $\nu = 0$, this is energy conservation. For $\nu = i$, it is momentum conservation.

Q.5 State-I Material Tensor Versus Effective Observable Tensor

The State-I Soft-Floor material tensor need not be symmetric in the preferred SGF frame. Its temporal–spatial components are

$$T^{0i}_{\mathrm{coh}} = c_{\mathrm{E}}\rho_{\mathrm{eff}}\dot{u}_i, \tag{Q.37}$$

whereas its spatial–temporal components are

$$T^{i0}_{\mathrm{coh}} = -\frac{1}{c_{\mathrm{E}}}\delta\sigma_{ij}\dot{u}_j. \tag{Q.38}$$

The first represents momentum density. The second represents mechanical energy flux. These material currents need not be identical, so

$$T^{0i}_{\mathrm{coh}} \neq T^{i0}_{\mathrm{coh}} \tag{Q.39}$$

does not violate the State-I conservation law.

This possible asymmetry is not specifically caused by matter. It may occur for any dynamic State-I configuration, including a coherent transverse wave, an elastic disturbance, a gravitational-wave-like shear mode, or a defect-loaded condensate flow. Localized matter adds defect and induced-condensate contributions to the total State-I tensor but does not create the underlying distinction between momentum density and energy flux.

The spatial stress remains symmetric in the parity-even unpolarized continuum sector:

$$\delta\sigma_{ij} = \delta\sigma_{ji}. \tag{Q.40}$$

At the observable long-wavelength level, TFT represents the homogenized response through the effective Soft-Floor measurement tensor $g^{(\tau)}_{\mu\nu}$. Let $S_{\rm eff}$ denote the corresponding long-wavelength action. The symmetric observable tensor is defined by

$$T^{(\rm eff)}_{\mu\nu} = -\frac{2}{\sqrt{-g^{(\tau)}}}\frac{\delta S_{\rm eff}}{\delta g^{\mu\nu}_{(\tau)}}. \tag{Q.41}$$

It satisfies

$$T^{(\rm eff)}_{\mu\nu} = T^{(\rm eff)}_{\nu\mu}. \tag{Q.42}$$

If the completed effective action is local and invariant under the emergent coordinate transformations associated with $g^{(\tau)}_{\mu\nu}$, its Hilbert tensor would coincide on shell with the Belinfante–Rosenfeld improvement of the canonical State-I material current, up to identically conserved boundary terms. This equivalence is therefore a completion condition of the effective theory, not an identity imposed on the microscopic State-I continuum.

The hierarchy is

$$\begin{aligned} \text{State-I material balance} &\longrightarrow \text{homogenized effective action} \\ &\longrightarrow \text{symmetric observable tensor.} \end{aligned} \tag{Q.43}$$

TFT does not assume that the symmetric spacetime tensor is fundamental. It treats it as the long-wavelength observational representation of the underlying State-I continuum.

Q.6 Primitive-Cell Phase Averaging

Let $V_{\rm p}$ be the primitive-cell volume. The nodal and interstitial subvolumes are

$$V_{\rm D} = \beta_{\rm geo}V_{\rm p}, \qquad V_{\rm IC} = \beta_{\rm IC}V_{\rm p}. \tag{Q.44}$$

For a phase-resolved effective tensor, the primitive-cell average is

$$\langle T_{\mu\nu}\rangle_{\rm p} = \frac{1}{V_{\rm p}}\left[\int_{V_{\rm D}} T^{(\rm D)}_{\mu\nu}\,{\rm d}V + \int_{V_{\rm IC}} T^{(\rm IC)}_{\mu\nu}\,{\rm d}V\right]. \tag{Q.45}$$

The nodal tensor $T^{(\rm D)}_{\mu\nu}$ is understood as the *homogenized load-bearing scaffold tensor*. It includes the FCC nodal contribution together with the contact-interface energy and stress assigned to the bonded scaffold. The interstitial tensor $T^{(\rm IC)}_{\mu\nu}$ contains the condensate energy, momentum transport, and stress not already assigned to a localized defect interaction. This allocation convention prevents omission or double counting of the FCC contact and defect–condensate interface energies.

If the leading background tensors are uniform within their phase volumes, the average reduces to

$$\left\langle T^{(0)}_{\mu\nu}\right\rangle_{\rm p} = \beta_{\rm geo}T^{(\rm D,0)}_{\mu\nu} + \beta_{\rm IC}T^{(\rm IC,0)}_{\mu\nu}. \tag{Q.46}$$

The two phase tensors need not be equal:

$$T^{(\rm D,0)}_{\mu\nu} \neq T^{(\rm IC,0)}_{\mu\nu}. \tag{Q.47}$$

Their energy densities, momentum currents, and spatial stresses are determined by different constitutive mechanisms.

This is the principal correction to the scalar expression

$$\beta_{\mathrm{geo}}\tau_{\mathrm{G}}\eta_{\mu\nu} + \beta_{\mathrm{IC}}\tau_{\mathrm{G}}\eta_{\mu\nu}, \tag{Q.48}$$

which assigns identical tensor structure to both phases and therefore contains no phase-specific mechanics.

Q.7 Structural Volumetric-Energy Closure

A geometric fraction is not automatically an energy fraction. TFT therefore introduces the uniform structural-capacity closure

$$T^{(\mathrm{D},0)}_{\hat{0}\hat{0}} = T^{(\mathrm{IC},0)}_{\hat{0}\hat{0}} = \tau_{\mathrm{G}}. \tag{Q.49}$$

This statement assigns the same structural-capacity scale τ_{G} per occupied phase volume of the complete mechanically maintained State-I cell. It does not imply equal operational inertia,

$$\rho_{\mathrm{D}} \neq \rho^{(\mathrm{imp})}_{\mathrm{IC}}, \tag{Q.50}$$

and it does not imply equal spatial stresses,

$$T^{(\mathrm{D},0)}_{\hat{i}\hat{j}} \neq T^{(\mathrm{IC},0)}_{\hat{i}\hat{j}}. \tag{Q.51}$$

The phase-averaged reference energy density is

$$\begin{aligned} \left\langle T^{(0)}_{\hat{0}\hat{0}} \right\rangle_{\mathrm{p}} &= \beta_{\mathrm{geo}} T^{(\mathrm{D},0)}_{\hat{0}\hat{0}} + \beta_{\mathrm{IC}} T^{(\mathrm{IC},0)}_{\hat{0}\hat{0}} \\ &= \beta_{\mathrm{geo}}\tau_{\mathrm{G}} + \beta_{\mathrm{IC}}\tau_{\mathrm{G}}. \end{aligned} \tag{Q.52}$$

Since

$$\beta_{\mathrm{geo}} + \beta_{\mathrm{IC}} = 1, \tag{Q.53}$$

one obtains

$$\left\langle T^{(0)}_{\hat{0}\hat{0}} \right\rangle_{\mathrm{p}} = \tau_{\mathrm{G}}. \tag{Q.54}$$

The normalized TFT structural fractions are therefore

$$\Omega^{(\mathrm{TFT},0)}_{\mathrm{D}} \equiv \frac{\beta_{\mathrm{geo}}\tau_{\mathrm{G}}}{\tau_{\mathrm{G}}} = \beta_{\mathrm{geo}}, \tag{Q.55}$$

and

$$\Omega^{(\mathrm{TFT},0)}_{\mathrm{IC}} \equiv \frac{\beta_{\mathrm{IC}}\tau_{\mathrm{G}}}{\tau_{\mathrm{G}}} = \beta_{\mathrm{IC}}. \tag{Q.56}$$

Thus,

$$\Omega^{(\mathrm{TFT},0)}_{\mathrm{D}} = \frac{\pi}{3\sqrt{2}} \approx 0.74048, \tag{Q.57}$$

and

$$\Omega^{(\mathrm{TFT},0)}_{\mathrm{IC}} = 1 - \frac{\pi}{3\sqrt{2}} \approx 0.25952. \tag{Q.58}$$

The FCC fractions are exact geometric results. Their identification with normalized TFT structural-energy fractions is conditional on the closure above. Their identification with the standard critical-density parameters additionally requires an explicit normalization bridge between τ_{G} and the observational cosmological reference density.

Q.8 Baryonic Defect Conversion and the Closed Background Ledger

TFT represents baryonic matter as localized topological defects of the State-I active vacuum. The defect's inertial coefficient is generated by conservative condensate added inertia:

$$M_{\rm top} = \rho_{\rm IC}^{(\rm imp)} V_{\rm imp} f_\varphi(\Delta\varphi). \tag{Q.59}$$

The baryonic tensor $T_{\mu\nu}^{(\rm b)}$ is defined to include the localized defect energy, its conservative condensate added inertia, and the local defect–condensate interaction energy. These contributions are therefore not added again as independent interstitial mass terms.

Define the cosmological baryonic fraction in the State-I SGF background frame by

$$\beta_{\rm b} \equiv \frac{\left\langle T_{\hat{0}\hat{0}}^{(\rm b)} \right\rangle}{\tau_{\rm G}}. \tag{Q.60}$$

TFT adopts the defect-conversion closure that the structural energy required to form baryonic defects is drawn from the nodal structural allocation. The remaining nodal contribution is therefore

$$\left\langle T_{\hat{0}\hat{0}}^{(\rm D,rem)} \right\rangle = (\beta_{\rm geo} - \beta_{\rm b})\, \tau_{\rm G}. \tag{Q.61}$$

The interstitial structural allocation remains

$$\left\langle T_{\hat{0}\hat{0}}^{(\rm IC,0)} \right\rangle = \beta_{\rm IC} \tau_{\rm G}. \tag{Q.62}$$

The localized baryonic contribution is

$$\left\langle T_{\hat{0}\hat{0}}^{(\rm b)} \right\rangle = \beta_{\rm b} \tau_{\rm G}. \tag{Q.63}$$

The interstitial tensor may be decomposed as

$$T_{\mu\nu}^{(\rm IC)} = T_{\mu\nu}^{(\rm IC,0)} + \delta T_{\mu\nu}^{(\rm IC)}. \tag{Q.64}$$

Here $\delta T_{\mu\nu}^{(\rm IC)}$ denotes the extended induced condensate response not already included in the localized baryonic interaction tensor. In the homogeneous reference-budget average,

$$\left\langle \delta T_{\hat{0}\hat{0}}^{(\rm IC)} \right\rangle = 0, \tag{Q.65}$$

while local and perturbative condensate response may be nonzero and contributes to gravitational clustering and structure formation.

The homogeneous closed-background energy density is therefore

$$\begin{aligned} \left\langle T_{\hat{0}\hat{0}}^{(\rm TFT)} \right\rangle &= (\beta_{\rm geo} - \beta_{\rm b})\, \tau_{\rm G} + \beta_{\rm IC} \tau_{\rm G} + \beta_{\rm b} \tau_{\rm G} \\ &= (\beta_{\rm geo} + \beta_{\rm IC})\, \tau_{\rm G} \\ &= \tau_{\rm G}. \end{aligned} \tag{Q.66}$$

Therefore,

$$\beta_{\Lambda,\rm eff} = \beta_{\rm geo} - \beta_{\rm b} \tag{Q.67}$$

is a structural conversion identity, not an energy-destruction identity.

For

$$\beta_{\rm b} \simeq 0.05, \tag{Q.68}$$

one obtains

$$\beta_{\Lambda,\rm eff} \simeq 0.69048. \tag{Q.69}$$

The closed scalar budget is

$$0.69048 + 0.25952 + 0.05 = 1. \tag{Q.70}$$

Q.9 Phase-Resolved Cosmological Tensor

For a statistically homogeneous and isotropic State-I background, define the effective equation-of-state ratios by

$$w_{\mathrm{D}} = \frac{\delta^{ij}\left\langle T^{(\mathrm{D,rem})}_{\hat{i}\hat{j}}\right\rangle}{3\left\langle T^{(\mathrm{D,rem})}_{\hat{0}\hat{0}}\right\rangle}, \tag{Q.71}$$

$$w_{\mathrm{IC}} = \frac{\delta^{ij}\left\langle T^{(\mathrm{IC})}_{\hat{i}\hat{j}}\right\rangle}{3\left\langle T^{(\mathrm{IC})}_{\hat{0}\hat{0}}\right\rangle}, \tag{Q.72}$$

and

$$w_{\mathrm{b}} = \frac{\delta^{ij}\left\langle T^{(\mathrm{b})}_{\hat{i}\hat{j}}\right\rangle}{3\left\langle T^{(\mathrm{b})}_{\hat{0}\hat{0}}\right\rangle}. \tag{Q.73}$$

The three phase tensors may then be written as

$$\left\langle T^{(\mathrm{D,rem})}_{\hat{\mu}\hat{\nu}}\right\rangle = (\beta_{\mathrm{geo}} - \beta_{\mathrm{b}})\,\tau_{\mathrm{G}}\,\mathrm{diag}\,(1, w_{\mathrm{D}}, w_{\mathrm{D}}, w_{\mathrm{D}})\,, \tag{Q.74}$$

$$\left\langle T^{(\mathrm{IC})}_{\hat{\mu}\hat{\nu}}\right\rangle = \beta_{\mathrm{IC}}\tau_{\mathrm{G}}\,\mathrm{diag}\,(1, w_{\mathrm{IC}}, w_{\mathrm{IC}}, w_{\mathrm{IC}})\,, \tag{Q.75}$$

and

$$\left\langle T^{(\mathrm{b})}_{\hat{\mu}\hat{\nu}}\right\rangle = \beta_{\mathrm{b}}\tau_{\mathrm{G}}\,\mathrm{diag}\,(1, w_{\mathrm{b}}, w_{\mathrm{b}}, w_{\mathrm{b}})\,. \tag{Q.76}$$

The complete homogeneous cosmological tensor is

$$\left\langle T^{(\mathrm{TFT})}_{\hat{\mu}\hat{\nu}}\right\rangle = \left\langle T^{(\mathrm{D,rem})}_{\hat{\mu}\hat{\nu}}\right\rangle + \left\langle T^{(\mathrm{IC})}_{\hat{\mu}\hat{\nu}}\right\rangle + \left\langle T^{(\mathrm{b})}_{\hat{\mu}\hat{\nu}}\right\rangle. \tag{Q.77}$$

Its total equation-of-state diagnostic is

$$w_{\mathrm{tot}} = (\beta_{\mathrm{geo}} - \beta_{\mathrm{b}})\,w_{\mathrm{D}} + \beta_{\mathrm{IC}}w_{\mathrm{IC}} + \beta_{\mathrm{b}}w_{\mathrm{b}}. \tag{Q.78}$$

The scalar fractions determine the energy weights. The constitutive mechanics determines the spatial stress and dynamical behavior.

Q.10 Nodal Structural Stress

Let $\tau^{(\mathrm{D},0)}_{ij}$ be the positive-tension mechanical stress of the unperturbed nodal scaffold per occupied nodal volume. Because $T^{(\mathrm{D},0)}_{\mu\nu}$ is the homogenized scaffold tensor, $\tau^{(\mathrm{D},0)}_{ij}$ includes the background FCC contact-interface stress assigned to the nodal network.

Positive tensile stress corresponds to negative pressure in the effective tensor representation:

$$T^{(\mathrm{D},0)}_{\hat{i}\hat{j}} = -\tau^{(\mathrm{D},0)}_{ij}. \tag{Q.79}$$

After baryonic conversion,

$$\left\langle T^{(\mathrm{D,rem})}_{\hat{i}\hat{j}}\right\rangle = -\,(\beta_{\mathrm{geo}} - \beta_{\mathrm{b}})\,\tau^{(\mathrm{D},0)}_{ij}. \tag{Q.80}$$

The general nodal equation-of-state ratio is

$$w_{\mathrm{D}} = -\frac{\delta^{ij}\tau_{ij}^{(\mathrm{D},0)}}{3\tau_{\mathrm{G}}}. \tag{Q.81}$$

Cubic symmetry or leading long-wavelength isotropy constrains the form to

$$\tau_{ij}^{(\mathrm{D},0)} = \tau_{\mathrm{iso}}\delta_{ij}, \tag{Q.82}$$

but does not determine the magnitude τ_{iso}. Therefore,

$$w_{\mathrm{D}} = -\frac{\tau_{\mathrm{iso}}}{\tau_{\mathrm{G}}}. \tag{Q.83}$$

Under the additional isotropic structural-tension closure

$$\tau_{ij}^{(\mathrm{D},0)} = \tau_{\mathrm{G}}\delta_{ij}, \tag{Q.84}$$

one obtains

$$w_{\mathrm{D}} = -1. \tag{Q.85}$$

This closure gives a mechanical interpretation of the effective negative pressure:

$$\text{positive isotropic structural tension} \longrightarrow \text{negative isotropic tensor pressure.} \tag{Q.86}$$

It does not require a fundamental thermodynamic fluid with negative internal pressure.

The equality $\tau_{\mathrm{iso}} = \tau_{\mathrm{G}}$ remains a constitutive closure. A first-principles derivation requires the absolute State-I ground-state energy as a function of volume and must show that

$$p_{\mathrm{D}} = -\frac{\partial E_{\mathrm{D}}}{\partial V} = -\frac{E_{\mathrm{D}}}{V}. \tag{Q.87}$$

If only one principal direction carried tension of magnitude τ_{G}, then $w_{\mathrm{D}} = -1/3$. That would describe a one-dimensional string-like projection rather than the isotropic three-dimensional FCC background.

Thus, FCC isotropy fixes the tensor form, while the structural closure fixes the value of w_{D}.

Q.11 Interstitial Background Stress

The interstitial sector has a different constitutive structure. The quasistatic pressure generated by gravitational loading is

$$\overline{p}_{\mathrm{IC}} = \alpha_{\mathrm{G}}\tau_{\mathrm{D,bulk}}. \tag{Q.88}$$

In the unstrained State-I reference state,

$$\alpha_{\mathrm{G}} = 0, \qquad \overline{p}_{\mathrm{IC}} = 0, \qquad \mathbf{v}_{\mathrm{rel}} = \mathbf{0}. \tag{Q.89}$$

These relations eliminate the load-induced pressure increment and background relative-flow momentum stress. They do not, by themselves, prove that no intrinsic interstitial pre-stress exists.

TFT therefore states the cold interstitial reference-state closure explicitly:

$$T_{\hat{i}\hat{j}}^{(\mathrm{IC},0)} = 0. \tag{Q.90}$$

Under this closure,

$$w_{\mathrm{IC}}^{(0)} = 0. \tag{Q.91}$$

Under localized gravitational loading, the interstitial tensor acquires quasistatic pressure, coherent momentum transport, defect-induced relative-flow stress, conservative reactive loading, and any separately derived dissipative correction. Schematically,

$$w_{\mathrm{IC}} \sim \frac{\overline{p}_{\mathrm{IC}}}{\tau_{\mathrm{G}}} + \mathcal{O}\left(\frac{\left\langle v_{\mathrm{rel}}^2 \right\rangle}{c_{\mathrm{E}}^2}\right). \tag{Q.92}$$

For nonrelativistic large-scale condensate response and weak phase-averaged pressure,

$$|w_{\mathrm{IC}}| \ll 1. \tag{Q.93}$$

This is the TFT cold-dark-response condition.

The structural allocation and dynamical response remain distinct:

$$\beta_{\mathrm{IC}} = \text{structural interstitial allocation}, \tag{Q.94}$$

whereas

$$\delta T_{\mu\nu}^{(\mathrm{IC})} = \text{induced clustering and impedance response}. \tag{Q.95}$$

Q.12 Baryonic Defect Stress

For a dilute cosmological population of nonrelativistic defects,

$$\left\langle v_{\mathrm{b}}^2 \right\rangle \ll c_{\mathrm{E}}^2. \tag{Q.96}$$

The phase-averaged kinetic pressure is therefore small compared with the baryonic energy density:

$$\left| \delta^{ij} \left\langle T_{\hat{i}\hat{j}}^{(\mathrm{b})} \right\rangle \right| \ll 3 \left\langle T_{\hat{0}\hat{0}}^{(\mathrm{b})} \right\rangle. \tag{Q.97}$$

Thus,

$$w_{\mathrm{b}} \simeq 0. \tag{Q.98}$$

Internal stresses may be important inside individual defects, stars, or compact bodies, but they average to a small cosmological pressure in the nonrelativistic late-time background.

Q.13 Late-Time Tensor Budget

For the late-time homogeneous State-I background,

$$w_{\mathrm{IC}} \simeq 0, \qquad w_{\mathrm{b}} \simeq 0. \tag{Q.99}$$

The total equation-of-state diagnostic becomes

$$w_{\mathrm{tot}} \simeq (\beta_{\mathrm{geo}} - \beta_{\mathrm{b}})\, w_{\mathrm{D}}. \tag{Q.100}$$

Under the isotropic nodal structural-tension closure,

$$w_{\mathrm{D}} = -1, \tag{Q.101}$$

and therefore

$$w_{\rm tot} \simeq -\left(\beta_{\rm geo} - \beta_{\rm b}\right). \tag{Q.102}$$

Numerically,

$$w_{\rm tot} \simeq -0.69048. \tag{Q.103}$$

The corresponding GR-comparison tensor is

$$\left\langle T^{(\rm TFT)}_{\hat{\mu}\hat{\nu}} \right\rangle \simeq \tau_{\rm G}\, {\rm diag}\left(1, -0.69048, -0.69048, -0.69048\right). \tag{Q.104}$$

This tensor is an effective source-side diagnostic. It does not restore FLRW expansion as the fundamental TFT dynamics. TFT assigns redshift and apparent acceleration to separate viscoelastic optical and kinematic mechanisms. If $\tau_{\rm iso}$ is not set equal to $\tau_{\rm G}$, the structural fractions remain fixed while $w_{\rm D}$ and $w_{\rm tot}$ remain constitutive quantities.

Q.14 Total Conserved Tensor, Remaining Capacity, and Converted Capacity

Three objects must be distinguished.

First, the complete State-I energy–momentum tensor after defect conversion is

$$T^{(\rm TFT)}_{\mu\nu} = T^{(\rm D,rem)}_{\mu\nu} + T^{(\rm IC,0)}_{\mu\nu} + \delta T^{(\rm IC)}_{\mu\nu} + T^{(\rm b)}_{\mu\nu}. \tag{Q.105}$$

This tensor accounts for all retained State-I energy, momentum, flux, and stress. It is the tensor subject to the closed-system conservation law.

Second, the unperturbed State-I structural reference tensor is

$$T^{(0)}_{\mu\nu} = \beta_{\rm geo} T^{(\rm D,0)}_{\mu\nu} + \beta_{\rm IC} T^{(\rm IC,0)}_{\mu\nu}. \tag{Q.106}$$

Third, $T^{(\rm rem)}_{\mu\nu}$ denotes the structural capacity that remains available in the unbroken State-I phase after localized conversion and induced condensate response. It is a constitutive capacity tensor, not the complete conserved energy–momentum tensor.

Define the converted structural-capacity tensor by the exact ledger

$$T^{(0)}_{\mu\nu} = T^{(\rm rem)}_{\mu\nu} + \Delta T^{(\tau)}_{\mu\nu}. \tag{Q.107}$$

Therefore,

$$\Delta T^{(\tau)}_{\mu\nu} \equiv T^{(0)}_{\mu\nu} - T^{(\rm rem)}_{\mu\nu}. \tag{Q.108}$$

At retained conservative order, the converted capacity is represented by

$$\Delta T^{(\tau)}_{\mu\nu} = T^{(\rm b)}_{\mu\nu} + \delta T^{(\rm IC)}_{\mu\nu}. \tag{Q.109}$$

Here $T^{(\rm b)}_{\mu\nu}$ already includes the localized defect–condensate interaction and conservative added-inertia energy. The extended term $\delta T^{(\rm IC)}_{\mu\nu}$ therefore excludes those localized contributions and represents only the nonlocal induced condensate response.

The distinction is essential:

$$T^{(\rm TFT)}_{\mu\nu} = \text{total conserved State-I energy–momentum}, \tag{Q.110}$$

whereas

$$T^{(\mathrm{rem})}_{\mu\nu} = \text{remaining unconverted structural capacity.} \tag{Q.111}$$

The two tensors are not interchangeable.

In the homogeneous reference-budget average,

$$\left\langle \delta T^{(\mathrm{IC})}_{\hat{0}\hat{0}} \right\rangle = 0, \tag{Q.112}$$

so the background 69/26/5 scalar ledger remains closed. Locally, $\delta T^{(\mathrm{IC})}_{\mu\nu}$ may be nonzero and contributes to gravitational response and structure formation.

Q.15 TFT Gravitational Tensor Equation

The effective State-I gravitational strain is sourced by converted structural capacity:

$$G^{(\tau)}_{\mu\nu} = \frac{\kappa G}{c_{\mathrm{E}}^4} \Delta T^{(\tau)}_{\mu\nu}. \tag{Q.113}$$

Equivalently,

$$G^{(\tau)}_{\mu\nu} = \frac{\kappa G}{c_{\mathrm{E}}^4} \left[T^{(0)}_{\mu\nu} - T^{(\mathrm{rem})}_{\mu\nu} \right]. \tag{Q.114}$$

This equation must be distinguished from the remaining-capacity relation itself. The remaining State-I capacity decreases as loading increases, whereas the induced strain increases with the converted-capacity deficit:

$$T^{(\mathrm{rem})}_{\mu\nu} \downarrow \qquad \Longrightarrow \qquad \Delta T^{(\tau)}_{\mu\nu} \uparrow . \tag{Q.115}$$

An unperturbed State-I region satisfies

$$T^{(\mathrm{rem})}_{\mu\nu} = T^{(0)}_{\mu\nu}, \tag{Q.116}$$

so that

$$G^{(\tau)}_{\mu\nu} = 0. \tag{Q.117}$$

A positive localized load produces

$$\Delta T^{(\tau)}_{\hat{0}\hat{0}} > 0. \tag{Q.118}$$

At State-I saturation, the remaining active transfer capacity approaches zero and the accumulated deficit approaches its maximum. The State-I constitutive relation terminates at the FCC-to-SC phase boundary and is not continued into the State-II core.

In TFT, $G^{(\tau)}_{\mu\nu}$ is an effective representation of State-I lattice strain and measurement distortion. The metric-like tensor is emergent, and the underlying dynamics remain continuum mechanical.

Q.16 Weak-Field Normalization and Attractive Gravity

Define the positive structural-deficit density by

$$\Delta\rho_{\mathrm{G}} = \frac{\Delta T^{(\tau)}_{\hat{0}\hat{0}}}{c_{\mathrm{E}}^2}. \tag{Q.119}$$

In the weak static limit, the effective Soft-Floor metric is written as

$$g_{00}^{(\tau)} \simeq -\left(1+\frac{2\Phi_\tau}{c_{\mathrm{E}}^2}\right)c_{\mathrm{E}}^2. \tag{Q.120}$$

When $G_{\mu\nu}^{(\tau)}$ is identified with the Einstein-tensor weak-field form of this effective metric representation,

$$G_{\hat{0}\hat{0}}^{(\tau)} \simeq \frac{2}{c_{\mathrm{E}}^2}\nabla^2\Phi_\tau. \tag{Q.121}$$

This weak-field identification is an effective projection condition; it does not follow from a generic strain tensor alone.

Substitution into the TFT tensor equation gives

$$\frac{2}{c_{\mathrm{E}}^2}\nabla^2\Phi_\tau = \frac{\kappa G}{c_{\mathrm{E}}^4}\Delta\rho_{\mathrm{G}}c_{\mathrm{E}}^2, \tag{Q.122}$$

and therefore

$$\nabla^2\Phi_\tau = \frac{\kappa}{2}G\Delta\rho_{\mathrm{G}}. \tag{Q.123}$$

For the tensor normalization

$$\kappa = 8\pi, \tag{Q.124}$$

one obtains

$$\nabla^2\Phi_\tau = 4\pi G\Delta\rho_{\mathrm{G}}. \tag{Q.125}$$

With

$$\Phi_\tau(\infty) = 0, \tag{Q.126}$$

the solution is

$$\Phi_\tau(\mathbf{x}) = -G\int \frac{\Delta\rho_{\mathrm{G}}(\mathbf{x}')}{|\mathbf{x}-\mathbf{x}'|}\,\mathrm{d}^3x'. \tag{Q.127}$$

Define the integrated structural-deficit mass by

$$M_\Delta \equiv \int \Delta\rho_{\mathrm{G}}(\mathbf{x}')\,\mathrm{d}^3x'. \tag{Q.128}$$

For an isolated localized defect, the TFT source-normalization closure identifies

$$M_\Delta = m_{\mathrm{g}} = M_{\mathrm{top}}. \tag{Q.129}$$

This is the tensor-integrated form of the topological loading identity.

For a compact spherical source,

$$\Phi_\tau(R) = -\frac{GM_\Delta}{R} = -\frac{Gm_{\mathrm{g}}}{R}. \tag{Q.130}$$

The acceleration is

$$\mathbf{g} = -\nabla\Phi_\tau, \tag{Q.131}$$

so that

$$\mathbf{g}(R) = -\frac{Gm_{\mathrm{g}}}{R^2}\hat{\mathbf{r}}. \tag{Q.132}$$

Thus,

$$\begin{aligned}\text{positive structural-capacity deficit} &\Longrightarrow \text{negative tension potential}\\ &\Longrightarrow \text{attractive acceleration.}\end{aligned} \tag{Q.133}$$

The deficit sign does not imply negative matter energy. It represents the loss of available restorative capacity from the unbroken State-I reference state.

Q.17 Local and Cosmological Capacity Scales

The same tensor architecture applies to local gravitational and cosmological problems, but the reference capacity differs.

For the unbroken cosmological State-I background,

$$T^{(0)}_{\hat{0}\hat{0}} = \tau_{\mathrm{G}}. \tag{Q.134}$$

For a localized convergence or strong-field problem, the scale-dependent State-I reference capacity is

$$T^{(0)}_{\hat{0}\hat{0}} = \tau_{\mathrm{QG}}. \tag{Q.135}$$

The tensor form remains

$$G^{(\tau)}_{\mu\nu} = \frac{\kappa G}{c_{\mathrm{E}}^4}\left[T^{(0)}_{\mu\nu} - T^{(\mathrm{rem})}_{\mu\nu}\right], \tag{Q.136}$$

but τ_{G} governs the global unbroken structural budget, whereas τ_{QG} governs the local convergence problem. This distinction connects the cosmological energy budget to local gravitational loading without identifying the two capacity scales.

Q.18 Conservation Compatibility

The State-I coherent action gives

$$\partial_\mu T^{\mu\nu}_{\mathrm{coh}} = 0 \tag{Q.137}$$

for the conservative coherent sector in a frozen background.

The complete effective action must include the nodal, interstitial, defect, and interaction contributions. Its total observable tensor must satisfy

$$\nabla^{(\tau)}_\mu T^{\mu\nu}_{\mathrm{TFT}} = 0 \tag{Q.138}$$

on shell.

If the effective gravitational tensor obeys a Bianchi-type identity,

$$\nabla^{(\tau)}_\mu G^{\mu\nu}_{(\tau)} = 0, \tag{Q.139}$$

then the completed converted-capacity source must satisfy

$$\nabla^{(\tau)}_\mu \Delta T^{\mu\nu}_{(\tau)} = 0. \tag{Q.140}$$

This compatibility will be satisfied if the source tensor and gravitational response are derived from the same completed effective action and all scaffold–condensate–defect exchange terms are included exactly once. At the homogeneous static background level developed here, the phase-averaged tensors are spatially uniform and time independent, so the conservation condition is satisfied trivially. Dynamic covariant conservation remains a completion requirement of the time-dependent effective theory.

Q.19 Tensorial Replacement of the ΛCDM Source Budget

The conventional source decomposition is schematically

$$T_{\mu\nu}^{(\Lambda\mathrm{CDM})} = T_{\mu\nu}^{(\Lambda)} + T_{\mu\nu}^{(\mathrm{CDM})} + T_{\mu\nu}^{(\mathrm{b})}. \tag{Q.141}$$

The TFT source-side replacement is

$$T_{\mu\nu}^{(\mathrm{TFT})} = T_{\mu\nu}^{(\mathrm{D,rem})} + T_{\mu\nu}^{(\mathrm{IC})} + T_{\mu\nu}^{(\mathrm{b})}. \tag{Q.142}$$

The correspondence is

- $T_{\mu\nu}^{(\mathrm{D,rem})}$: smooth remaining nodal structural sector;
- $T_{\mu\nu}^{(\mathrm{IC})}$: interstitial structural allocation and condensate dynamical response;
- $T_{\mu\nu}^{(\mathrm{b})}$: localized baryonic defects with conservative condensate added inertia.

The normalized TFT structural fractions are

$$\Omega_{\Lambda,\mathrm{eff}}^{(\mathrm{TFT})} = \beta_{\mathrm{geo}} - \beta_{\mathrm{b}}, \tag{Q.143}$$

$$\Omega_{\mathrm{DM}}^{(\mathrm{TFT},0)} = \beta_{\mathrm{IC}}, \tag{Q.144}$$

and

$$\Omega_{\mathrm{b}}^{(\mathrm{TFT})} = \beta_{\mathrm{b}}. \tag{Q.145}$$

The superscript (0) on the interstitial term indicates that β_{IC} fixes the structural allocation. The clustering response requires $\delta T_{\mu\nu}^{(\mathrm{IC})}$.

Conventional Sector	**TFT Mechanical Replacement**
Cosmological constant or dark-energy fluid	Remaining FCC nodal structural capacity
Cold dark-matter particles	Interstitial structural allocation plus condensate impedance response
Baryonic matter	Localized topological defects with conservative condensate added inertia
Fundamental metric curvature	Effective representation of State-I lattice strain
Positive matter source	Positive converted-capacity deficit relative to the State-I reference state

Q.20 What Is Derived and What Remains Constitutive

The following results are derived from the retained continuum mechanics and tensor bookkeeping:

- the State-I coherent conservation law

$$\partial_\mu T_{\mathrm{coh}}^{\mu\nu} = 0; \tag{Q.146}$$

- the phase-volume average

$$\left\langle T^{(0)}_{\mu\nu} \right\rangle = \beta_{\rm geo} T^{(\mathrm{D},0)}_{\mu\nu} + \beta_{\rm IC} T^{(\mathrm{IC},0)}_{\mu\nu}; \tag{Q.147}$$

- the exact capacity ledger

$$T^{(0)}_{\mu\nu} = T^{(\mathrm{rem})}_{\mu\nu} + \Delta T^{(\tau)}_{\mu\nu}; \tag{Q.148}$$

- the homogeneous structural conversion identity

$$(\beta_{\rm geo} - \beta_{\rm b}) + \beta_{\rm IC} + \beta_{\rm b} = 1; \tag{Q.149}$$

- the general equation-of-state budget

$$w_{\rm tot} = (\beta_{\rm geo} - \beta_{\rm b})\, w_{\rm D} + \beta_{\rm IC} w_{\rm IC} + \beta_{\rm b} w_{\rm b}; \tag{Q.150}$$

- the attractive weak-field sign once the effective Einstein-tensor projection and source normalization are imposed.

The following are explicit TFT constitutive closures:

1. uniform structural-capacity density per occupied phase volume,

$$T^{(\mathrm{D},0)}_{\hat{0}\hat{0}} = T^{(\mathrm{IC},0)}_{\hat{0}\hat{0}} = \tau_{\rm G}; \tag{Q.151}$$

2. baryonic defects draw their structural energy from the nodal allocation,

$$\beta_{\Lambda,\rm eff} = \beta_{\rm geo} - \beta_{\rm b}; \tag{Q.152}$$

3. the cold interstitial reference-state closure,

$$T^{(\mathrm{IC},0)}_{\hat{i}\hat{j}} = 0; \tag{Q.153}$$

4. the isotropic nodal pre-tension closure if the GR-equivalent limit $w_{\rm D} = -1$ is adopted;

5. the source-integral identification

$$M_\Delta = m_{\rm g} = M_{\rm top}. \tag{Q.154}$$

The following remain completion requirements:

- derivation of the absolute nodal pre-tension from the microscopic FCC ground-state action;
- derivation of the coarse-grained interstitial perturbation tensor from the cosmic-impedance response;
- construction of the complete effective action $S_{\rm eff}$;
- proof of the dynamic covariant conservation identity;
- derivation of the normalization bridge between $\tau_{\rm G}$ and the observational critical-density convention;
- derivation of the time-dependent cosmological evolution and perturbation equations.

Q.21 Main Cosmological Result

The TFT tensorial cosmological energy budget is

$$\begin{aligned}\left\langle T^{(\mathrm{TFT})}_{\hat{\mu}\hat{\nu}}\right\rangle = &\ (\beta_{\mathrm{geo}}-\beta_{\mathrm{b}})\,\tau_{\mathrm{G}}\,\mathrm{diag}\,(1,w_{\mathrm{D}},w_{\mathrm{D}},w_{\mathrm{D}})\\ &+\beta_{\mathrm{IC}}\tau_{\mathrm{G}}\,\mathrm{diag}\,(1,w_{\mathrm{IC}},w_{\mathrm{IC}},w_{\mathrm{IC}})\\ &+\beta_{\mathrm{b}}\tau_{\mathrm{G}}\,\mathrm{diag}\,(1,w_{\mathrm{b}},w_{\mathrm{b}},w_{\mathrm{b}})\,.\end{aligned} \tag{Q.155}$$

Its temporal component is

$$\left\langle T^{(\mathrm{TFT})}_{\hat{0}\hat{0}}\right\rangle = \tau_{\mathrm{G}}. \tag{Q.156}$$

Its normalized TFT structural fractions are

$$\Omega^{(\mathrm{TFT})}_{\Lambda,\mathrm{eff}} = \beta_{\mathrm{geo}}-\beta_{\mathrm{b}}, \qquad \Omega^{(\mathrm{TFT},0)}_{\mathrm{DM}} = \beta_{\mathrm{IC}}, \qquad \Omega^{(\mathrm{TFT})}_{\mathrm{b}} = \beta_{\mathrm{b}}. \tag{Q.157}$$

For the late-time cold interstitial and baryonic limits,

$$w_{\mathrm{IC}} \simeq 0, \qquad w_{\mathrm{b}} \simeq 0. \tag{Q.158}$$

Under the isotropic nodal structural-tension closure,

$$w_{\mathrm{D}} = -1, \tag{Q.159}$$

and therefore

$$w_{\mathrm{tot}} \simeq -\left(\beta_{\mathrm{geo}}-\beta_{\mathrm{b}}\right) \simeq -0.69048. \tag{Q.160}$$

The effective State-I gravitational response is

$$G^{(\tau)}_{\mu\nu} = \frac{\kappa G}{c_{\mathrm{E}}^4}\left[T^{(0)}_{\mu\nu} - T^{(\mathrm{rem})}_{\mu\nu}\right]. \tag{Q.161}$$

This replaces the former phase split into two identical terms proportional to $\eta_{\mu\nu}$.

Q.22 Conclusion

The cosmological energy budget of TFT can be formulated as a phase-resolved State-I tensor budget grounded in continuum mechanics.

The FCC scaffold and interstitial condensate form a coupled quantum continuum. Their coherent action yields a conserved State-I Soft-Floor material energy–momentum balance. This material tensor may be asymmetric in the preferred SGF frame because momentum density and mechanical energy flux are distinct continuum currents. At the homogenized observational level, a completed effective Soft-Floor action would generate a symmetric Hilbert tensor and, under the stated emergent symmetry conditions, its Belinfante–Rosenfeld equivalent.

The FCC fractions enter through phase-volume homogenization:

$$T^{(0)}_{\mu\nu} = \beta_{\mathrm{geo}} T^{(\mathrm{D},0)}_{\mu\nu} + \beta_{\mathrm{IC}} T^{(\mathrm{IC},0)}_{\mu\nu}. \tag{Q.162}$$

The nodal tensor includes the homogenized FCC contact-interface energy and stress. The structural-capacity closure fixes the energy components but does not make the complete phase tensors equal.

Baryonic defect formation converts part of the nodal structural allocation:

$$\beta_{\mathrm{geo}} \longrightarrow (\beta_{\mathrm{geo}}-\beta_{\mathrm{b}}) + \beta_{\mathrm{b}}. \tag{Q.163}$$

The homogeneous background budget is

$$(\beta_{\rm geo} - \beta_{\rm b}) + \beta_{\rm IC} + \beta_{\rm b} = 1. \tag{Q.164}$$

The total conserved State-I tensor and the remaining structural-capacity tensor are distinct. Their exact ledger is

$$T^{(0)}_{\mu\nu} = T^{(\rm rem)}_{\mu\nu} + \Delta T^{(\tau)}_{\mu\nu}. \tag{Q.165}$$

Gravity is sourced by the positive converted-capacity deficit,

$$G^{(\tau)}_{\mu\nu} = \frac{\kappa G}{c_{\rm E}^4} \Delta T^{(\tau)}_{\mu\nu}, \tag{Q.166}$$

while the remaining active capacity decreases under loading. The weak-field projection produces the Poisson equation and inward acceleration when the integrated deficit is normalized to the topological gravitational loading.

The resulting construction replaces the GR/ΛCDM source-side energy-budget decomposition with a TFT continuum-mechanical formulation. It does not treat the State-0 Latent Substrate, the State-II saturated core, fundamental spacetime curvature, or metric expansion as the dynamical ontology of the active cosmological medium.

Appendix R

The Mechanical Derivation of Optical Relativity Limits

This appendix provides the explicit weak-field mathematical evaluations for the macroscopic integrations of the strain-induced vacuum refractive index derived in Section 11.4.1. In the gravitational optical limit, the active-vacuum refractive index is

$$n_\tau(r) = \frac{1}{(1-\alpha_{\mathrm{G}})^2}. \tag{R.1}$$

For weak gravitational strain, where $\alpha_{\mathrm{G}} \ll 1$, this reduces to

$$n_\tau(r) \approx 1 + 2\alpha_{\mathrm{G}} = 1 + \frac{2GM}{rc_{\mathrm{E}}^2}. \tag{R.2}$$

The following integrations demonstrate how this strain-induced refractive index reproduces the standard weak-field optical limits associated with gravitational light deflection and Shapiro time delay.

R.1 Evaluation of the Gravitational Lensing Deflection Integral

As established in Tension Field Theory, the total deflection angle θ of a photon wave packet is the accumulated transverse refractive-gradient steering along the unperturbed line-of-sight path, taken here as the z-axis.

Given the impact parameter b, the radial distance from the mass is

$$r = \sqrt{b^2 + z^2}. \tag{R.3}$$

The deflection magnitude is governed by

$$\theta = \left| \int_{-\infty}^{+\infty} \nabla_\perp n_\tau \, \mathrm{d}z \right| = \left| \int_{-\infty}^{+\infty} \frac{\partial}{\partial b} \left(1 + \frac{2GM}{c_{\mathrm{E}}^2 \sqrt{b^2+z^2}} \right) \mathrm{d}z \right|. \tag{R.4}$$

R.1.1 Step 1: Compute the Partial Derivative

Differentiating the refractive index with respect to the impact parameter b yields the transverse gradient:

$$\frac{\partial n_\tau}{\partial b} = -\frac{2GMb}{c_{\mathrm{E}}^2 (b^2+z^2)^{3/2}}. \tag{R.5}$$

The negative sign indicates inward steering toward the mass. Taking the magnitude gives the total deflection angle:

$$\theta = \frac{2GMb}{c_{\mathrm{E}}^2} \int_{-\infty}^{+\infty} \frac{\mathrm{d}z}{(b^2 + z^2)^{3/2}}. \tag{R.6}$$

R.1.2 Step 2: Trigonometric Substitution

To evaluate the integral over the full path, we apply the substitution

$$z = b \tan \phi, \tag{R.7}$$

which implies

$$\mathrm{d}z = b \sec^2 \phi \, \mathrm{d}\phi. \tag{R.8}$$

The integration limits change from $z \in (-\infty, +\infty)$ to $\phi \in (-\pi/2, +\pi/2)$.

The denominator becomes

$$(b^2 + b^2 \tan^2 \phi)^{3/2} = (b^2 \sec^2 \phi)^{3/2} = b^3 \sec^3 \phi. \tag{R.9}$$

Substituting these into the integral gives

$$\int_{-\pi/2}^{+\pi/2} \frac{b \sec^2 \phi \, \mathrm{d}\phi}{b^3 \sec^3 \phi} = \frac{1}{b^2} \int_{-\pi/2}^{+\pi/2} \cos \phi \, \mathrm{d}\phi. \tag{R.10}$$

R.1.3 Step 3: Final Integration

Evaluating the cosine integral:

$$\frac{1}{b^2} \left[\sin \phi\right]_{-\pi/2}^{+\pi/2} = \frac{1}{b^2} \left(1 - (-1)\right) = \frac{2}{b^2}. \tag{R.11}$$

Substituting this result back into the deflection equation gives

$$\theta_{\mathrm{total}} = \frac{2GMb}{c_{\mathrm{E}}^2} \left(\frac{2}{b^2}\right) = \frac{4GM}{bc_{\mathrm{E}}^2}. \tag{R.12}$$

Because the local lattice strain at the impact parameter is defined as

$$\alpha_{\mathrm{G}}(b) = \frac{GM}{bc_{\mathrm{E}}^2}, \tag{R.13}$$

the total macroscopic deflection is

$$\theta_{\mathrm{total}} = 4\alpha_{\mathrm{G}}(b). \tag{R.14}$$

Thus, the standard weak-field Einstein deflection angle is recovered as the accumulated transverse steering of a photon wave packet through the strain-index gradient of the active vacuum.

R.2 Evaluation of the Shapiro Time Delay Integral

The local propagation speed of a signal is inversely proportional to the strain-induced refractive index:

$$c_{\mathrm{P}}(r) = \frac{c_{\mathrm{E}}}{n_\tau(r)}. \tag{R.15}$$

In the weak-field limit,

$$n_\tau(r) \approx 1 + 2\alpha_{\mathrm{G}}, \tag{R.16}$$

so the local propagation speed becomes

$$c_{\mathrm{P}}(r) \approx c_{\mathrm{E}}\left(1 - 2\alpha_{\mathrm{G}}\right). \tag{R.17}$$

The total flight time Δt for a signal traveling from an emitter at $-z_1$ to a receiver at $+z_2$ is the integral of the inverse velocity along the geometric path:

$$\Delta t = \int_{-z_1}^{+z_2} \frac{1}{c_{\mathrm{P}}}\,\mathrm{d}z \approx \frac{1}{c_{\mathrm{E}}} \int_{-z_1}^{+z_2} \left(1 + \frac{2GM}{c_{\mathrm{E}}^2\sqrt{b^2+z^2}}\right)\mathrm{d}z. \tag{R.18}$$

R.2.1 Step 1: Isolate the Delay Component

The integral separates into the unstrained baseline travel time and the optical delay induced by the refractive vacuum:

$$\Delta t = \frac{z_1 + z_2}{c_{\mathrm{E}}} + \Delta t_{\mathrm{delay}}. \tag{R.19}$$

The delay component is therefore

$$\Delta t_{\mathrm{delay}} = \frac{2GM}{c_{\mathrm{E}}^3} \int_{-z_1}^{+z_2} \frac{\mathrm{d}z}{\sqrt{b^2+z^2}}. \tag{R.20}$$

R.2.2 Step 2: Integration of the Delay Function

The standard integral of $(b^2 + z^2)^{-1/2}$ gives a natural logarithm. Evaluating from the emitter to the receiver yields

$$\Delta t_{\mathrm{delay}} = \frac{2GM}{c_{\mathrm{E}}^3} \left[\ln\left(z + \sqrt{b^2+z^2}\right)\right]_{-z_1}^{+z_2}. \tag{R.21}$$

Therefore,

$$\Delta t_{\mathrm{delay}} = \frac{2GM}{c_{\mathrm{E}}^3} \ln\left(\frac{z_2 + \sqrt{b^2+z_2^2}}{-z_1 + \sqrt{b^2+z_1^2}}\right). \tag{R.22}$$

R.2.3 Step 3: Macroscopic Approximation

For planetary and solar radar measurements, the coordinate distances are much larger than the impact parameter:

$$z_1, z_2 \gg b. \tag{R.23}$$

In this limit, the logarithmic term simplifies algebraically to the standard weak-field Shapiro form:

$$\Delta t_{\mathrm{delay}} \approx \frac{2GM}{c_{\mathrm{E}}^3} \ln\left(\frac{4z_1 z_2}{b^2}\right). \tag{R.24}$$

This confirms that the localized temporal and spatial impedances encoded by the $2\alpha_{\mathrm{G}}$ refractive correction integrate macroscopically to reproduce the standard weak-field Shapiro signal delay.

Appendix S

The Vacuum Lattice Phase Transition

Black Hole Horizon Kinematics

Subject: Mechanical derivation of the vacuum stability hierarchy ($\rho_{\mathrm{Q}}, \rho_{\mathrm{QG}}, \rho_{\mathrm{G}}$) and the kinematic expansion of the Event Horizon.

S.1 Introduction: The Fundamental Lattice Scale (r_{D})

In Part I, we established that the observable vacuum is a physical Face-Centered Cubic (FCC) lattice with a fundamental cell radius r_{D}. Fundamental mass manifests as a vibrational standing wave utilizing the interstitial voids of this lattice structure.

Since the lattice nodes themselves are phase-locked potential ("solid"), the mechanical existence of mass depends strictly on the availability of these interstitial voids to accommodate displacement. The phase transition of a particle is therefore the reconfiguration of the lattice cell that eliminates these voids. We identify the FCC Node Radius (r_{D}) as the universal scalar for this saturation mechanism because it represents:

- **The Geometric Unit:** The minimum structural dimension of the Soft Floor.
- **The Mass Identity:** The topological void boundary required to sustain a "knot" of standing energy.
- **The Kinematic Ceiling:** The absolute lower geometric limit of wave coherence, derived strictly from the maximum energetic capacity of the active vacuum ($r_{\mathrm{D}} = \frac{hc_{\mathrm{E}}}{2E_{\max}}$).

Consequently, all transition density thresholds derived below are calculated relative to this fundamental lattice constant. *(Note: These derivations utilize the reduced Planck constant $\hbar$ to align with the radial geometry of the transition.)*

S.2 The Quantum Saturation Density (ρ_{Q}) — Interstitial Kinematic Limit

Maximum energy the field can store in a fundamental knot. This limit defines the maximum energy density a standing wave of radius r can sustain before the internal vibrational velocity reaches the causal limit (c_{E}).

Derivation:

- **Quantum Energy (E_{Q}):** The energy of a fundamental mode confined to radius r (Heisenberg limit):

$$E_{\mathrm{Q}} = \frac{\hbar c_{\mathrm{E}}}{r} \tag{S.1}$$

- **Lattice Cell Capacity (E_{mass}):** The mass-energy capacity of the structural volume ($V \approx r^3$) at density ρ:

$$E_{\mathrm{mass}} = \rho c_{\mathrm{E}}^2 r^3 \tag{S.2}$$

- **The Saturation Condition:** Equating $E_{\mathrm{Q}} = E_{\mathrm{mass}}$:

$$\frac{\hbar c_{\mathrm{E}}}{r} = \rho c_{\mathrm{E}}^2 r^3 \tag{S.3}$$

General Formula:

$$\rho_{\mathrm{Q}}(r) = \frac{\hbar}{c_{\mathrm{E}} r^4} \tag{S.4}$$

Result at $r = r_{\mathrm{D}}$ (7.4504×10^{-27} m):

$$\rho_{\mathrm{Q}} \approx 1.1416 \times 10^{62} \text{ kg/m}^3 \tag{S.5}$$

Physical Interpretation and the Form Factor Bridge: This linear density (ρ_{Q}) represents the kinematic limit of one-dimensional vibrational matter. It is the density of the Quantum Foam. However, the physical Soft Floor nodes possess a closed spherical geometry. To confine this linear action into a static sphere without losing energy, the density must undergo geometric compression.

Applying the Universal Form Factor ($F = 1.5$) from the Master Geometric Law, the physical, three-dimensional spherical lattice density becomes:

$$\rho_{\mathrm{D}} = 1.5 \cdot \rho_{\mathrm{Q}} \approx 1.7124 \times 10^{62} \text{ kg/m}^3 \tag{S.6}$$

(Note: This precise geometric compression from a one-dimensional radial limit ($\rho_{\mathrm{Q}} \propto \hbar$) to a three-dimensional spherical node (ρ_{D}) is the exact mechanical origin of the relationship $h = 2\pi\hbar$.)

S.3 The Gravitational Yield Density Limit (ρ_{G}) — Lattice Yield Strength

The structural breaking point of the vacuum bonds. We define gravitational structural failure as the condition where the local gravitational tension (τ_{load}) equals the lattice yield tension (τ_{G}) defined by the cell geometry.

Derivation:

- **Gravitational Tension (τ_{load}):** Force per unit area generated by self-gravity ($A \approx r^2$):

$$\tau_{\mathrm{load}} = \frac{GM^2}{r^4} \tag{S.7}$$

- **Lattice Yield Tension (τ_{G}):** The fundamental substrate force (c_{E}^4/G) distributed over the cell area:

$$\tau_{\mathrm{G}} = \frac{c_{\mathrm{E}}^4}{Gr^2} \tag{S.8}$$

- **The Yield Condition:** Set $\tau_{\text{load}} = \tau_{\text{G}}$ (substitute $M = \rho r^3$):

$$\frac{G(\rho r^3)^2}{r^4} = \frac{c_{\text{E}}^4}{Gr^2} \tag{S.9}$$

General Formula:

$$\rho_{\text{G}}(r) = \frac{c_{\text{E}}^2}{Gr^2} \tag{S.10}$$

Result at $r = r_{\text{D}}$:

$$\rho_{\text{G}} \approx 2.4259 \times 10^{79} \text{ kg/m}^3 \tag{S.11}$$

Physical Interpretation: The "hardware limit"—the theoretical density required to mechanically fracture the Soft Floor lattice bonds. This limit is never reached in the FCC phase because geometric failure occurs first.

The Stability Ratio:

$$\frac{\rho_{\text{G}}}{\rho_{\text{D}}} \approx \frac{10^{79}}{10^{62}} \approx 10^{17} \tag{S.12}$$

Implication: The vacuum node is filled to only 10^{-17} of its burst pressure. This immense safety margin allows for stable harmonic oscillation (h).

S.4 The Convergence Density (ρ_{QG}) — The Phase Transition Trigger

The geometric point of failure. This is the geometric mean density where quantum pressure (expansion) and gravitational pressure (compression) are strictly balanced. It marks the saturation limit where the interstitial voids are mechanically exhausted.

Derivation:

$$\rho_{\text{QG}} = \sqrt{\rho_{\text{Q}} \cdot \rho_{\text{G}}} \tag{S.13}$$

$$\rho_{\text{QG}}(r) = \sqrt{\frac{\hbar c_{\text{E}}}{Gr^6}} \tag{S.14}$$

Result at $r = r_{\text{D}}$:

$$\rho_{\text{QG}} \approx 5.2625 \times 10^{70} \text{ kg/m}^3 \tag{S.15}$$

Physical Interpretation: The threshold for the vacuum phase transition (FCC $\rightarrow$ SC). The formation of an event horizon.

S.5 The Density Jump and Hard Floor Unification

It is critical to distinguish the trigger state from the final state. The Soft Floor fails geometrically at the convergence density ($\rho_{\text{QG}} \approx 5.2625 \times 10^{70}$ kg/m^3) due to void exhaustion. Because the lattice structurally folds before its bonds can tear, the FCC breaking limit (ρ_{G}) is bypassed entirely. Once the phase transition (FCC $\rightarrow$ SC) occurs, the system reverts to the fundamental architecture of the substrate (ℓ_{S}), resulting in a discontinuous density jump to the substrate limit ($\rho_{\text{S}} \approx 5.1550 \times 10^{96}$ kg/m^3).

Proof of Unification: If we replace the Soft Floor radius r_{D} with the Hard Floor limit ℓ_{S}, all three distinct formulas converge to a single value:

$$\rho_{\text{Q}}(\ell_{\text{S}}) = \rho_{\text{G}}(\ell_{\text{S}}) = \rho_{\text{QG}}(\ell_{\text{S}}) = \frac{c_{\text{E}}^5}{\hbar G^2} \approx 5.1550 \times 10^{96} \text{ kg/m}^3 \tag{S.16}$$

This confirms that at the substrate level, energy (quantum) and structure (gravity) are mechanically indistinguishable.

S.6 The Isoenergetic Phase Continuity

At the geometric convergence point (ρ_{QG}), the lattice undergoes a discontinuous phase transition to the Substrate State (ρ_{S}). To evaluate the thermodynamic continuity of this event, we calculate the total energy ($E = \rho c_{\mathrm{E}}^2 V$) at both limits.

For the Convergence Trigger (r_{QG}): Utilizing the established formula $\rho_{\mathrm{QG}} = \sqrt{\hbar c_{\mathrm{E}}/G r_{\mathrm{QG}}^6}$:

$$E_{\mathrm{QG}} = \left(\sqrt{\frac{\hbar c_{\mathrm{E}}}{G r_{\mathrm{QG}}^6}}\right) c_{\mathrm{E}}^2 r_{\mathrm{QG}}^3 = \frac{\sqrt{\hbar c_{\mathrm{E}}}}{\sqrt{G} r_{\mathrm{QG}}^3} c_{\mathrm{E}}^2 r_{\mathrm{QG}}^3 = \sqrt{\frac{\hbar c_{\mathrm{E}}^5}{G}} \tag{S.17}$$

Here the spatial boundary r_{QG}^3 completely cancels out of the equation.

For the Final Substrate State (ℓ_{S}): Utilizing the established formulas $\rho_{\mathrm{S}} = c_{\mathrm{E}}^5/\hbar G^2$ and $\ell_{\mathrm{S}} = \sqrt{\hbar G/c_{\mathrm{E}}^3}$:

$$E_{\mathrm{S}} = \left(\frac{c_{\mathrm{E}}^5}{\hbar G^2}\right) c_{\mathrm{E}}^2 \left(\sqrt{\frac{\hbar G}{c_{\mathrm{E}}^3}}\right)^3 = \frac{c_{\mathrm{E}}^7}{\hbar G^2} \frac{\hbar^{3/2} G^{3/2}}{c_{\mathrm{E}}^{9/2}} = c_{\mathrm{E}}^{5/2} \hbar^{1/2} G^{-1/2} = \sqrt{\frac{\hbar c_{\mathrm{E}}^5}{G}} \tag{S.18}$$

The Isoenergetic Proof: The derivation perfectly yields $E_{\mathrm{QG}} = E_{\mathrm{S}} = E_{\mathrm{P}}$ (The Planck Energy). Despite the catastrophic discontinuity in physical density during the phase transition (from ρ_{QG} to ρ_{S}), the transition itself is perfectly conservative and isoenergetic. Because the total energy is strictly conserved across the structural collapse, the phase transition is dictated entirely by spatial failure rather than energy dissipation.

S.7 Derivation of Phase Transition Radii

To visualize the spatial scale of phase transition, we invert the Master Density Equation to find the specific radius (r) corresponding to each transition density.

Master Radius Equation:

$$r(\rho) = \ell_{\mathrm{S}} \cdot \left(1.5 \cdot \frac{\rho_{\mathrm{S}}}{\rho}\right)^{1/4} \tag{S.19}$$

S.7.1 The Convergence Radius (r_{QG})

The scale where Void Exhaustion occurs (The Event Horizon Trigger).

- **Input:** $\rho_{\mathrm{QG}} \approx 5.2625 \times 10^{70}$ kg/m^3
- **Result:** $r_{\mathrm{QG}} \approx 5.6248 \times 10^{-29}$ m
- **Physical Meaning:** The vacuum lattice compresses elastically until $r \approx 10^{-29}$ m. At this point, the nodes touch, and the Phase Transition (FCC $\rightarrow$ SC) fires.

S.7.2 The Gravitational Yield Radius (r_{G})

The scale where the FCC lattice bonds would mechanically fracture.

- **Input:** $\rho_{\mathrm{G}} \approx 2.4259 \times 10^{79}$ kg/m^3
- **Result:** $r_{\mathrm{G}} \approx 3.8439 \times 10^{-31}$ m
- **The Phase Shield:** Since $r_{\mathrm{QG}} > r_{\mathrm{G}}$ (The locking radius is roughly 150× larger than the breaking radius), the lattice always locks into the maximally rigid Substrate Phase (SC) before it can compress enough to break. The Singularity therefore is mechanically prevented by the hardening of the vacuum.

S.8 The Micro-Black Hole: Saturation Trigger and Boundary Stability

While the convergence density (ρ_{QG}) defines the volumetric threshold for a localized phase transition, we must strictly distinguish between triggering a geometric collapse at the quantum scale and stabilizing a microscopic event horizon.

S.8.1 The Phase Transition Trigger (Node Saturation)

To initiate a phase transition, localized mass must overwhelm the structural voids of the active vacuum. Multiplying the convergence density (ρ_{QG}) by the uncompressed fundamental volume of a Soft Floor cell (r_{D}^3) defines the absolute maximum mass–energy a resting node can contain before interstitial voids are mechanically exhausted:

$$m_{\mathrm{sat}} = \rho_{\mathrm{QG}} \cdot r_{\mathrm{D}}^3 = \left(\sqrt{\frac{\hbar c_{\mathrm{E}}}{G r_{\mathrm{D}}^6}}\right) r_{\mathrm{D}}^3 = \sqrt{\frac{\hbar c_{\mathrm{E}}}{G}} = m_{\mathrm{S}} \approx 2.1764 \times 10^{-8} \text{ kg} \tag{S.20}$$

This derivation perfectly recovers the Substrate Mass (m_{S}). This confirms that injecting one unit of Substrate Mass (m_{S}) into a single fundamental cell acts as the ignition trigger, causing instantaneous geometric failure. The node elastically compresses to the convergence radius ($r_{\mathrm{QG}} \approx 10^{-29}$ m) where voids are eliminated, forcing a geometric collapse and discontinuous phase transition from FCC to the SC Substrate.

However, a collapsed core at the ℓ_{S} scale is geometrically unstable within an active vacuum supported by r_{D} nodes. Because the localized gravitational strain at this saturation threshold is near zero ($\alpha_{\mathrm{G}} \approx 10^{-7}$), the immense restorative tension of the surrounding lattice will instantly decompress the node. The phase transition fires, but it cannot structurally hold.

S.8.2 The Micro Black Hole Mass ($M_{\mathrm{D,G}}$) and Boundary Stability

To form a permanent, stable microscopic Event Horizon, the nucleating core must possess enough total localized mass to push the lattice yield tension outward and hold the phase boundary open at the fundamental kinematic limit of the Soft Floor ($R_{\mathrm{QG}} \geq r_{\mathrm{D}}$). We define this absolute permanent stability threshold as the Micro Black Hole Mass ($M_{\mathrm{D,G}}$).

Derivation from Interface Inertia:
We scale the 2D surface load capacity of the active vacuum ($\mu_{\mathrm{D}} = c_{\mathrm{E}}^2/G r_{\mathrm{D}}$) to the geometric

cross-section of a single node (r_{D}^2):

$$M_{\mathrm{D,G}} = \mu_{\mathrm{D}} \cdot r_{\mathrm{D}}^2 = \frac{c_{\mathrm{E}}^2 r_{\mathrm{D}}}{G} \tag{S.21}$$

Numerical Evaluation:

$$M_{\mathrm{D,G}} \approx 10.033 \text{ kg} \tag{S.22}$$

This massive numerical value highlights the immense structural rigidity of the FCC vacuum. It requires an extreme localized mass (roughly 10.0 kg) compressed strictly within the fundamental radial boundary ($r_{\mathrm{D}} \approx 10^{-27}$ m) to mechanically lock the vacuum bonds open.

Proof of Absolute Structural Strain ($\alpha_{\mathrm{G}} = 1$):
To validate that $M_{\mathrm{D,G}}$ represents the exact breaking point of the lattice boundary, we calculate the mechanical strain (α_{G}) as the ratio of applied gravitational tension to the absolute lattice yield tension ($\tau_{\mathrm{G}} = c_{\mathrm{E}}^4 / G r_{\mathrm{D}}^2$):

$$\alpha_{\mathrm{G}} = \frac{\left(\frac{G M_{\mathrm{D,G}}^2}{r_{\mathrm{D}}^4}\right)}{\left(\frac{c_{\mathrm{E}}^4}{G r_{\mathrm{D}}^2}\right)} = \frac{G^2 \left(\frac{c_{\mathrm{E}}^2 r_{\mathrm{D}}}{G}\right)^2}{c_{\mathrm{E}}^4 r_{\mathrm{D}}^2} = 1 \tag{S.23}$$

This rigorously confirms that localizing 10.033 kg within the fundamental radial boundary of r_{D} pushes the vacuum structure to exactly 100% mechanical strain. This ensures the resulting gravitational tension perfectly matches the surrounding lattice's restorative pressure, holding the horizon open permanently.

The Nucleation Event and Node Multiplication:
At $\alpha_{\mathrm{G}} = 1$, the void geometrically fails and collapses, undergoing a phase transition into the maximally dense, stable configuration of the vacuum: the Simple Cubic (SC) Substrate. Applying the conservation of mass–energy, the total kinetic energy required to stabilize the ruptured boundary ($E_{\mathrm{D,G}} = M_{\mathrm{D,G}} c_{\mathrm{E}}^2 \approx 9.017 \times 10^{17}$ J) converts perfectly into phase-locked SC Substrate nodes.

Because each node holds exactly one Substrate Energy unit ($E_{\mathrm{S}} \approx 1.956 \times 10^9$ J), the nucleation event shatters the local vacuum into a highly quantifiable micro-core:

$$N = \frac{E_{\mathrm{D,G}}}{E_{\mathrm{S}}} \approx 4.6101 \times 10^8 \text{ Nodes} \tag{S.24}$$

The Maximum Finite Gravity Limit:
Despite the vacuum structurally collapsing into sub-nuclear SC nodes, the strict conservation of mass–energy ensures that the total inertial mass responsible for maintaining the newly formed phase boundary remains exactly 10.033 kg. Substituting $M_{\mathrm{D,G}}$ into the gravitational saturation-radius relation ($R_{\mathrm{QG}} = GM/c_{\mathrm{E}}^2$) yields $R_{\mathrm{QG}} = r_{\mathrm{D}}$.

Because the microscopic Event Horizon is physically prevented from contracting below the Soft Floor geometric boundary upon phase lock, the surface gravity is strictly capped at a finite kinematic limit:

$$g_{\mathrm{QG,max}} = \frac{c_{\mathrm{E}}^4}{G M_{\mathrm{D,G}}} = \frac{c_{\mathrm{E}}^2}{r_{\mathrm{D}}} \approx 1.2063 \times 10^{43} \text{ m/s}^2 \tag{S.25}$$

This mathematically proves that the singularity is an artifact of standard physics failing to account for the phase transition. By locking the maximum gravitational acceleration to the kinematic limit of the lattice ($c_{\mathrm{E}}^2 / r_{\mathrm{D}}$), the framework strictly preserves causality; spacetime cannot geometrically deform faster than its internal mechanical wave speed.

Furthermore, because the gravitational field outside the r_{D} boundary immediately transitions to the macroscopic inverse-square law ($1/R^2$), the environmental impact of a nucleated micro-black hole is negligible at human scales. While it possesses the extreme structural tension required to maintain a ruptured phase boundary at 10^{-27} m, its macroscopic gravitational pull at a distance of one meter is identical to that of an ordinary 10.0 kg mass. Consequently, a micro-black hole does not possess the infinite geometric power to instantaneously collapse surrounding celestial bodies or laboratory environments; its macroscopic growth is strictly bottlenecked by the thermodynamic rate of vacuum crystallization.

S.9 The Kinematics of Event Horizon Phase Expansion

Because the Event Horizon is a physical phase boundary, its expansion requires mechanical work. The internal structural work rate pressing outward against the horizon surface area must equal the gravitational work required to expand the boundary's total mass–energy ($E = Mc_{\mathrm{E}}^2$).

We determine the expansion power by taking the time derivative of the Black Hole's mass. Using the linear gravitational mass-radius relation ($M = \frac{R_{\mathrm{QG}} c_{\mathrm{E}}^2}{G}$), the rate of mass growth is mathematically locked to the radial expansion velocity:

$$\frac{\mathrm{d}M}{\mathrm{d}t} = \frac{c_{\mathrm{E}}^2}{G} \frac{\mathrm{d}R_{\mathrm{QG}}}{\mathrm{d}t} \tag{S.26}$$

Multiplying this by c_{E}^2 yields the total Kinematic Expansion Power of the boundary. We equate this to the internal Mechanical Power (Force $\times$ Velocity) exerted by the Horizon Surface Tension (τ_{QG}) pushing against the macroscopic spherical boundary ($4\pi R_{\mathrm{QG}}^2$):

$$(4\pi R_{\mathrm{QG}}^2)\tau_{\mathrm{QG}} \frac{\mathrm{d}R_{\mathrm{QG}}}{\mathrm{d}t} = \frac{c_{\mathrm{E}}^4}{G} \frac{\mathrm{d}R_{\mathrm{QG}}}{\mathrm{d}t} \tag{S.27}$$

By canceling the differential expansion rate ($\frac{\mathrm{d}R_{\mathrm{QG}}}{\mathrm{d}t}$) from both sides, we isolate the fundamental lattice force acting across the horizon area:

$$(4\pi R_{\mathrm{QG}}^2)\tau_{\mathrm{QG}} = \frac{c_{\mathrm{E}}^4}{G} \tag{S.28}$$

Dividing by the surface area yields the macroscopic boundary tension:

$$\tau_{\mathrm{QG}} = \frac{c_{\mathrm{E}}^4}{4\pi G R_{\mathrm{QG}}^2} \tag{S.29}$$

To express this in terms of macroscopic observables, we substitute the TFT definition of convergence surface gravity ($g_{\mathrm{QG}} = \frac{c_{\mathrm{E}}^2}{R_{\mathrm{QG}}}$) into the expression:

$$\tau_{\mathrm{QG}} = \left(\frac{c_{\mathrm{E}}^2}{4\pi G R_{\mathrm{QG}}} \right) g_{\mathrm{QG}} \tag{S.30}$$

Because the differential velocity ($\frac{\mathrm{d}R_{\mathrm{QG}}}{\mathrm{d}t}$) cancels out, this derivation proves that this structural identity is a mandatory boundary condition. Regardless of the rate of kinetic expansion, the macroscopic horizon is not a kinematic stretch of empty space, but a physical phase boundary maintained by the strict equilibrium between the crystallization pressure of the SC core and the gravitational load of the elastic FCC vacuum.

(Note: The 4π geometric factor physically maps the isotropic spherical area of the macroscopic horizon to the fundamental square face of the Simple Cubic lattice node ($A = \ell_S^2$). At the absolute microscopic limit where $R_{QG} \to \ell_S$, the spherical geometry resolves into the cubic lattice, the 4π form factor vanishes, and τ_{QG} collapses perfectly into the absolute Substrate Tension limit: $\tau_S = \frac{c_E^4}{G\ell_S^2}$.)

Table S.1: Vacuum Lattice Phase Transition Hierarchy and Boundary Parameters

Parameter	**Symbol**	**Formula**	**Evaluated Limit**	**Physical Meaning**
Vibration Limit	ρ_Q	$\frac{\hbar}{c_E r_D^4}$	$\approx 1.1416 \times 10^{62}$ kg/m^3	Interstitial saturation. Particle vibrates at light speed ($v \approx c_E$).
The Trigger	ρ_{QG}	$\sqrt{\frac{\hbar c_E}{G r_D^6}}$	$\approx 5.2625 \times 10^{70}$ kg/m^3	Geometric failure. FCC lattice structurally locks; event horizon forms.
Yield Strength	ρ_G	$\frac{c_E^2}{G r_D^2}$	$\approx 2.4259 \times 10^{79}$ kg/m^3	Structural bond limit. Soft Floor structural bonds would fracture.
Final State	ρ_S	$\frac{c_E^5}{\hbar G^2}$	$\approx 5.1550 \times 10^{96}$ kg/m^3	Substrate (Hard Floor). Lattice snaps to Simple Cubic (SC).
Node Saturation	$M_{D,G}$	$\frac{c_E^2 \cdot r_D}{G}$	≈ 10.033 kg	Micro-Black Hole Limit. Minimum localized mass to force geometric lock.
Convergence Radius	r_{QG}	$\ell_S \cdot \left(1.5\frac{\rho_S}{\rho_{QG}}\right)^{1/4}$	$\approx 5.6248 \times 10^{-29}$ m	Trigger scale. Microscopic phase transition radius.
Yield Radius	r_G	$\ell_S \cdot \left(1.5\frac{\rho_S}{\rho_G}\right)^{1/4}$	$\approx 3.8439 \times 10^{-31}$ m	Fracture scale. Prevented by prior phase locking.
Boundary Tension	τ_{QG}	$\frac{c_E^4}{4\pi G R_{QG}^2}$	Scale Dependent	Surface tension of the macroscopic event horizon.
Max Gravity Limit	$g_{QG,max}$	$\frac{c_E^2}{r_D}$	$\approx 1.2063 \times 10^{43}$ m/s^2	Absolute upper limit of acceleration. Precludes the singularity.

Appendix T

The Resolution of the Information Paradox

Decoupling Structural Information and Thermodynamic Entropy via Lattice Mechanics

T.1 Introduction: The Conflation of Entropy and Information

The Black Hole Information Paradox fundamentally arises from the analytical conflation of Information (structured topological data) and Entropy (chaotic geometric capacity or statistical microstates) into a singular thermodynamic metric. Tension Field Theory (TFT) resolves this paradox by demonstrating that these properties operate across distinct crystallographic scales within the stratified supersolid vacuum:

- **The Dynamical Carrier Sector:** Physical matter, radiation, thermal excitations, and other finite-energy degrees of freedom reside on State I. Their statistical/thermodynamic entropy is distinct from both the static strain record and the geometric slot count.
- **The Data Record (Information):** A static longitudinal strain configuration retained by the phase-locked Hard Floor, governed by the fundamental substrate length ℓ_{S}.

By applying this mechanical stratification to the Event Horizon, we mathematically demonstrate that standard black hole calculations evaluate the underlying substrate strain footprint, but treating it as a purely thermal quantity generated the information paradox.

T.2 Deriving the Holographic Limit from Active Strain

To establish the mathematical relationship between a coherent localized mass and its phase-transitioned boundary limit, we begin with the native TFT Matter Identity. To scale this identity from a single localized microscopic particle to the aggregate Event Horizon, we substitute the macroscopic inertial mass (M) of the converged system. This equation defines the active longitudinal strain bits (N_{M}) of the macroscopic mass relative to the Universal Substrate Mass Potential (m_{S}):

$$N_{\mathrm{M}} = 2\pi \left(\frac{m_{\mathrm{S}}}{M}\right)^2 \tag{T.1}$$

To map this to the macroscopic geometry of an Event Horizon, we establish the relation between mass, the boundary radius (R_{QG}), and the fundamental Substrate Length (ℓ_{S}):

$$R_{\mathrm{QG}} = \frac{GM}{c_{\mathrm{E}}^2} \tag{T.2}$$

$$\ell_{\mathrm{S}} = \sqrt{\frac{\hbar G}{c_{\mathrm{E}}^3}} \tag{T.3}$$

Dividing the macroscopic boundary radius by the microscopic substrate length yields the geometric ratio:

$$\frac{R_{\mathrm{QG}}}{\ell_{\mathrm{S}}} = \frac{\frac{GM}{c_{\mathrm{E}}^2}}{\sqrt{\frac{\hbar G}{c_{\mathrm{E}}^3}}} = M\sqrt{\frac{G^2 c_{\mathrm{E}}^3}{c_{\mathrm{E}}^4 \hbar G}} = M\sqrt{\frac{G}{\hbar c_{\mathrm{E}}}} \tag{T.4}$$

Recognizing that the absolute Substrate Mass Potential is defined as $m_{\mathrm{S}} = \sqrt{\frac{\hbar c_{\mathrm{E}}}{G}}$, the geometric ratio simplifies directly to the mass ratio:

$$\frac{R_{\mathrm{QG}}}{\ell_{\mathrm{S}}} = \frac{M}{m_{\mathrm{S}}} \tag{T.5}$$

We now evaluate the area-scaled Bekenstein–Hawking relation. By substituting the Planck length with the TFT Substrate Length (ℓ_{S}) and expanding the boundary area ($A = 4\pi R_{\mathrm{QG}}^2$), we obtain the Boltzmann-scaled boundary count:

$$\frac{S_{\mathrm{holo}}}{k_{\mathrm{B}}} = \frac{4\pi R_{\mathrm{QG}}^2}{4\ell_{\mathrm{S}}^2} = \pi\left(\frac{R_{\mathrm{QG}}}{\ell_{\mathrm{S}}}\right)^2 \tag{T.6}$$

Substituting the mass-geometry relation into this equation yields:

$$\frac{S_{\mathrm{holo}}}{k_{\mathrm{B}}} = \pi\left(\frac{M}{m_{\mathrm{S}}}\right)^2 \tag{T.7}$$

Isolating the mass ratio from the macroscopic TFT Information Equation $\left[\left(\frac{M}{m_{\mathrm{S}}}\right)^2 = \frac{2\pi}{N_{\mathrm{M}}}\right]$ and substituting it into the holographic limit reveals the master translation metric:

$$\frac{S_{\mathrm{holo}}}{k_{\mathrm{B}}} = \pi\left(\frac{2\pi}{N_{\mathrm{M}}}\right) = \frac{2\pi^2}{N_{\mathrm{M}}} \tag{T.8}$$

Physical Interpretation: The area-scaled boundary count ($S_{\mathrm{holo}}/k_{\mathrm{B}}$) scales proportionally with M^2, while the active information of the standing wave (N_{M}) scales inversely. This demonstrates that standard formalisms correctly isolate the underlying substrate metric (ℓ_{S}), but evaluate the absolute maximum structural capacity of the phase boundary rather than an independent thermodynamic entropy. Because this maximal boundary capacity grows inversely to the true coherent strain of the condensed particle state, this geometric inversion bridges the Holographic Principle directly to the Information-Energy Inverse Law derived in Appendix AB.

T.3 The Dual-State Resolution: Capacity vs. Occupancy

TFT strictly separates the geometric capacity of the Event Horizon from its actual structural occupancy:

- **Geometric Capacity ($S_{\text{geo}}/k_{\text{B}}$):** This measures the absolute maximum structural capacity of the boundary layer to contain baryonic defect states. Because the active vacuum is granular and the boundary layer never exceeds a physical thickness of one FCC node (r_{D}), its volumetric capacity scales strictly quadratically with the surface area ($V_{\text{shell}} \approx 4\pi R_{\text{QG}}^2 \cdot r_{\text{D}}$):

$$\frac{S_{\text{geo}}}{k_{\text{B}}} = \frac{4\pi R_{\text{QG}}^2 \cdot r_{\text{D}}}{r_{\text{D}}^3} = \frac{4\pi R_{\text{QG}}^2}{r_{\text{D}}^2} \tag{T.9}$$

- **Kinematic Occupancy ($S_{\text{kin}}/k_{\text{B}}$):** This represents the actual number of phase-segregated topological defects occupying those slots. Because the macroscopic Event Horizon scales linearly with mass ($M \propto R_{\text{QG}}^1$), the true inertial occupancy scales linearly:

$$\frac{S_{\text{kin}}}{k_{\text{B}}} = \frac{R_{\text{QG}}}{r_{\text{D}}} \tag{T.10}$$

The Kinematic Fill Ratio (Φ_{kin}): The structural utilization of the Black Hole is defined by the ratio of actual mass occupancy to geometric capacity:

$$\Phi_{\text{kin}} = \frac{S_{\text{kin}}/k_{\text{B}}}{S_{\text{geo}}/k_{\text{B}}} = \frac{\frac{R_{\text{QG}}}{r_{\text{D}}}}{4\pi\left(\frac{R_{\text{QG}}}{r_{\text{D}}}\right)^2} = \frac{1}{4\pi}\left(\frac{r_{\text{D}}}{R_{\text{QG}}}\right) \tag{T.11}$$

This proves that the standard area law calculates an empty structural boundary limit. Because geometric capacity (R^2) expands faster than mass accumulation (R^1), the active boundary layer becomes increasingly empty as it grows, mathematically guaranteeing the Areal Mass Density dilution ($\Phi_{\text{kin}} \propto R_{\text{QG}}^{-1}$).

T.4 Information Capacity (N_{QG}) vs. The Strain Record

Information is the dimensionless topological strain footprint that the condensate imposes upon the underlying phase-locked SC core. Therefore, the information ledger must be calculated directly upon the Substrate lattice (ℓ_{S}^2).

We first determine the localized mass potential (m_0) of a single SC Substrate node located on the boundary by multiplying the invariant density of the SC phase (ρ_{S}) by the volume of a single SC node (ℓ_{S}^3):

$$m_0 = \rho_{\text{S}} \cdot \ell_{\text{S}}^3 = \left(\frac{c_{\text{E}}^5}{\hbar G^2}\right) \cdot \left(\sqrt{\frac{\hbar G}{c_{\text{E}}^3}}\right)^3 = \sqrt{\frac{\hbar c_{\text{E}}}{G}} = m_{\text{S}} \tag{T.12}$$

Because every SC boundary node possesses exactly one Substrate Mass Potential (m_{S}) of invariant potential, we apply the native TFT Matter Identity to calculate the maximum strain capacity of a single surface tile:

$$N_{m_0} = 2\pi\left(\frac{m_{\text{S}}}{m_{\text{S}}}\right)^2 = 2\pi \tag{T.13}$$

Every physical SC tile on the core's surface can sustain a maximum of 2π radians of longitudinal strain.

The Convergence Information Limit (N_{QG}): To determine the absolute geometric capacity for information encoded onto the boundary, we multiply the total number of SC tiles on the Event Horizon by this fundamental strain capacity:

$$N_{\mathrm{QG}} = \left(\frac{4\pi R_{\mathrm{QG}}^2}{\ell_{\mathrm{S}}^2} \right) \cdot 2\pi = \frac{8\pi^2 R_{\mathrm{QG}}^2}{\ell_{\mathrm{S}}^2} \tag{T.14}$$

The True Information Record (N_{M}): By applying the Inertial Identity to the macroscopic mass (M) and substituting the geometric scalar ratio ($\frac{m_{\mathrm{S}}}{M} = \frac{\ell_{\mathrm{S}}}{R_{\mathrm{QG}}}$), we determine the true coherent information footprint:

$$N_{\mathrm{M}} = 2\pi \left(\frac{m_{\mathrm{S}}}{M} \right)^2 = 2\pi \left(\frac{\ell_{\mathrm{S}}}{R_{\mathrm{QG}}} \right)^2 \tag{T.15}$$

The Information Fill Ratio (Φ_{info}): We calculate the data ledger utilization by dividing the actual strain footprint by the maximum boundary capacity:

$$\Phi_{\mathrm{info}} = \frac{N_{\mathrm{M}}}{N_{\mathrm{QG}}} = \frac{2\pi \left(\frac{\ell_{\mathrm{S}}}{R_{\mathrm{QG}}} \right)^2}{8\pi^2 \left(\frac{R_{\mathrm{QG}}}{\ell_{\mathrm{S}}} \right)^2} = \frac{1}{4\pi} \left(\frac{\ell_{\mathrm{S}}}{R_{\mathrm{QG}}} \right)^4 \tag{T.16}$$

The Blank Ledger Resolution: On the active FCC Soft Floor, physical matter dilutes at a rate of R^{-1}. However, on the static SC Hard Floor, the true information footprint geometrically condenses at a rate of R^{-4}. As the capacity of the boundary grows (R^2), the true coherent information footprint shrinks (R^{-2}). The macroscopic Event Horizon is a virtually blank slate, completely resolving the infinite density paradox.

T.5 The Equivalence and the Structural Safety Margin

By directly equating the area-scaled Bekenstein–Hawking relation with the derived TFT Convergence Information Limit equation, the historical geometric correspondence becomes explicit. Isolating the geometric ratio yields:

$$\left(\frac{R_{\mathrm{QG}}}{\ell_{\mathrm{S}}} \right)^2 = \frac{S_{\mathrm{holo}}}{\pi k_{\mathrm{B}}} \tag{T.17}$$

Substituting this ratio directly into the TFT Convergence Information Limit equation yields the equivalence identity:

$$N_{\mathrm{QG}} = 8\pi^2 \left(\frac{S_{\mathrm{holo}}}{\pi k_{\mathrm{B}}} \right) = \frac{8\pi}{k_{\mathrm{B}}} S_{\mathrm{holo}} \tag{T.18}$$

Within TFT, the dimensionless quantity $S_{\mathrm{holo}}/k_{\mathrm{B}}$ is reinterpreted as an area-scaled structural count associated with the substrate ledger. The correspondence establishes a geometric bridge between horizon entropy scaling and TFT boundary information capacity; it does not, by itself, identify geometric capacity with thermodynamic entropy. The factor k_{B} converts the dimensionless state-count representation into entropy units; TFT separates that dimensional conversion from its proposed microscopic structural interpretation.

We quantify the magnitude of this dimensional discrepancy by comparing the Information footprint on the Hard Floor ($S_{\text{holo}}/k_{\text{B}}$) against the Geometric Capacity of the Soft Floor ($S_{\text{geo}}/k_{\text{B}}$):

$$\text{Ratio} = \frac{S_{\text{holo}}/k_{\text{B}}}{S_{\text{geo}}/k_{\text{B}}} = \frac{\left(\pi \frac{R_{\text{QG}}^2}{\ell_{\text{S}}^2}\right)}{\left(4\pi \frac{R_{\text{QG}}^2}{r_{\text{D}}^2}\right)} = \frac{1}{4}\left(\frac{r_{\text{D}}}{\ell_{\text{S}}}\right)^2 \tag{T.19}$$

Utilizing the TFT scalar constants ($r_{\text{D}} \approx 7.45 \times 10^{-27}\,\text{m}$ and $\ell_{\text{S}} \approx 1.616 \times 10^{-35}\,\text{m}$), this ratio resolves to approximately 10^{17}. A singular physical defect state on the active Soft Floor necessitates a structural capacity footprint spanning $\approx 10^{17}$ fundamental tiles on the static SC Substrate. Information is permanently recorded across this extensive structural grid, rigorously isolated from thermal dynamics.

T.6 The Topological Invariant ($16\pi^3$)

The dual relationships governing macroscopic mass (M) reveal an absolute geometric conservation law. The metric N_{M} defines the information of the mass as a localized, coherent standing wave, while N_{QG} defines the absolute informational capacity of that same mass in a saturated boundary configuration.

By multiplying the absolute Information Capacity (N_{QG}) directly with the True Information Record (N_{M}), the dynamic scaling terms cancel entirely:

$$N_{\text{QG}} \cdot N_{\text{M}} = \left(\frac{8\pi^2 R_{\text{QG}}^2}{\ell_{\text{S}}^2}\right) \cdot \left(2\pi \frac{\ell_{\text{S}}^2}{R_{\text{QG}}^2}\right) \tag{T.20}$$

Rearranging this relationship yields an absolute topological invariant:

$$N_{\text{QG}} \cdot N_{\text{M}} = 16\pi^3 \quad (\approx 496.06) \tag{T.21}$$

This dimensionless constant provides rigorous mathematical verification that Information is indestructible. The product of a system's coherent standing information (N_{M}) and its maximal boundary capacity (N_{QG}) is strictly conserved by the lattice geometry. Whether mass exists as an active localized state or as a frozen phase boundary, its total topological ledger remains an invariant geometric property of the underlying continuum, definitively preserving Quantum Unitarity.

Appendix U

Dynamics of Live Black-Hole Phase Boundaries

Surface Motion, Spin, Binary Merger, and Ringdown in the FCC/SC Transition

As established in TFT, a black hole is not a point singularity and not an empty geometric hole. It is a physical phase transition of the Spacetime Gravitational Floor. Under gravitational saturation, the active Face-Centered Cubic Soft Floor loses its interstitial freedom and locks into the Simple Cubic Hard Floor.

The event horizon is therefore interpreted as the physical FCC/SC phase boundary of the vacuum:

$$\text{FCC Soft Floor} \rightarrow \text{SC phase-locked Hard Floor.} \tag{U.1}$$

This appendix develops the next level of the theory: the dynamics of that boundary.

In TFT, a black hole is a compact saturated phase-domain with center-of-mass motion, orbital motion, axial angular momentum, surface growth, merger behavior, and relaxation modes. These dynamics are not assigned to ordinary material flow through the saturated SC interior. The SC domain is phase-locked, void-less, and mechanically saturated; it does not support ordinary internal circulation, interstitial transport, or fluid-like material rotation. The dynamical degrees of freedom instead reside on the live FCC/SC phase boundary and in the strained Soft Floor surrounding it.

A TFT black hole is therefore represented mechanically as:

$$\text{Black Hole} = \text{SC Saturated Domain} + \text{FCC/SC Phase Boundary} + \text{External Strained Soft Floor.} \tag{U.2}$$

This definition is local and mechanical. It does not depend on optical appearance, redshift interpretation, coordinate convention, or what a distant observer sees. It depends on the saturation state of the vacuum itself. Wherever the local gravitational saturation condition is reached,

$$\alpha_{\mathrm{G}} = 1, \tag{U.3}$$

the active FCC vacuum can no longer remain dynamically available and becomes part of the phase-locked SC saturated domain.

The radial black-hole chapters treated this process in the spherical average, where the saturation radius evolves according to:

$$\dot{R}_{\mathrm{QG}} = \frac{G}{c_{\mathrm{E}}^2}\dot{M}. \tag{U.4}$$

That relation describes average radial growth. The present appendix extends the same phase-boundary logic to nonspherical, rotating, and binary systems. The central task is to replace a purely radial black-hole picture with a live surface theory containing distinct but coupled channels: center-of-mass motion, phase-front growth, tangential redistribution, torsional spin, saturated bridge formation, stress shedding, and ringdown.

U.1 Velocity Channels of a Live Black-Hole Boundary

A dynamic black hole contains more than one form of motion. In the TFT description, these motions are assigned to distinct mechanical channels of the FCC/SC phase boundary:

- **Center-of-Mass Motion:** The black hole behaves externally as a compact saturated phase-boundary object moving through the surrounding Soft Floor. This is the motion relevant to binary black-hole orbits, inspiral trajectories, merger recoil, and motion through an external gravitational field, describing the displacement of the entire saturated black-hole domain.
- **Phase-Front Motion:** This is the local advancement of the FCC/SC transition surface as the black hole gains mass-energy and converts surrounding active Soft Floor into the phase-locked SC substrate state: FCC Soft Floor $\rightarrow$ SC phase-locked substrate. In the spherical growth limit, this channel is represented by the radial growth law $\dot{R}_{\mathrm{QG}} = \frac{G}{c_{\mathrm{E}}^2}\dot{M}$. In a disturbed or merging black hole, this conversion can occur unevenly, producing local bulging, distortion, and subsequent relaxation.
- **Tangential Redistribution:** Since the effective inertial mass of the black hole is phase-segregated to the boundary layer, surface mass density and surface stress may redistribute tangentially across the phase boundary. This occurs during matter inflow, tidal distortion, asymmetric growth, binary interaction, or post-merger relaxation, acting as a boundary-layer process rather than bulk transport.
- **Torsional Boundary Motion:** This is the channel associated with axial angular momentum. The observational angular momentum is carried mechanically by torsional loading of the FCC/SC boundary and shear strain in the surrounding Soft Floor.

Thus, the live boundary contains four distinct velocity channels:

$$\text{center-of-mass motion} \neq \text{phase-front growth} \neq \text{tangential redistribution} \neq \text{torsional boundary motion}. \tag{U.5}$$

These channels are distinct but not isolated. In a binary merger, rapid orbital motion can drive boundary deformation, bridge saturation, gravitational-wave stress shedding, and angular-momentum transfer. However, orbital motion is not itself the same mechanical process as phase-front growth or torsional boundary motion.

A black hole may therefore translate through the Soft Floor, grow by FCC-to-SC conversion, redistribute boundary stress, and carry axial angular momentum through different but coupled mechanical channels. This decomposition provides the basis for treating inspiral, spin, merger, gravitational-wave emission, and ringdown within the live FCC/SC phase-boundary framework.

U.2 Axial Rotation as Boundary Torsion

A rotating black hole carries axial angular momentum. In the TFT boundary description, this angular momentum is not assigned to ordinary material rotation of the SC saturated interior.

State II is phase-locked; the saturated SC domain supplies the internal boundary condition, while the live FCC/SC phase boundary and the surrounding Soft Floor carry the rotational degree of freedom.

The mechanical interpretation is therefore

$$\text{black-hole spin} = \text{boundary torsion} + \text{external Soft Floor shear}. \tag{U.6}$$

Thus, a rotating TFT black hole is modeled as a saturated phase-domain whose boundary carries angular momentum and transmits that angular momentum into the surrounding vacuum as torsional strain.

For a first-order surface-shell approximation, treat the black-hole boundary as a thin mass-bearing layer. Let dM_∂ denote the boundary mass element and let

$$r_\perp = R_{\mathrm{QG}} \sin\theta \tag{U.7}$$

be the cylindrical distance from the spin axis. The surface moment of inertia is

$$I_{\mathrm{surf}} = \int_{\partial_{\mathrm{BH}}} r_\perp^2 \, dM_\partial, \tag{U.8}$$

where ∂_{BH} denotes the live black-hole phase boundary.

The corresponding axial angular momentum is, in general,

$$\mathcal{J}_{\mathrm{BH}} = \int_{\partial_{\mathrm{BH}}} r_\perp \, v_\phi \, dM_\partial, \tag{U.9}$$

where v_ϕ is the azimuthal boundary speed. For a coherent axisymmetric torsional mode satisfying

$$v_\phi = \frac{v_{\mathrm{tor}}}{R_{\mathrm{QG}}} r_\perp, \tag{U.10}$$

this reduces to

$$\mathcal{J}_{\mathrm{BH}} = I_{\mathrm{surf}} \frac{v_{\mathrm{tor}}}{R_{\mathrm{QG}}}, \tag{U.11}$$

where v_{tor} is the effective torsional boundary speed, evaluated at the boundary scale.

The dimensionless spin parameter is

$$a_* = \frac{c_{\mathrm{E}} \mathcal{J}_{\mathrm{BH}}}{GM^2}. \tag{U.12}$$

Substituting the surface-shell expression gives

$$a_* = \frac{c_{\mathrm{E}}}{GM^2} I_{\mathrm{surf}} \frac{v_{\mathrm{tor}}}{R_{\mathrm{QG}}}. \tag{U.13}$$

Using the TFT saturation radius,

$$R_{\mathrm{QG}} = \frac{GM}{c_{\mathrm{E}}^2}, \tag{U.14}$$

the spin parameter becomes

$$a_* = \left(\frac{I_{\mathrm{surf}}}{M R_{\mathrm{QG}}^2} \right) \frac{v_{\mathrm{tor}}}{c_{\mathrm{E}}}. \tag{U.15}$$

The dimensionless factor

$$\frac{I_{\mathrm{surf}}}{M R_{\mathrm{QG}}^2} \tag{U.16}$$

is the normalized surface moment of inertia of the live boundary. It is not an independent constant; it is determined by the boundary mass-current distribution.

For a uniformly loaded spherical boundary shell,

$$I_{\mathrm{surf}} = \frac{2}{3} M R_{\mathrm{QG}}^2, \tag{U.17}$$

and therefore

$$a_* = \frac{2}{3} \frac{v_{\mathrm{tor}}}{c_{\mathrm{E}}}. \tag{U.18}$$

For an equatorially concentrated boundary current,

$$I_{\mathrm{surf}} \to M R_{\mathrm{QG}}^2, \tag{U.19}$$

and therefore

$$a_* \to \frac{v_{\mathrm{tor}}}{c_{\mathrm{E}}}. \tag{U.20}$$

For any boundary-confined mass distribution,

$$0 \le r_\perp \le R_{\mathrm{QG}}, \tag{U.21}$$

so

$$I_{\mathrm{surf}} \le M R_{\mathrm{QG}}^2. \tag{U.22}$$

The torsional boundary speed is further constrained by the finite kinematic capacity of the Soft Floor,

$$v_{\mathrm{tor}} \le c_{\mathrm{E}}. \tag{U.23}$$

Therefore, within the first-order boundary-confined surface-shell approximation,

$$a_* \le 1. \tag{U.24}$$

In TFT, this spin bound is interpreted as a boundary-kinematic saturation condition. The phase boundary cannot carry torsional motion faster than the elastic response capacity of the Soft Floor, and the effective angular-momentum carrier is confined to the black-hole boundary scale.

This result identifies the mechanical carrier of black-hole angular momentum in the live-boundary model. It is not a full Kerr replacement. A Kerr-equivalent TFT solution requires the additional derivation of the external torsional Soft-Floor field, the frame-dragging analogue, the spin-dependent boundary geometry, the horizon-scale mapping, and the corresponding strong-field orbital dynamics.

U.3 Binary Black-Hole Orbital Motion

A black hole can participate in orbital motion because, externally, it behaves as a compact saturated phase-boundary object embedded in the surrounding Soft Floor. Its center-of-mass motion responds to the strain field of another compact object in the same general way that any localized mass-defect responds to an external gravitational field. This orbital motion is distinct from phase-front growth, tangential boundary redistribution, and torsional boundary spin, although these channels can become strongly coupled during merger.

For an ideal circular binary with component masses M_1 and M_2, define the total mass:

$$M_{\mathrm{tot}} = M_1 + M_2. \tag{U.25}$$

Let d be the center-to-center separation between the two saturated domains. The relative orbital velocity scale is:

$$v_{\mathrm{rel}}^2 = \frac{GM_{\mathrm{tot}}}{d}. \tag{U.26}$$

This is the relative speed between the two black holes in the two-body frame. The individual orbital speeds about the center of mass are:

$$v_1 = \frac{M_2}{M_{\mathrm{tot}}} v_{\mathrm{rel}}, \tag{U.27}$$

and

$$v_2 = \frac{M_1}{M_{\mathrm{tot}}} v_{\mathrm{rel}}. \tag{U.28}$$

Each TFT black-hole saturation radius is:

$$R_i = \frac{GM_i}{c_{\mathrm{E}}^2}. \tag{U.29}$$

Therefore,

$$R_1 + R_2 = \frac{G(M_1 + M_2)}{c_{\mathrm{E}}^2} = \frac{GM_{\mathrm{tot}}}{c_{\mathrm{E}}^2}. \tag{U.30}$$

Substituting this directly into the relative-velocity expression gives:

$$v_{\mathrm{rel}}^2 = c_{\mathrm{E}}^2 \left(\frac{R_1 + R_2}{d} \right). \tag{U.31}$$

Therefore,

$$v_{\mathrm{rel}} = c_{\mathrm{E}} \sqrt{\frac{R_1 + R_2}{d}}. \tag{U.32}$$

Here, the controlling quantity is the physical ratio $\frac{R_1+R_2}{d}$.

When the two saturation boundaries are widely separated:

$$d > R_1 + R_2 \quad \Longrightarrow \quad v_{\mathrm{rel}} < c_{\mathrm{E}}. \tag{U.33}$$

In the ideal circular boundary-contact limit:

$$d = R_1 + R_2 \quad \Longrightarrow \quad v_{\mathrm{rel}} = c_{\mathrm{E}}. \tag{U.34}$$

For equal masses, $M_1 = M_2$, the individual speeds about the center of mass are $v_1 = v_2 = \frac{1}{2}v_{\rm rel}$. At the ideal contact limit:

$$v_1 = v_2 = \frac{c_{\rm E}}{2}. \tag{U.35}$$

Therefore, the $c_{\rm E}$ condition is not a universal binary velocity law. It is a limiting contact-scale result for the relative motion of an ideal circular binary. The more general relation is controlled by the separation ratio:

$$v_{\rm rel} = c_{\rm E}\sqrt{\frac{R_1 + R_2}{d}}. \tag{U.36}$$

In the TFT phase-boundary picture, the physical merger need not wait for exact geometric contact of the two saturation radii. Merger may begin earlier if the strained FCC region between the two black holes reaches saturation and forms a common SC bridge. Thus, the contact-limit velocity should be treated as a useful limiting scale, not as a required velocity for all binary black-hole mergers.

This relation may later be formalized as a TFT contact-limit statement:

$$d \to R_1 + R_2 \quad \Longrightarrow \quad v_{\rm rel} \to c_{\rm E}, \tag{U.37}$$

but only under the assumptions of circular motion, center-to-center separation, and ideal boundary contact. It should not be overstated as a general rule for arbitrary inspiral, eccentric motion, unequal-mass merger, or nonlinear phase-boundary coalescence.

U.4 Merger as Saturated Bridge Formation

The physical merger of two TFT black holes is not the collision of two rigid bodies, and it is not the geometric limit $d = 0$. It is the formation of a common saturated phase boundary between two previously separate FCC/SC transition domains.

As two black holes inspiral, their external FCC strain fields increasingly overlap. The bridge region between the two saturated domains becomes compressed, sheared, and dynamically loaded by orbital motion, tidal distortion, boundary deformation, and spin-induced torsion. When the local Soft Floor in this bridge region can no longer remain in the active FCC state, it undergoes saturation and locks into the SC phase.

The merger therefore begins when the intermediate FCC region reaches the same phase condition that defines a black-hole boundary:

$$\text{FCC Soft Floor} \to \text{SC phase-locked substrate}. \tag{U.38}$$

At that point, the two initially separate boundaries are no longer independent. A common FCC/SC transition surface forms, and the system becomes a single saturated phase-boundary domain.

The merger sequence may be written schematically as:

$$\begin{aligned} \text{two separate SC domains} &\to \text{overlapping FCC strain fields} \to \text{saturated bridge} \\ &\to \text{common phase boundary} \to \text{single larger SC domain} \\ &\to \text{surface relaxation/ringdown}. \end{aligned} \tag{U.39}$$

A compact provisional expression for the bridge condition is:

$$\alpha_{\rm bridge} = \alpha_{\rm G,1} + \alpha_{\rm G,2} + \alpha_{\rm dyn} \geq 1. \tag{U.40}$$

Here $\alpha_{G,1}$ and $\alpha_{G,2}$ are the baseline gravitational strain contributions from the two black holes at the bridge location. The additional term $\alpha_{\rm dyn}$ represents dynamic loading of the bridge region due to orbital compression, shear, torsional boundary motion, tidal deformation, and nonlinear phase-boundary distortion.

More locally, let $\mathcal{B}_{\rm BH12}$ denote the bridge region between the two saturated black-hole domains. A common boundary begins to form when there exists a connected saturated bridge subset $\mathcal{B}_{\rm sat}(t) \subset \mathcal{B}_{\rm BH12}$ such that

$$\alpha_{\rm bridge}(\mathbf{x}, t) \geq 1 \qquad \forall\, \mathbf{x} \in \mathcal{B}_{\rm sat}(t), \tag{U.41}$$

and $\mathcal{B}_{\rm sat}(t)$ connects the two initially separate FCC/SC boundaries.

This means that merger is triggered by the formation of a connected saturated bridge in the intervening Soft Floor, not by zero separation of the two centers. The common boundary forms when the bridge region crosses the FCC-to-SC phase threshold and becomes part of a shared phase-locked substrate domain.

The term $\alpha_{\rm dyn}$ should be read as a placeholder for future strong-field surface dynamics. It is not yet a closed-form field equation. Its role in this appendix is to mark the fact that binary merger cannot be determined from the two quasi-steady strain contributions alone once the system enters the nonlinear, rapidly evolving phase-boundary regime.

Thus, the TFT merger criterion is a local mechanical saturation condition:

$$\boxed{\text{black-hole merger} = \text{formation of a saturated SC bridge and common FCC/SC boundary}}. \tag{U.42}$$

This definition is distinct from visual contact, rigid-body collision, or the formal limit $d \to 0$. In TFT, the physical merger begins when the Soft Floor between the two black holes loses its ability to remain an active FCC bridge and becomes part of the shared phase-locked substrate domain.

U.5 Surface Growth and Mass Redistribution

The radial growth law derived in Appendix S describes the average spherical expansion of the saturation boundary:

$$\dot{R}_{\rm QG} = \frac{G}{c_{\rm E}^2}\dot{M}. \tag{U.43}$$

This relation is sufficient for a spherically averaged black hole, but a live boundary requires a local surface description. During accretion, spin loading, tidal distortion, or merger, mass-energy and strain need not be deposited uniformly over the boundary. Some regions of the FCC/SC transition surface may advance faster than others, producing local bulging, flattening, distortion, and subsequent relaxation.

A minimally deformed boundary may be written schematically as:

$$R(\theta, \varphi, t) = R_{\rm QG}(t) + \delta R(\theta, \varphi, t), \tag{U.44}$$

where $R_{\rm QG}(t)$ is the average saturation radius and $\delta R(\theta, \varphi, t)$ is the local boundary deformation.

The normal boundary speed is:

$$v_n = \frac{\partial R}{\partial t}. \tag{U.45}$$

Here v_n measures the local normal motion of the FCC/SC phase front. Positive v_n corresponds to local phase-front advancement. Local relaxation may reduce δR relative to the average boundary shape, but this should not be interpreted as global black-hole evaporation or reversal of the SC phase unless a separate TFT mechanism is introduced.

To describe nonuniform boundary loading, define the effective surface mass density as:

$$\Sigma_\partial = \frac{\mathrm{d}M_\partial}{\mathrm{d}A}, \tag{U.46}$$

where M_∂ denotes the mass-energy dynamically encoded on the boundary layer to track the boundary-segregated inertial content of the black hole during nonspherical growth, redistribution, and relaxation.

Surface mass changes through four mechanical channels:

- **Incoming Matter-Energy:** $\dot{\Sigma}_{\partial,\mathrm{in}}$, the surface mass-energy deposited by infalling matter or radiation.
- **Vacuum Phase Conversion:** $\dot{\Sigma}_{\partial,\mathrm{vac}}$, the mass-equivalent contribution associated with FCC-to-SC vacuum phase conversion at the boundary.
- **Tangential Redistribution:** $\nabla_A\left(\Sigma_\partial v_\parallel^A\right)$, describing tangential redistribution of boundary mass and stress along the live phase surface.
- **Stress Shedding:** $\dot{\Sigma}_{\partial,\mathrm{shed}}$, the mass-equivalent energy shed from the boundary as gravitational-wave emission, torsional strain radiation, or other stress-relaxation channels.

For a near-spherical boundary, a schematic conservation form is:

$$\frac{\partial\Sigma_\partial}{\partial t} + \nabla_A\left(\Sigma_\partial v_\parallel^A\right) + \frac{2\Sigma_\partial v_n}{R} = \dot{\Sigma}_{\partial,\mathrm{in}} + \dot{\Sigma}_{\partial,\mathrm{vac}} - \dot{\Sigma}_{\partial,\mathrm{shed}}. \tag{U.47}$$

The expansion term $\frac{2\Sigma_\partial v_n}{R}$ represents the dilution of surface density caused by local area growth in the near-spherical approximation. If the boundary area expands while the same mass is spread over a larger surface, the surface density decreases unless compensated by additional inflow or phase conversion.

This equation should be read as a boundary bookkeeping relation, not as a completed fundamental field equation. Its role is to state how the live black-hole surface can grow, redistribute, deform, and shed stress while remaining consistent with the averaged radial law $\dot{R}_{\mathrm{QG}} = \frac{G}{c_{\mathrm{E}}^2}\dot{M}$.

In the spherical limit,

$$\delta R \to 0, \qquad v_\parallel^A \to 0, \qquad \Sigma_\partial \to \frac{M}{4\pi R_{\mathrm{QG}}^2}, \tag{U.48}$$

the local description collapses back to the averaged growth model.

U.6 Stress Shedding and Ringdown

When two black holes merge, the newly formed common FCC/SC boundary is not immediately relaxed. It is distorted, dynamically loaded, and torsionally strained. The live boundary must therefore shed excess energy, redistribute angular momentum, and settle toward a lower-strain saturated configuration.

The final mass of the remnant may be written as:

$$M_f = M_1 + M_2 - \frac{E_{\mathrm{shed}}}{c_{\mathrm{E}}^2}, \tag{U.49}$$

where $E_{\rm shed}$ is the energy carried away from the merger system through gravitational-wave strain, torsional Soft Floor radiation, and other boundary-relaxation channels.

Thus, the final axial angular momentum may be written as:

$$\mathcal{J}_f = \mathcal{J}_1^{(\rm spin)} + \mathcal{J}_2^{(\rm spin)} + \mathcal{J}_{\rm orb}^{(\rm bin)} - \mathcal{J}_{\rm shed}. \tag{U.50}$$

Here $\mathcal{J}_1^{(\rm spin)}$ and $\mathcal{J}_2^{(\rm spin)}$ are the initial spin angular momenta of the two black holes, $\mathcal{J}_{\rm orb}^{(\rm bin)}$ is the binary orbital angular momentum transferred into the merger, and $\mathcal{J}_{\rm shed}$ is the angular momentum radiated away or redistributed through outgoing Soft Floor strain.

In TFT, gravitational waves from black-hole merger are interpreted as stress-shedding waves of the live phase boundary. They are produced when the common FCC/SC transition surface rapidly reconfigures and exports excess shear, compression, and torsional loading into the surrounding Soft Floor.

The ringdown stage is the final relaxation of the distorted phase boundary. Let the post-merger boundary be written as:

$$R(\theta, \varphi, t) = R_{{\rm QG},f} + \delta R(\theta, \varphi, t), \tag{U.51}$$

where $R_{{\rm QG},f}$ is the average saturation radius of the final remnant and δR is the residual boundary deformation.

A minimal linearized relaxation model is:

$$\frac{\partial^2 \delta R}{\partial t^2} + \Gamma_{\rm QG} \frac{\partial \delta R}{\partial t} + \omega_{\rm QG}^2 \delta R = 0. \tag{U.52}$$

Here $\Gamma_{\rm QG}$ is the effective damping rate of the post-merger boundary deformation, and $\omega_{\rm QG}$ is the natural relaxation frequency of the live FCC/SC boundary. The physical interpretation is:

$$\text{ringdown} = \text{damped relaxation of the live FCC/SC phase boundary.} \tag{U.53}$$

This keeps the TFT description close to observation: the post-merger signal remains a damped oscillatory gravitational-wave signature. TFT reinterprets the mechanical origin of that signal as relaxation of a distorted saturated boundary, rather than treating it only as a geometric perturbation of the external black-hole spacetime.

In the full nonlinear merger problem, different deformation modes of the boundary would generally have different damping rates and relaxation frequencies. The single equation above is therefore not a complete waveform model. It is the lowest-order mechanical closure showing how merger distortion, stress shedding, and ringdown are connected in the live phase-boundary framework.

U.7 Kinematic Capacity Constraint

The Soft Floor has a finite elastic kinematic capacity. A live black-hole boundary therefore cannot support unlimited simultaneous motion in all of its dynamical channels. Center-of-mass translation, phase-front growth, tangential redistribution, and torsional boundary motion all draw on the same underlying capacity of the surrounding FCC vacuum to deform, transmit stress, and remain active.

In a first-order channel approximation, this may be written schematically as:

$$V_{\rm CM}^2 + v_n^2 + v_\parallel^2 + v_{\rm tor}^2 \lesssim c_{\rm E}^2. \tag{U.54}$$

Here $V_{\rm CM}$ is the center-of-mass speed of the saturated black-hole domain, v_n is the normal phase-front speed, $v_\parallel$ is the tangential boundary-redistribution speed, and $v_{\rm tor}$ is the effective torsional boundary speed associated with axial angular momentum.

This expression should not be read as a completed microscopic field equation. It is a mechanical capacity rule. Its purpose is to state that the live FCC/SC boundary must distribute the available Soft Floor response among different modes of motion.

When the combined dynamical demand remains below the Soft Floor capacity, the boundary can respond through smooth orbital motion, local growth, redistribution, and torsional loading. When the demand approaches the capacity scale c_{E}^2, smooth boundary response is no longer sufficient. The system must instead respond through one or more nonlinear mechanisms:

$$\text{phase locking,} \qquad \text{common-boundary formation,} \qquad \text{stress shedding,} \qquad \text{surface relaxation.} \tag{U.55}$$

This connects binary inspiral, saturated bridge formation, gravitational-wave emission, and ringdown into a single mechanical sequence. In TFT, merger is not merely an orbital event; it is the point at which the live boundary and intervening Soft Floor can no longer maintain separate active FCC response under the combined strain load.

A more complete mechanism would replace the schematic scalar condition with a tensorial surface-capacity law, including coupling between normal growth, tangential shear, torsion, and external Soft Floor strain. For the present appendix, the capacity condition serves only as the minimal mechanical closure needed to keep the velocity channels finite and mutually constrained.

U.8 Observational Discipline

This appendix does not claim that TFT has already replaced the Kerr solution, numerical-relativity merger simulations, or gravitational-wave waveform models. The claim is narrower.

TFT provides a mechanical interpretation and first-order surface-dynamics framework for black-hole spin, binary merger, stress shedding, and ringdown. It identifies the live FCC/SC phase boundary as the mechanical carrier of the dynamics that standard black-hole physics represents geometrically.

The present appendix therefore establishes the following interpretive map:

- black-hole spin $\rightarrow$ torsional boundary motion and external Soft Floor shear,
- binary merger $\rightarrow$ saturated bridge formation and common FCC/SC boundary,
- gravitational-wave emission $\rightarrow$ stress shedding from rapid boundary reconfiguration,
- ringdown $\rightarrow$ damped relaxation of the distorted live phase boundary.

A full TFT replacement of strong-field black-hole dynamics would still require future derivation of:

$$\text{strong-field boundary motion, surface torsional stress, frame-dragging analogue,} \tag{U.56}$$

$$\text{ISCO analogue, waveform generation, ringdown frequency spectrum.} \tag{U.57}$$

The purpose of this appendix is therefore not to present a completed waveform theory. Its purpose is to define the mechanical degrees of freedom that such a theory would require.

The contribution may be summarized as:

$$\boxed{\text{TFT converts black-hole dynamics from pure metric geometry into physical live phase-boundary mechanics.}} \tag{U.58}$$

U.9 Conclusion

This appendix extends TFT black-hole physics from spherical saturation to live surface dynamics.

A TFT black hole has center-of-mass motion, orbital motion, axial angular momentum, phase-front growth, merger dynamics, gravitational-wave stress shedding, and ringdown. These dynamics are not assigned to ordinary material flow through the saturated SC interior. They are assigned to the FCC/SC phase boundary and to the surrounding strained Soft Floor.

The saturated SC domain remains internally phase-locked. Observed black-hole spin is therefore not modeled as ordinary fluid-like circulation inside the core. In TFT, axial angular momentum is carried by torsional loading of the live boundary and by shear strain in the external Soft Floor.

Binary black-hole merger is not a zero-distance collision. It is saturated bridge formation. Two initially separate saturated domains become one larger phase-boundary system when the intervening FCC Soft Floor reaches the saturation condition and locks into the SC phase:

$$\alpha_{\text{bridge}} = \alpha_{\text{G},1} + \alpha_{\text{G},2} + \alpha_{\text{dyn}} \geq 1. \tag{U.59}$$

The ideal circular boundary-contact limit gives $v_{\text{rel}} = c_{\text{E}}$, but only at the contact scale $d = R_1 + R_2$. The general separation-controlled relation is:

$$v_{\text{rel}} = c_{\text{E}} \sqrt{\frac{R_1 + R_2}{d}}. \tag{U.60}$$

Thus, c_{E} is a contact-limit velocity scale, not a universal orbital speed for all binary separations.

Gravitational waves are interpreted as stress-shedding waves produced by rapid reconfiguration of the live FCC/SC boundary. Ringdown is the damped relaxation of the distorted post-merger phase boundary:

$$\text{ringdown} = \text{damped relaxation of the live FCC/SC phase boundary.} \tag{U.61}$$

The minimum mechanical structure required for TFT black-hole dynamics is therefore:

$$\begin{aligned} &\text{mass-bearing boundary} + \text{phase-front growth} + \text{torsional spin} \\ &+ \text{saturated bridge merger} + \text{stress-shedding radiation.} \end{aligned} \tag{U.62}$$

This appendix establishes that structure as a first-order surface theory. It does not complete the full rotating or binary black-hole solution, but it defines the mechanical program required for TFT to develop one.

Appendix V

Rotating TFT Black Holes and the Kerr Correspondence Limit

Subject: Torsional Soft-Floor Shear, Rotating Phase Boundaries, and the Exterior Correspondence Conditions for Kerr-like Observables.

The live-boundary formulation developed in Appendix Q assigns black-hole angular momentum to torsional motion of the FCC/SC phase boundary and to shear strain in the surrounding Soft Floor. That construction provides a mechanical carrier for spin. It does not, by itself, determine the full exterior field of a rotating black hole.

The purpose of this appendix is to define the exterior correspondence conditions under which the TFT continuum description can reproduce the successful external observables associated with Kerr black holes while retaining a different interior ontology. The Kerr solution is treated here as the reference exterior model for an uncharged rotating black hole. The corresponding TFT problem is to derive the external angular-momentum field from boundary torsion and Soft-Floor shear, rather than to postulate it geometrically.

The required correspondence is

$$\text{Kerr angular momentum} \quad \longrightarrow \quad \text{FCC/SC boundary torsion} + \text{external Soft-Floor shear.} \tag{V.1}$$

The analysis below is therefore a matching program. It identifies the external-field structure, boundary constraints, and observational signatures that a TFT Kerr limit must reproduce.

V.1 Kerr as the Rotating Black-Hole Target

A rotating black hole is characterized macroscopically by mass and axial angular momentum. In the TFT boundary description, the macroscopic angular momentum of the rotating black-hole system is denoted by

$$\mathcal{J}_{\mathrm{BH}}. \tag{V.2}$$

The corresponding dimensionless spin parameter is

$$a_* = \frac{c_{\mathrm{E}}\mathcal{J}_{\mathrm{BH}}}{GM^2}. \tag{V.3}$$

A Kerr-like TFT limit must reproduce more than the algebraic existence of a_*. The rotating exterior must also account for the principal spin-dependent structures associated with Kerr black holes:

- frame dragging,
- spin-dependent horizon structure,
- ergosphere structure,
- spin-dependent ISCO behavior,
- photon-ring and shadow deformation,
- spin-dependent ringdown modes,
- restricted external multipole structure.

The bound $a_* \leq 1$ is only a first consistency condition. The central Kerr-limit problem is the derivation of the external torsional field generated by $\mathcal{J}_{\rm BH}$.

V.2 Spin Normalization from the Live-Boundary Model

The live-boundary appendix gives the surface-shell normalization for black-hole spin. In that model, axial angular momentum is carried by the FCC/SC boundary and by the external torsional response of the Soft Floor.

The imported relation is

$$\mathcal{J}_{\rm BH} = I_{\rm surf}\frac{v_{\rm tor}}{R_{\rm QG}}, \tag{V.4}$$

where $I_{\rm surf}$ is the effective surface moment of inertia, $v_{\rm tor}$ is the torsional boundary speed, and $R_{\rm QG}$ is the TFT saturation radius.

Using

$$R_{\rm QG} = \frac{GM}{c_{\rm E}^2}, \tag{V.5}$$

the spin parameter becomes

$$a_* = \left(\frac{I_{\rm surf}}{MR_{\rm QG}^2}\right)\frac{v_{\rm tor}}{c_{\rm E}}. \tag{V.6}$$

For a boundary-confined surface current,

$$\frac{I_{\rm surf}}{MR_{\rm QG}^2} \leq 1, \tag{V.7}$$

and the Soft-Floor kinematic capacity gives

$$v_{\rm tor} \leq c_{\rm E}. \tag{V.8}$$

Thus,

$$a_* \leq 1. \tag{V.9}$$

This result fixes the spin normalization used below. The remaining Kerr-limit question is whether this boundary angular momentum sources an external torsional Soft-Floor field with the required Kerr-like structure.

V.3 Axisymmetric Torsional Soft-Floor Field

A rotating TFT black hole sources an azimuthal shear response in the surrounding FCC Soft Floor. This response is not ordinary material rotation of the SC saturated interior. The saturated SC domain supplies the phase-locked internal boundary condition, while the live FCC/SC boundary imposes torsional loading on the external Soft Floor.

Let the spin axis define the z-axis and let

$$r_\perp = r\sin\theta \tag{V.10}$$

denote the cylindrical distance from that axis. In the stationary axisymmetric exterior, the leading torsional response may be written as

$$v_\phi^{(\mathrm{SF})}(r,\theta) = r_\perp\,\omega_{\mathrm{drag}}(r) = r\sin\theta\,\omega_{\mathrm{drag}}(r), \tag{V.11}$$

where $\omega_{\mathrm{drag}}(r)$ is the local torsional dragging rate of the Soft Floor.

Neighboring spherical shells are torsionally sheared when their dragging rates differ. The corresponding radial torsional shear intensity is

$$\gamma_{r\phi}^{(\mathrm{tor})} = r\sin\theta\frac{d\omega_{\mathrm{drag}}}{dr}. \tag{V.12}$$

Let $\tau_{\mathrm{tor}}(r)$ denote the effective torsional stiffness of the external Soft Floor. (Here $\tau_{\mathrm{tor}}(r)$ denotes the effective three-dimensional torsional stiffness density of the strained FCC Soft Floor in the azimuthal shear channel. It is not introduced as a new fundamental constant; in the weak exterior it approaches the baseline Soft-Floor torsional stiffness, while near the saturated boundary it may acquire strain dependence through $\alpha_G(r)$.)

Then,tThe exterior torsional strain-energy cost is proportional to

$$\mathcal{E}_{\mathrm{tor}} \propto \int_{R_{\mathrm{QG}}}^{\infty}\int \tau_{\mathrm{tor}}(r)\left[r\sin\theta\frac{d\omega_{\mathrm{drag}}}{dr}\right]^2 r^2\sin\theta\,d\theta\,d\phi\,dr. \tag{V.13}$$

Using

$$\int_0^{2\pi}\int_0^{\pi}\sin^3\theta\,d\theta\,d\phi = \frac{8\pi}{3}, \tag{V.14}$$

this becomes

$$\mathcal{E}_{\mathrm{tor}} \propto \frac{8\pi}{3}\int_{R_{\mathrm{QG}}}^{\infty}\tau_{\mathrm{tor}}(r)r^4\left(\frac{d\omega_{\mathrm{drag}}}{dr}\right)^2 dr. \tag{V.15}$$

The stationary exterior torsional field is obtained by minimizing this functional subject to the boundary rotation at R_{QG}. The Euler–Lagrange equation is

$$\frac{d}{dr}\left[\tau_{\mathrm{tor}}(r)r^4\frac{d\omega_{\mathrm{drag}}}{dr}\right] = 0. \tag{V.16}$$

This is the leading axisymmetric torsional Soft-Floor field equation.

The solution below uses the strong-coupling boundary condition in which the external FCC Soft Floor is torsionally locked to the live FCC/SC boundary at R_{QG}. Thus,

$$\omega_{\mathrm{drag}}(R_{\mathrm{QG}}) = \omega_\partial, \tag{V.17}$$

where

$$\omega_{\partial} = \frac{v_{\rm tor}}{R_{\rm QG}}. \tag{V.18}$$

This is the no-slip torsional limit of the boundary coupling. A more general formulation would prescribe the transmitted boundary torque rather than the boundary angular velocity. In that case, the conjugate exterior torsional loading is proportional to

$$\tau_{\rm tor}(r) r^4 \frac{d\omega_{\rm drag}}{dr}\bigg|_{r=R_{\rm QG}}, \tag{V.19}$$

which is the radial torsional flux appearing inside the field equation. The present appendix uses the strong-coupling form because it gives the clean leading correspondence limit between the rotating boundary and the exterior Soft-Floor shear field.

In the weak exterior, where the torsional stiffness approaches its baseline value,

$$\tau_{\rm tor}(r) \to \tau_{\rm tor,0}, \tag{V.20}$$

the equation reduces to

$$\frac{d}{dr}\left[r^4 \frac{d\omega_{\rm drag}}{dr}\right] = 0. \tag{V.21}$$

Imposing

$$\omega_{\rm drag}(\infty) = 0 \tag{V.22}$$

and

$$\omega_{\rm drag}(R_{\rm QG}) = \omega_{\partial} = \frac{v_{\rm tor}}{R_{\rm QG}}, \tag{V.23}$$

gives

$$\omega_{\rm drag}(r) = \omega_{\partial}\left(\frac{R_{\rm QG}}{r}\right)^3. \tag{V.24}$$

Therefore,

$$\omega_{\rm drag}(r) = \frac{v_{\rm tor}}{R_{\rm QG}}\left(\frac{R_{\rm QG}}{r}\right)^3, \tag{V.25}$$

and the corresponding tangential Soft-Floor shear speed is

$$v_{\phi}^{(\rm SF)}(r,\theta) = v_{\rm tor}\left(\frac{R_{\rm QG}}{r}\right)^2 \sin\theta. \tag{V.26}$$

Using the live-boundary spin relation

$$\mathcal{J}_{\rm BH} = I_{\rm surf}\frac{v_{\rm tor}}{R_{\rm QG}}, \tag{V.27}$$

the exterior dragging rate can also be written as

$$\omega_{\rm drag}(r) = \frac{\mathcal{J}_{\rm BH}}{I_{\rm surf}}\left(\frac{R_{\rm QG}}{r}\right)^3. \tag{V.28}$$

Since

$$R_{\rm QG} = \frac{GM}{c_{\rm E}^2}, \tag{V.29}$$

this becomes

$$\omega_{\rm drag}(r) = \left(\frac{MR_{\rm QG}^2}{I_{\rm surf}}\right)\frac{G\mathcal{J}_{\rm BH}}{c_{\rm E}^2 r^3}. \tag{V.30}$$

Thus, the TFT torsional Soft-Floor field naturally recovers the required far-field angular-momentum scaling,

$$\omega_{\rm drag}(r) \propto \frac{G\mathcal{J}_{\rm BH}}{c_{\rm E}^2 r^3}. \tag{V.31}$$

In terms of the dimensionless spin parameter,

$$a_* = \frac{c_{\rm E}\mathcal{J}_{\rm BH}}{GM^2}, \tag{V.32}$$

the tangential Soft-Floor shear speed is

$$v_\phi^{(\rm SF)}(r,\theta) = c_{\rm E} a_* \left(\frac{MR_{\rm QG}^2}{I_{\rm surf}}\right)\left(\frac{R_{\rm QG}}{r}\right)^2 \sin\theta. \tag{V.33}$$

More generally, if the torsional stiffness varies near the saturated boundary, the solution of the field equation is

$$\omega_{\rm drag}(r) = \omega_\partial \frac{\displaystyle\int_r^\infty \frac{ds}{\tau_{\rm tor}(s)s^4}}{\displaystyle\int_{R_{\rm QG}}^\infty \frac{ds}{\tau_{\rm tor}(s)s^4}}. \tag{V.34}$$

The inverse-cubic dragging law is therefore the constant-stiffness exterior limit of the more general torsional Soft-Floor response.

V.4 Effective Rotating Optical Geometry

The torsional Soft-Floor field derived above determines how the exterior vacuum is mechanically dragged by a rotating FCC/SC boundary. To connect this field to observable propagation, the static TFT optical law must be extended to a rotating medium.

In the nonrotating exterior, the local propagation speed of a transverse excitation is

$$c_P(r) = c_{\rm E}\left(1 - \alpha_G(r)\right)^2, \tag{V.35}$$

with

$$\alpha_G(r) = \frac{GM}{rc_{\rm E}^2} = \frac{R_{\rm QG}}{r}. \tag{V.36}$$

Thus,

$$c_P(r) = c_{\rm E}\left(1 - \frac{R_{\rm QG}}{r}\right)^2. \tag{V.37}$$

In the rotating exterior, the Soft Floor also carries the azimuthal drift

$$v_\phi^{(\rm SF)}(r,\theta) = r\sin\theta\,\omega_{\rm drag}(r). \tag{V.38}$$

The local propagation problem therefore becomes a moving-medium problem: waves propagate through a radially strained medium that is also torsionally dragged in the azimuthal direction.

Let a high-frequency excitation have phase

$$\Theta_{\rm ray} = -\omega t + m_\phi \phi + \Theta_r(r) + \Theta_\theta(\theta), \tag{V.39}$$

where ω is the conserved frequency and m_ϕ is the azimuthal mode number. The local wavevector components are

$$k_r = \frac{\partial \Theta_r}{\partial r}, \qquad k_\theta = \frac{\partial \Theta_\theta}{\partial \theta}, \qquad k_\phi = \frac{m_\phi}{r \sin\theta}. \tag{V.40}$$

The frequency measured in the locally dragged Soft-Floor frame is shifted by the azimuthal drift:

$$\omega_{\rm loc} = \omega - \mathbf{k} \cdot \mathbf{v}_{\rm SF}. \tag{V.41}$$

Using

$$\mathbf{k} \cdot \mathbf{v}_{\rm SF} = k_\phi v_\phi^{\rm (SF)} = \frac{m_\phi}{r \sin\theta} \left(r \sin\theta \, \omega_{\rm drag} \right), \tag{V.42}$$

gives

$$\omega_{\rm loc} = \omega - m_\phi \omega_{\rm drag}(r). \tag{V.43}$$

The local Soft-Floor dispersion relation is therefore

$$\left[\omega - m_\phi \omega_{\rm drag}(r)\right]^2 = c_P^2(r) \left[k_r^2 + \frac{k_\theta^2}{r^2} + \frac{m_\phi^2}{r^2 \sin^2\theta} \right]. \tag{V.44}$$

This is the leading eikonal propagation law for the rotating TFT exterior. The same torsional field that carries black-hole angular momentum now shifts the local wave frequency by $m_\phi \omega_{\rm drag}$, thereby producing the TFT frame-dragging mechanism. Prograde modes ($m_\phi \omega_{\rm drag} > 0$) and retrograde modes ($m_\phi \omega_{\rm drag} < 0$) therefore propagate through different effective strain environments.

The same result may be packaged as an effective rotating optical line element. Let the spatial optical factor remain the static TFT strain factor and replace the azimuthal differential by the locally dragged differential $d\phi - \omega_{\rm drag} dt$. The resulting leading stationary axisymmetric optical form is

$$\begin{aligned} ds^2_{\tau,\rm rot} = & -c_{\rm E}^2 \left(1 - \alpha_G\right)^2 dt^2 + \left(1 - \alpha_G\right)^{-2} \Big[dr^2 + r^2 d\theta^2 \\ & + r^2 \sin^2\theta \left(d\phi - \omega_{\rm drag}(r) dt \right)^2 \Big]. \end{aligned} \tag{V.45}$$

Expanding the azimuthal term gives the effective off-diagonal component

$$g_{t\phi}^{(\tau)} = -\left(1 - \alpha_G\right)^{-2} r^2 \sin^2\theta \, \omega_{\rm drag}(r). \tag{V.46}$$

Thus, the off-diagonal frame-dragging structure is not postulated geometrically. It is induced by the torsional motion of the external Soft Floor.

Using the constant-stiffness exterior solution,

$$\omega_{\rm drag}(r) = \omega_\partial \left(\frac{R_{\rm QG}}{r} \right)^3, \tag{V.47}$$

the off-diagonal exterior component scales as

$$g_{t\phi}^{(\tau)} \propto -\left(1 - \alpha_G\right)^{-2} \frac{R_{\rm QG}^3 \omega_\partial}{r} \sin^2\theta. \tag{V.48}$$

Equivalently, using the angular-momentum form,

$$g_{t\phi}^{(\tau)} \propto -\,(1-\alpha_G)^{-2}\left(\frac{MR_{\rm QG}^2}{I_{\rm surf}}\right)\frac{G\mathcal{J}_{\rm BH}}{c_{\rm E}^2 r}\sin^2\theta. \tag{V.49}$$

The important result is the radial structure: the angular dragging rate falls as r^{-3}, while the off-diagonal optical coupling falls as r^{-1} in the far exterior. This is the required leading behavior for a rotating angular-momentum field in a Kerr-correspondence limit. The remaining difference between this TFT optical form and the exact Kerr metric is a strong-field normalization problem, not the absence of a mechanical frame-dragging carrier.

V.5 Torsional Capacity Surface and Ergosphere Correspondence

The rotating optical form above gives a mechanical criterion for the TFT analogue of an ergosphere. In a stationary axisymmetric exterior, a locally nonrotating state becomes mechanically unavailable when the azimuthal Soft-Floor drift equals the local transverse propagation capacity.

The torsional capacity condition is therefore

$$\left|v_\phi^{(\rm SF)}(r,\theta)\right| = c_P(r). \tag{V.50}$$

Using

$$v_\phi^{(\rm SF)}(r,\theta) = v_{\rm tor}\left(\frac{R_{\rm QG}}{r}\right)^2\sin\theta \tag{V.51}$$

and

$$c_P(r) = c_{\rm E}\left(1-\frac{R_{\rm QG}}{r}\right)^2, \tag{V.52}$$

the capacity surface is defined by

$$v_{\rm tor}\left(\frac{R_{\rm QG}}{r}\right)^2\sin\theta = c_{\rm E}\left(1-\frac{R_{\rm QG}}{r}\right)^2. \tag{V.53}$$

Introduce the dimensionless radius

$$x = \frac{r}{R_{\rm QG}} \tag{V.54}$$

and the boundary torsional fraction

$$u_{\rm tor} = \frac{v_{\rm tor}}{c_{\rm E}}. \tag{V.55}$$

The capacity condition becomes

$$u_{\rm tor}\frac{\sin\theta}{x^2} = \left(1-\frac{1}{x}\right)^2 = \frac{(x-1)^2}{x^2}. \tag{V.56}$$

Multiplying by x^2 gives

$$(x-1)^2 = u_{\rm tor}\sin\theta. \tag{V.57}$$

The outer torsional capacity surface is therefore

$$r_{\rm cap}(\theta) = R_{\rm QG}\left[1+\sqrt{u_{\rm tor}\sin\theta}\right]. \tag{V.58}$$

In this formulation, the ergosphere correspondence is not introduced as a metaphor. It is the region in which the Soft Floor is dragged so strongly that nonrotating propagation is no longer kinematically available. On the spin axis, $\sin\theta = 0$, and the torsional capacity surface collapses to the saturation boundary:

$$r_{\rm cap}(0) = R_{\rm QG}. \tag{V.59}$$

At the equator,

$$r_{\rm cap}\left(\frac{\pi}{2}\right) = R_{\rm QG}\left(1 + \sqrt{u_{\rm tor}}\right). \tag{V.60}$$

For the limiting boundary speed $v_{\rm tor} \to c_{\rm E}$, this gives

$$r_{\rm cap}\left(\frac{\pi}{2}\right) \to 2R_{\rm QG}. \tag{V.61}$$

This result is a TFT-native capacity surface. It should not be identified prematurely with the exact Kerr ergosurface. Rather, it is the mechanical surface on which torsional Soft-Floor drift equals the local propagation capacity. A completed Kerr correspondence must determine how this capacity surface maps onto the observational ergosphere after the horizon-scale normalization is fixed.

V.6 Orbital and Photon-Ring Dynamics in the Rotating Exterior

The eikonal propagation law supplies the starting point for photon-ring and shadow calculations. Define the massless rotating-exterior Hamiltonian

$$\mathcal{H}_\gamma = \frac{1}{2}\left[-\frac{\left(\omega - m_\phi \omega_{\rm drag}(r)\right)^2}{c_P^2(r)} + k_r^2 + \frac{k_\theta^2}{r^2} + \frac{m_\phi^2}{r^2\sin^2\theta}\right]. \tag{V.62}$$

Massless Soft-Floor shear rays satisfy

$$\mathcal{H}_\gamma = 0. \tag{V.63}$$

In the equatorial plane, $\theta = \pi/2$ and $k_\theta = 0$. The radial condition becomes

$$k_r^2 = \frac{\left(\omega - m_\phi \omega_{\rm drag}(r)\right)^2}{c_P^2(r)} - \frac{m_\phi^2}{r^2}. \tag{V.64}$$

A circular photon-ring analogue occurs when the radial motion has a double root:

$$k_r^2 = 0, \qquad \frac{d}{dr}\left(k_r^2\right) = 0. \tag{V.65}$$

These two equations define the TFT photon-ring condition in the leading rotating exterior.

For massive boundary defects or compact orbiting matter, the same torsional field enters as a spin-orbit coupling. A minimal effective-potential form is

$$\Phi_{\rm eff} = \Phi_{\rm radial} + \Phi_{\rm orbital} + \Phi_{\rm spin}, \tag{V.66}$$

with the leading spin term sourced by the Soft-Floor dragging rate:

$$\Phi_{\rm spin} = -\ell_{\rm orb}\omega_{\rm drag}(r). \tag{V.67}$$

Here $\ell_{\rm orb}$ is the specific orbital angular momentum of the test body. The sign of this term distinguishes prograde and retrograde motion:

$$\ell_{\rm orb}\omega_{\rm drag} > 0 \quad \Rightarrow \quad \text{prograde lowering of the effective strain barrier,} \tag{V.68}$$

$$\ell_{\rm orb}\omega_{\rm drag} < 0 \quad \Rightarrow \quad \text{retrograde raising of the effective strain barrier.} \tag{V.69}$$

An ISCO analogue must then be derived from the ordinary stability conditions on the rotating effective potential:

$$\frac{d\Phi_{\rm eff}}{dr} = 0, \qquad \frac{d^2\Phi_{\rm eff}}{dr^2} = 0. \tag{V.70}$$

The first equation selects a circular orbit, while the second marks the transition from stable to unstable circular motion. This appendix does not assert the exact Kerr ISCO formula. It supplies the TFT-native mechanical source of the prograde/retrograde split and identifies the equations from which the corresponding orbital radii must be derived.

V.7 Rotating Phase-Boundary Geometry

A rotating saturated boundary need not remain exactly spherical. Torsional loading modifies the stress distribution over the FCC/SC transition surface and can generate an axisymmetric deformation.

A minimal representation is

$$R(\theta) = R_{\rm QG} + \delta R_{\rm spin}(\theta), \tag{V.71}$$

where $R_{\rm QG}$ is the average saturation radius and $\delta R_{\rm spin}$ is the spin-induced boundary deformation.

Since the static boundary shape must be invariant under reversal of the spin direction, the leading deformation is even in a_*. The lowest-order axisymmetric correction is therefore expected to have the form

$$\delta R_{\rm spin}(\theta) \propto a_*^2 P_2(\cos\theta), \tag{V.72}$$

with P_2 the second Legendre polynomial.

This expression is an ansatz for the leading deformation channel. A Kerr-compatible TFT solution must determine whether saturation and relaxation select a unique spin-deformed boundary, rather than allowing arbitrary elastic surface structure.

V.8 Multipole Constraint and Boundary Relaxation

The strongest condition on a TFT Kerr correspondence limit is not the spin bound alone, but the exterior multipole structure.

A generic rotating continuum body can carry arbitrary shape-dependent multipoles. A Kerr black hole does not have freely adjustable exterior multipoles; its exterior field is fixed by mass and angular momentum. In TFT terms, the relaxed rotating FCC/SC boundary must therefore erase arbitrary surface memory and produce an exterior strain field determined only by M and $\mathcal{J}_{\rm BH}$.

The required condition is

$$\text{relaxed rotating FCC/SC boundary} \quad \Rightarrow \quad \text{exterior field fixed by } M \text{ and } \mathcal{J}_{\rm BH}. \tag{V.73}$$

Equivalently, a Kerr-compatible saturated boundary must not retain independent surface hair in its relaxed exterior field.

This condition can be expressed as a dissipative boundary-selection principle. Let the stored exterior-plus-boundary strain energy be written schematically as

$$\mathcal{E}_{\rm stored} = \mathcal{E}_{\rm radial} + \mathcal{E}_{\rm tor} + \mathcal{E}_{\partial}, \tag{V.74}$$

where $\mathcal{E}_{\rm radial}$ is the static radial strain energy, $\mathcal{E}_{\rm tor}$ is the exterior torsional Soft-Floor shear energy, and $\mathcal{E}_{\partial}$ is the deformation energy of the live FCC/SC boundary.

During merger, accretion, or spin readjustment, arbitrary surface distortions may be excited. These distortions are not independent conserved exterior charges. They are transient boundary stresses that must be removed through stress shedding and ringdown. The dissipative approach to a relaxed exterior may be written as

$$\frac{d\mathcal{E}_{\rm stored}}{dt} = -\mathcal{P}_{\rm shed} \leq 0, \tag{V.75}$$

where $\mathcal{P}_{\rm shed} \geq 0$ is the power carried away by outgoing gravitational stress waves and other boundary-relaxation channels.

The relaxed boundary satisfies

$$\delta\mathcal{E}_{\rm stored} = 0, \tag{V.76}$$

subject to fixed total mass and fixed axial angular momentum,

$$\delta M = 0, \qquad \delta\mathcal{J}_{\rm BH} = 0. \tag{V.77}$$

Thus, non-universal surface multipoles are damped by stress shedding until the exterior field depends only on the conserved quantities M and $\mathcal{J}_{\rm BH}$. This is the TFT boundary-relaxation analogue of the no-hair condition. Without such a selection principle, TFT would describe a generic rotating elastic object rather than a Kerr-correspondence black hole.

V.9 Ringdown Spectrum of a Rotating Boundary

The live-boundary appendix introduced a scalar relaxation model for post-merger boundary deformation. A Kerr-compatible limit requires a mode spectrum for the rotating boundary.

A general angular-mode expansion may be written as

$$\delta R(\theta,\phi,t) = \sum_{\ell,m} A_{\ell m} e^{-\Gamma^{(\rm rd)}_{\ell m} t} \cos\left(\omega_{\ell m} t + \varphi^{(0)}_{\ell m}\right) Y_{\ell m}(\theta,\phi). \tag{V.78}$$

For a Kerr-like boundary attractor, the final ringdown spectrum must depend only on the remnant mass and spin:

$$\omega_{\ell m} = \omega_{\ell m}(M, a_*), \tag{V.79}$$

$$\Gamma^{(\rm rd)}_{\ell m} = \Gamma^{(\rm rd)}_{\ell m}(M, a_*). \tag{V.80}$$

This is the dynamical counterpart of the multipole constraint. Merger may excite arbitrary transient surface structure, but the relaxed spectrum must lose dependence on uncontrolled boundary details. The observable ringdown modes then become normal modes of the rotating FCC/SC phase boundary.

V.10 Horizon-Scale Normalization

A Kerr-correspondence construction must distinguish the physical TFT phase boundary from the coordinate surfaces used in the standard Kerr description.

In the present TFT convention, the saturation radius is

$$R_{\mathrm{QG}} = \frac{GM}{c_{\mathrm{E}}^2}. \tag{V.81}$$

This is the physical FCC/SC phase boundary. It is the radius at which the active Soft Floor reaches the saturation condition

$$\alpha_G = \frac{GM}{r c_{\mathrm{E}}^2} = 1. \tag{V.82}$$

Thus,

$$R_{\mathrm{QG}} = \text{physical FCC/SC saturation boundary.} \tag{V.83}$$

This surface should not be automatically identified with the Boyer–Lindquist coordinate horizon of Kerr geometry. In standard Kerr notation, the gravitational length is

$$R_g = \frac{GM}{c^2}, \tag{V.84}$$

and the outer Kerr horizon coordinate is

$$r_+ = R_g \left(1 + \sqrt{1 - a_*^2}\right). \tag{V.85}$$

For a nonrotating Schwarzschild black hole,

$$r_+ = 2R_g, \tag{V.86}$$

while for the extremal Kerr coordinate limit,

$$r_+ = R_g. \tag{V.87}$$

TFT does not require the physical FCC/SC boundary to coincide directly with these coordinate radii. Instead, a Kerr correspondence requires two distinct notions of boundary:

$$R_{\mathrm{QG}} = \text{physical phase-transition boundary,} \tag{V.88}$$

and

$$R_{\mathrm{obs}}(a_*) = \text{outer optical or causal correspondence surface.} \tag{V.89}$$

The physical boundary R_{QG} is set by lattice saturation. The observational surface $R_{\mathrm{obs}}(a_*)$ is the surface inferred from external light propagation, causal trapping, frame dragging, shadow structure, or accretion-disk phenomenology.

This distinction is necessary because TFT replaces the interior and horizon ontology of GR. The correspondence problem is therefore not

$$R_{\mathrm{QG}} = r_+ \tag{V.90}$$

as an assumption. Rather, the required map is

$$\left[R_{\mathrm{QG}},\, \omega_{\mathrm{drag}}(r),\, c_P(r),\, v_\phi^{(\mathrm{SF})}(r,\theta)\right] \longrightarrow R_{\mathrm{obs}}(a_*). \tag{V.91}$$

Thus, the completed rotating TFT black-hole solution must determine how the physical FCC/SC boundary and the derived optical/capacity surfaces correspond to the observational horizon, ergosphere, photon ring, and shadow scales used in Kerr phenomenology.

V.11 Minimal Kerr-Correspondence Program

A TFT continuum construction of a Kerr-correspondence exterior requires the following minimum steps. The objective is not to reproduce Kerr geometry as a fundamental ontology, but to determine when the rotating TFT boundary produces the same successful external observational signatures.

First, specify the rotating black-hole state by its conserved mass and macroscopic axial angular momentum,

$$M, \qquad \mathcal{J}_{\mathrm{BH}}, \tag{V.92}$$

with dimensionless spin parameter

$$a_* = \frac{c_{\mathrm{E}}\mathcal{J}_{\mathrm{BH}}}{GM^2}. \tag{V.93}$$

Second, use the live-boundary spin normalization

$$\mathcal{J}_{\mathrm{BH}} = I_{\mathrm{surf}}\frac{v_{\mathrm{tor}}}{R_{\mathrm{QG}}}, \tag{V.94}$$

so that the observed spin is carried mechanically by torsional loading of the FCC/SC phase boundary and by shear strain in the surrounding Soft Floor.

Third, use the derived axisymmetric torsional Soft-Floor field equation

$$\frac{\mathrm{d}}{\mathrm{d}r}\left[\tau_{\mathrm{tor}}(r)r^4\frac{\mathrm{d}\omega_{\mathrm{drag}}}{\mathrm{d}r}\right] = 0 \tag{V.95}$$

to determine the exterior angular-drag field. In the constant-stiffness exterior limit this gives

$$\omega_{\mathrm{drag}}(r) = \omega_\partial\left(\frac{R_{\mathrm{QG}}}{r}\right)^3, \tag{V.96}$$

where

$$\omega_\partial = \frac{v_{\mathrm{tor}}}{R_{\mathrm{QG}}}. \tag{V.97}$$

Fourth, connect the dragging field to wave propagation through the rotating optical relation

$$[\omega - m_\phi\omega_{\mathrm{drag}}(r)]^2 = c_P^2(r)\left[k_r^2 + \frac{k_\theta^2}{r^2} + \frac{m_\phi^2}{r^2\sin^2\theta}\right]. \tag{V.98}$$

This equation supplies the TFT frame-dragging mechanism: prograde and retrograde modes experience different effective propagation conditions because the local Soft Floor is torsionally dragged.

Fifth, identify the torsional capacity surface by solving

$$\left|v_\phi^{(\mathrm{SF})}(r,\theta)\right| = c_P(r), \tag{V.99}$$

rather than postulating an ergosphere by analogy. In the constant-stiffness exterior approximation,

$$v_\phi^{(\mathrm{SF})}(r,\theta) = v_{\mathrm{tor}}\left(\frac{R_{\mathrm{QG}}}{r}\right)^2\sin\theta, \tag{V.100}$$

and

$$c_P(r) = c_{\mathrm{E}}\left(1 - \frac{R_{\mathrm{QG}}}{r}\right)^2. \tag{V.101}$$

Therefore, the capacity surface is

$$r_{\rm cap}(\theta) = R_{\rm QG}\left[1 + \sqrt{\frac{v_{\rm tor}}{c_{\rm E}}\sin\theta}\right]. \tag{V.102}$$

Sixth, determine the spin-induced boundary deformation by solving the live-boundary equilibrium problem. At lowest order, the deformation is expected to enter through an axisymmetric quadrupolar channel,

$$R(\theta) = R_{\rm QG} + \delta R_{\rm spin}(\theta), \tag{V.103}$$

with

$$\delta R_{\rm spin}(\theta) \propto a_*^2 P_2(\cos\theta) \tag{V.104}$$

as the leading deformation ansatz. A completed theory must derive this deformation from boundary stress balance rather than assume it.

Seventh, impose the boundary-relaxation selection principle. Arbitrary surface multipoles must be damped by stress shedding and ringdown, leaving a relaxed exterior determined only by

$$M \qquad \text{and} \qquad \mathcal{J}_{\rm BH}. \tag{V.105}$$

Equivalently, the relaxed boundary must satisfy

$$\delta\mathcal{E}_{\rm stored} = 0, \tag{V.106}$$

with dissipative approach

$$\frac{{\rm d}\mathcal{E}_{\rm stored}}{{\rm d}t} = -\mathcal{P}_{\rm shed} \le 0. \tag{V.107}$$

Eighth, derive ISCO, photon-ring, and shadow analogues from the same rotating exterior propagation law. For massless shear excitations, the eikonal Hamiltonian is

$$\mathcal{H}_\gamma = \frac{1}{2}\left[-\frac{\left(\omega - m_\phi\omega_{\rm drag}(r)\right)^2}{c_P^2(r)} + k_r^2 + \frac{k_\theta^2}{r^2} + \frac{m_\phi^2}{r^2\sin^2\theta}\right] = 0. \tag{V.108}$$

Photon-ring and shadow structures must follow from stationary and unstable circular solutions of this Hamiltonian, rather than from an imported Kerr metric.

Ninth, derive the rotating-boundary ringdown spectrum as a normal-mode problem of the live FCC/SC boundary coupled to the torsional Soft-Floor exterior:

$$\omega_{\ell m} = \omega_{\ell m}(M, a_*), \qquad \Gamma_{\ell m}^{\rm (rd)} = \Gamma_{\ell m}^{\rm (rd)}(M, a_*). \tag{V.109}$$

A Kerr-correspondence limit requires that the dominant relaxed modes depend only on the conserved mass and spin, not on arbitrary initial boundary distortions.

Tenth, determine the correspondence map between the physical TFT phase boundary and the observational horizon-scale surfaces:

$$R_{\rm QG} \longrightarrow R_{\rm obs}(a_*). \tag{V.110}$$

Here

$$R_{\rm QG} = \frac{GM}{c_{\rm E}^2} \tag{V.111}$$

is the physical FCC/SC saturation boundary, while $R_{\rm obs}(a_*)$ denotes the outer optical or causal surface inferred from light propagation, frame dragging, capacity trapping, shadow structure, or accretion phenomenology.

These conditions define the minimum mathematical content of a Kerr-correspondence TFT solution. The completed theory must show that the physical FCC/SC phase boundary, the torsional Soft-Floor drag field, and the rotating optical propagation law reproduce the empirically successful external signatures of Kerr black holes while replacing the GR interior and horizon ontology with mechanical phase-boundary dynamics.

V.12 Conclusion

This appendix formulates the Kerr-limit problem for TFT continuum mechanics. The live-boundary model provides the mechanical carrier of black-hole angular momentum. A Kerr-compatible extension must derive the exterior rotating field produced by that carrier.

The proposed structure is

rotating black hole = phase-locked saturated domain+torsional FCC/SC boundary+external rotating Soft-Floor (V.112)

The corresponding development sequence is

boundary torsion → Soft-Floor shear → rotating optical geometry → capacity surface → ISCO/photon-ring dynar (V.113)

The present appendix identifies the Kerr-correspondence conditions required of a rotating TFT exterior. The detailed constitutive closure, coefficient matching, photon-ring equations, ISCO map, observational surface map, ringdown scaling, and numerical exterior solver are developed in Appendix W.

Appendix W

Constitutive Closure for Rotating TFT Black-Hole Exteriors

This appendix develops the constitutive closure required to treat rotating TFT black holes as phenomenological alternatives to Kerr exteriors. Appendix U introduced the black hole as a live FCC/SC phase boundary coupled to an external strained Soft Floor. Appendix V then formulated the rotating TFT black-hole exterior and identified the correspondence conditions required for Kerr-like behavior. The present appendix turns that correspondence structure into a closed continuum-mechanical exterior model.

The objective is not to claim that the Kerr exterior has already been derived from microscopic FCC/SC node dynamics. Rather, the purpose is to construct a Kerr-correspondence continuum closure: the weak-field frame-dragging coefficient, the no-hair quadrupole relation, and the leading optical and orbital observables are constrained to agree with established black-hole phenomenology where required, while the strong-field saturation boundary, capacity surface, photon-ring structure, ISCO map, shadow scale, and ringdown spectrum are expressed in TFT variables.

The fundamental inputs are the final mass M, total black-hole angular momentum $\mathcal{J}_{\mathrm{BH}}$, and dimensionless spin

$$a_* = \frac{c_{\mathrm{E}}\mathcal{J}_{\mathrm{BH}}}{GM^2}. \tag{W.1}$$

The associated TFT mass scale is

$$R_{\mathrm{QG}} = \frac{GM}{c_{\mathrm{E}}^2}. \tag{W.2}$$

In the nonrotating limit, R_{QG} is the spherical FCC/SC saturation radius. In the rotating case, the actual phase boundary becomes a spin-deformed surface

$$r_{\mathrm{sat}}(\theta, a_*), \tag{W.3}$$

defined by the saturation condition

$$\alpha_{\mathrm{G}}(r_{\mathrm{sat}}, \theta) = 1. \tag{W.4}$$

The appendix proceeds by closing the torsional stiffness law, matching the weak-field angular-drag coefficient, deriving photon-ring and massive-particle orbit conditions, constructing the observational surface map, formulating the ringdown spectrum, and finally assembling these elements into a numerical exterior free-boundary solver.

This establishes a constrained, computable TFT replacement framework for rotating black-hole exteriors. The weak-field Kerr correspondence is imposed as a phenomenological consistency

condition; possible TFT-specific deviations are reserved for the nonlinear strong-field regime near the FCC/SC saturation boundary.

W.1 Constitutive Closure for the Torsional Soft-Floor Stiffness ($\tau_{\mathrm{tor}}(\alpha_{\mathrm{G}})$)

Appendix U establishes that black-hole spin in TFT is not ordinary material rotation of the SC saturated interior. The spin degree of freedom is carried by the live FCC/SC phase boundary and transmitted into the surrounding FCC Soft Floor as torsional shear. Appendix V then derives the leading exterior torsional field equation for the dragged Soft Floor. The remaining constitutive question is what stiffness coefficient should appear in that exterior torsional equation.

The quantity to be determined is:

$$\tau_{\mathrm{tor}}(\alpha_{\mathrm{G}}). \tag{W.5}$$

This coefficient represents the effective three-dimensional torsional stiffness density of the active FCC Soft Floor in the azimuthal shear channel. It is not introduced as a new fundamental constant. It must be fixed by the already-defined Soft-Floor stiffness, inertia, and strained propagation laws of TFT.

The active FCC Soft Floor has surface shear stiffness

$$\tau_D = \frac{c_{\mathrm{E}}^4}{G r_D}. \tag{W.6}$$

Dimensionally,

$$[\tau_D] = \mathrm{N/m}. \tag{W.7}$$

For a three-dimensional torsional shear field, the corresponding bulk stiffness density is obtained by projecting the surface stiffness across one FCC node scale (r_D):

$$\tau_{D,\mathrm{bulk}} = \frac{\tau_D}{r_D}. \tag{W.8}$$

Therefore,

$$\tau_{D,\mathrm{bulk}} = \frac{c_{\mathrm{E}}^4}{G r_D^2}. \tag{W.9}$$

This has the correct dimensional form of a three-dimensional stiffness density:

$$[\tau_{D,\mathrm{bulk}}] = \mathrm{N/m^2} = \mathrm{Pa}. \tag{W.10}$$

The central question is whether gravitational strain modifies this torsional stiffness as the black-hole phase boundary is approached.

The local gravitational strain variable is denoted by α_{G}. In the leading spherical exterior it reduces to

$$\alpha_{\mathrm{G}} = \frac{GM}{r c_{\mathrm{E}}^2}. \tag{W.11}$$

The FCC/SC saturation boundary occurs at

$$\alpha_{\mathrm{G}} = 1. \tag{W.12}$$

The strained propagation speed of a transverse excitation in the active Soft Floor is

$$c_P(\alpha_{\mathrm{G}}) = c_{\mathrm{E}}(1 - \alpha_{\mathrm{G}})^2. \tag{W.13}$$

Thus, as

$$\alpha_{\mathrm{G}} \to 1, \tag{W.14}$$

the local propagation speed collapses:

$$c_P(\alpha_{\mathrm{G}}) \to 0. \tag{W.15}$$

This causal slowing should not be interpreted as a disappearance of Soft-Floor stiffness. In TFT, the slowing is already accounted for by the divergence of the effective inertia. The effective surface inertia scales as

$$\mu_{\mathrm{eff}}(\alpha_{\mathrm{G}}) = \frac{\mu_D}{(1-\alpha_{\mathrm{G}})^4}. \tag{W.16}$$

Therefore,

$$\mu_{\mathrm{eff}}(\alpha_{\mathrm{G}}) \to \infty \qquad \text{as} \qquad \alpha_{\mathrm{G}} \to 1. \tag{W.17}$$

For the torsional exterior, the relevant inertia is the three-dimensional effective inertia density in the azimuthal shear channel. Since μ_{eff} is a surface inertia, the corresponding three-dimensional effective torsional inertia density is

$$\rho_{\mathrm{tor,eff}}(\alpha_{\mathrm{G}}) = \frac{\mu_{\mathrm{eff}}(\alpha_{\mathrm{G}})}{r_D}. \tag{W.18}$$

Substituting the TFT inertia scaling gives

$$\rho_{\mathrm{tor,eff}}(\alpha_{\mathrm{G}}) = \frac{\mu_D}{r_D}(1-\alpha_{\mathrm{G}})^{-4}. \tag{W.19}$$

The local shear-wave identity for the torsional channel is

$$c_P^2(\alpha_{\mathrm{G}}) = \frac{\tau_{\mathrm{tor}}(\alpha_{\mathrm{G}})}{\rho_{\mathrm{tor,eff}}(\alpha_{\mathrm{G}})}. \tag{W.20}$$

Solving for the torsional stiffness gives

$$\tau_{\mathrm{tor}}(\alpha_{\mathrm{G}}) = \rho_{\mathrm{tor,eff}}(\alpha_{\mathrm{G}}) c_P^2(\alpha_{\mathrm{G}}). \tag{W.21}$$

Now substitute

$$\rho_{\mathrm{tor,eff}}(\alpha_{\mathrm{G}}) = \frac{\mu_D}{r_D}(1-\alpha_{\mathrm{G}})^{-4}, \tag{W.22}$$

and

$$c_P^2(\alpha_{\mathrm{G}}) = c_{\mathrm{E}}^2(1-\alpha_{\mathrm{G}})^4. \tag{W.23}$$

Then

$$\tau_{\mathrm{tor}}(\alpha_{\mathrm{G}}) = \left[\frac{\mu_D}{r_D}(1-\alpha_{\mathrm{G}})^{-4}\right]\left[c_{\mathrm{E}}^2(1-\alpha_{\mathrm{G}})^4\right]. \tag{W.24}$$

The strain factors cancel exactly:

$$(1-\alpha_{\mathrm{G}})^{-4}(1-\alpha_{\mathrm{G}})^4 = 1. \tag{W.25}$$

Therefore,

$$\tau_{\mathrm{tor}}(\alpha_{\mathrm{G}}) = \frac{\mu_D c_{\mathrm{E}}^2}{r_D}. \tag{W.26}$$

Using the Soft-Floor identity

$$c_{\mathrm{E}}^2 = \frac{\tau_D}{\mu_D}, \tag{W.27}$$

this becomes

$$\tau_{\rm tor}(\alpha_{\rm G}) = \frac{\tau_D}{r_D}. \tag{W.28}$$

Thus, the leading constitutive closure is

$$\boxed{\tau_{\rm tor}(\alpha_{\rm G}) = \tau_{D,\rm bulk} = \frac{c_{\rm E}^4}{G r_D^2}, \qquad 0 \le \alpha_{\rm G} < 1.} \tag{W.29}$$

The result is physically significant. In the active FCC exterior, gravitational strain does not soften the baseline torsional stiffness at leading order. Instead, the approach to causal arrest is carried by the divergence of the effective inertia:

$$\rho_{\rm tor,eff}(\alpha_{\rm G}) = \frac{\mu_D}{r_D}(1-\alpha_{\rm G})^{-4}. \tag{W.30}$$

As

$$\alpha_{\rm G} \to 1, \tag{W.31}$$

one has

$$\rho_{\rm tor,eff} \to \infty, \tag{W.32}$$

and therefore

$$c_P(\alpha_{\rm G}) = \sqrt{\frac{\tau_{\rm tor}}{\rho_{\rm tor,eff}(\alpha_{\rm G})}} = c_{\rm E}(1-\alpha_{\rm G})^2 \to 0. \tag{W.33}$$

Thus, the mechanical interpretation is:

$$\boxed{\text{finite stiffness} + \text{divergent effective inertia} = \text{causal arrest.}} \tag{W.34}$$

This avoids double-counting the gravitational strain effect. If one instead assumed a softening law such as

$$\tau_{\rm tor}(\alpha_{\rm G}) = \tau_{D,\rm bulk}(1-\alpha_{\rm G})^p, \tag{W.35}$$

then the propagation law would become

$$c_P^2 \sim (1-\alpha_{\rm G})^{p+4}. \tag{W.36}$$

This would conflict with the already-established TFT propagation law

$$c_P^2 = c_{\rm E}^2(1-\alpha_{\rm G})^4 \tag{W.37}$$

unless $p = 0$. Therefore, the leading torsional stiffness is strain-independent, while the strain dependence resides in the effective inertia.

The domain of validity is essential. The closure

$$\tau_{\rm tor}(\alpha_{\rm G}) = \tau_{D,\rm bulk} \tag{W.38}$$

applies only in the active FCC exterior:

$$0 \le \alpha_{\rm G} < 1. \tag{W.39}$$

At

$$\alpha_{\rm G} = 1, \tag{W.40}$$

the FCC Soft Floor no longer remains an ordinary strained elastic medium. It undergoes the FCC-to-SC phase transition and becomes part of the internally phase-locked saturated domain. Therefore, $\tau_{\rm tor}$ is an exterior FCC constitutive coefficient. It should not be continued through the SC core as though the black-hole interior were still an active torsional medium.

The consequence for rotating black-hole exterior dynamics is direct. Appendix V writes the leading axisymmetric torsional equation as

$$\frac{\mathrm{d}}{\mathrm{d}r}\left[\tau_{\rm tor}(r) r^4 \frac{\mathrm{d}\omega_{\rm drag}}{\mathrm{d}r}\right] = 0. \tag{W.41}$$

With

$$\tau_{\rm tor}(r) = \tau_{D,\rm bulk}, \tag{W.42}$$

this reduces to

$$\boxed{\frac{\mathrm{d}}{\mathrm{d}r}\left[r^4 \frac{\mathrm{d}\omega_{\rm drag}}{\mathrm{d}r}\right] = 0.} \tag{W.43}$$

The exterior angular-drag field therefore has the radial form

$$\omega_{\rm drag}(r) = \frac{A_{\rm drag}}{r^3}, \tag{W.44}$$

after imposing vanishing drag at spatial infinity. The present constitutive closure fixes the radial dependence of the torsional field. The coefficient $A_{\rm drag}$ is not fixed by the stiffness closure alone; it is fixed in the next section by weak-field angular-momentum matching to the Lense–Thirring limit.

This completes the baseline torsional constitutive closure required for the rotating TFT black-hole exterior.

W.2 Weak-Field Coefficient Matching: Lense–Thirring Normalization

The previous section fixed the torsional stiffness sector of the rotating TFT exterior. In the active FCC exterior,

$$\tau_{\rm tor}(\alpha_{\rm G}) = \tau_{D,\rm bulk}, \tag{W.45}$$

so the leading axisymmetric torsional field equation reduces to

$$\frac{\mathrm{d}}{\mathrm{d}r}\left[r^4 \frac{\mathrm{d}\omega_{\rm drag}}{\mathrm{d}r}\right] = 0. \tag{W.46}$$

The exterior solution has the radial form

$$\omega_{\rm drag}(r) = \frac{A_{\rm drag}}{r^3}, \tag{W.47}$$

after imposing vanishing angular drag at spatial infinity. Thus, the torsional constitutive closure fixes the radial dependence,

$$\omega_{\rm drag}(r) \propto r^{-3}, \tag{W.48}$$

but it does not by itself fix the amplitude $A_{\rm drag}$.

The remaining problem is therefore the weak-field coefficient-matching problem:

$$A_{\rm drag} = ? \tag{W.49}$$

Appendix U identifies the rotating black hole as a live FCC/SC boundary carrying angular momentum, while Appendix V derives the leading torsional Soft-Floor exterior. The present section fixes the far-field normalization required for the TFT exterior to reproduce the empirically successful weak-field frame-dragging limit.

In the weak-field exterior of a rotating compact object, the Lense–Thirring angular-dragging rate is

$$\omega_{\mathrm{LT}}(r) = \frac{2G\mathcal{J}_{\mathrm{BH}}}{c_{\mathrm{E}}^2 r^3}, \tag{W.50}$$

where $\mathcal{J}_{\mathrm{BH}}$ is the total axial angular momentum of the black hole. Therefore, exact weak-field correspondence requires

$$\omega_{\mathrm{drag}}(r) \to \omega_{\mathrm{LT}}(r) \qquad \text{for} \qquad r \gg R_{\mathrm{QG}}. \tag{W.51}$$

Hence the far-field amplitude must be

$$A_{\mathrm{drag}} = \frac{2G\mathcal{J}_{\mathrm{BH}}}{c_{\mathrm{E}}^2}. \tag{W.52}$$

The weak-field matched TFT dragging law is therefore

$$\boxed{\omega_{\mathrm{drag}}^{\mathrm{TFT}}(r) = \frac{2G\mathcal{J}_{\mathrm{BH}}}{c_{\mathrm{E}}^2 r^3}.} \tag{W.53}$$

Using

$$R_{\mathrm{QG}} = \frac{GM}{c_{\mathrm{E}}^2}, \tag{W.54}$$

and

$$a_* = \frac{c_{\mathrm{E}}\mathcal{J}_{\mathrm{BH}}}{GM^2}, \tag{W.55}$$

the same expression becomes

$$\omega_{\mathrm{drag}}^{\mathrm{TFT}}(r) = 2a_* c_{\mathrm{E}} \frac{R_{\mathrm{QG}}^2}{r^3}. \tag{W.56}$$

The corresponding azimuthal Soft-Floor drift speed is

$$v_\phi^{(\mathrm{SF})}(r,\theta) = r\sin\theta\,\omega_{\mathrm{drag}}(r). \tag{W.57}$$

Therefore,

$$\boxed{v_\phi^{(\mathrm{SF})}(r,\theta) = 2a_* c_{\mathrm{E}} \left(\frac{R_{\mathrm{QG}}}{r}\right)^2 \sin\theta.} \tag{W.58}$$

This fixes the leading weak-field decision:

$$\boxed{\frac{\omega_{\mathrm{drag}}^{\mathrm{TFT}}}{\omega_{\mathrm{LT}}} \to 1 \qquad \text{for} \qquad r \gg R_{\mathrm{QG}}.} \tag{W.59}$$

Thus, TFT predicts no deviation from the standard Lense–Thirring coefficient in the weak-field exterior. Any deviation should be reserved for the strong-field saturation regime near the FCC/SC phase boundary, where $\alpha_{\mathrm{G}} \to 1$.

The important subtlety is that the far-field coefficient must be normalized by the conserved total angular momentum $\mathcal{J}_{\mathrm{BH}}$, not by a naive no-slip surface velocity alone.

The live-boundary spin relation is

$$\mathcal{J}_{\rm BH} = I_{\rm surf}\frac{v_{\rm tor}}{R_{\rm QG}}, \tag{W.60}$$

where $I_{\rm surf}$ is the effective surface moment of inertia of the phase-segregated boundary mass and $v_{\rm tor}$ is the effective torsional boundary speed.

A purely no-slip surface estimate would write

$$\omega_{\rm drag}(r) = \omega_\partial \left(\frac{R_{\rm QG}}{r}\right)^3, \tag{W.61}$$

with

$$\omega_\partial = \frac{v_{\rm tor}}{R_{\rm QG}}. \tag{W.62}$$

Combining this with the live-boundary spin relation gives

$$\omega_{\rm drag}(r) = \frac{\mathcal{J}_{\rm BH}}{I_{\rm surf}} \left(\frac{R_{\rm QG}}{r}\right)^3. \tag{W.63}$$

Using

$$R_{\rm QG} = \frac{GM}{c_{\rm E}^2}, \tag{W.64}$$

this may be rewritten as

$$\omega_{\rm drag}(r) = \left(\frac{MR_{\rm QG}^2}{I_{\rm surf}}\right)\frac{G\mathcal{J}_{\rm BH}}{c_{\rm E}^2 r^3}. \tag{W.65}$$

Comparing this expression with the Lense–Thirring coefficient,

$$\omega_{\rm LT}(r) = 2\frac{G\mathcal{J}_{\rm BH}}{c_{\rm E}^2 r^3}, \tag{W.66}$$

shows that exact coefficient matching through a pure no-slip surface-shell model would require

$$\frac{MR_{\rm QG}^2}{I_{\rm surf}} = 2. \tag{W.67}$$

Equivalently,

$$I_{\rm surf} = \frac{1}{2}MR_{\rm QG}^2. \tag{W.68}$$

This value is not mathematically forbidden. It lies within the boundary-confined range

$$0 \le I_{\rm surf} \le MR_{\rm QG}^2. \tag{W.69}$$

However, treating this as a universal no-slip identity would create a separate problem. The dimensionless spin relation is

$$a_* = \left(\frac{I_{\rm surf}}{MR_{\rm QG}^2}\right)\frac{v_{\rm tor}}{c_{\rm E}}. \tag{W.70}$$

If

$$I_{\rm surf} = \frac{1}{2}MR_{\rm QG}^2, \tag{W.71}$$

then

$$a_* = \frac{1}{2}\frac{v_{\rm tor}}{c_{\rm E}}. \tag{W.72}$$

Since the boundary torsional speed is limited by

$$v_{\rm tor} \le c_{\rm E}, \tag{W.73}$$

this would imply

$$a_* \le \frac{1}{2}. \tag{W.74}$$

That cannot be the complete rotating black-hole theory, because a Kerr-correspondence framework must allow the full spin range

$$0 \le a_* \le 1. \tag{W.75}$$

Therefore, the no-slip surface-shell expression should be interpreted as a local boundary estimate that reproduces the r^{-3} radial field shape. It should not be used as the universal coefficient closure for the exterior field.

The coefficient of the far exterior must instead be fixed by total angular-momentum matching:

$$\boxed{A_{\rm drag} = \frac{2G\mathcal{J}_{\rm BH}}{c_{\rm E}^2}.} \tag{W.76}$$

Thus, the weak-field exterior is angular-momentum normalized:

$$\boxed{\omega_{\rm drag}(r) = \frac{2G\mathcal{J}_{\rm BH}}{c_{\rm E}^2 r^3}.} \tag{W.77}$$

The surface quantities $I_{\rm surf}$ and $v_{\rm tor}$ remain essential for describing how angular momentum is stored and redistributed on the live FCC/SC boundary. However, the asymptotic exterior coefficient is fixed by the conserved total angular momentum $\mathcal{J}_{\rm BH}$, not by assuming that a single no-slip boundary velocity controls the entire exterior.

This resolves the coefficient-matching problem. The rotating TFT exterior exactly reproduces Lense–Thirring frame dragging in the weak-field regime:

$$\boxed{\omega_{\rm drag}^{\rm TFT} = \omega_{\rm LT} = \frac{2G\mathcal{J}_{\rm BH}}{c_{\rm E}^2 r^3} \qquad (r \gg R_{\rm QG}).} \tag{W.78}$$

The present section therefore fixes the weak-field coefficient of the rotating TFT exterior. The radial field shape follows from the torsional stiffness closure, while the amplitude follows from angular-momentum normalization. TFT deviations are not placed in the leading weak-field coefficient; they belong only to the nonlinear saturation regime near the FCC/SC phase boundary.

W.3 Photon-Ring Conditions from the Rotating Soft-Floor Hamiltonian

After fixing the torsional stiffness closure and the weak-field frame-dragging coefficient, the next task is to derive the circular photon-orbit conditions from the rotating TFT exterior Hamiltonian. Appendix U defines the black hole as a live FCC/SC phase boundary, while Appendix V gives the rotating Soft-Floor propagation structure used here as the starting point.

The rotating exterior propagation law is

$$\mathcal{H}_\gamma = \frac{1}{2}\left[-\frac{\left(\omega - m_\phi \omega_{\mathrm{drag}}(r)\right)^2}{c_P^2(r)} + k_r^2 + \frac{k_\theta^2}{r^2} + \frac{m_\phi^2}{r^2 \sin^2\theta}\right] = 0. \tag{W.79}$$

Here ω is the conserved wave frequency, m_ϕ is the azimuthal angular mode number, $\omega_{\mathrm{drag}}(r)$ is the torsional angular-drag rate of the Soft Floor, and $c_P(r)$ is the local strained propagation speed.

For equatorial circular photon orbits, restrict to

$$\theta = \frac{\pi}{2}, \tag{W.80}$$

and set

$$k_\theta = 0. \tag{W.81}$$

The Hamiltonian then reduces to

$$\mathcal{H}_\gamma = \frac{1}{2}\left[-\frac{\left(\omega - m_\phi \omega_{\mathrm{drag}}(r)\right)^2}{c_P^2(r)} + k_r^2 + \frac{m_\phi^2}{r^2}\right] = 0. \tag{W.82}$$

Solving for the radial wave number gives

$$k_r^2 = \frac{\left(\omega - m_\phi \omega_{\mathrm{drag}}(r)\right)^2}{c_P^2(r)} - \frac{m_\phi^2}{r^2}. \tag{W.83}$$

Define the signed photon impact parameter

$$b_\gamma = \frac{m_\phi}{\omega}. \tag{W.84}$$

In this normalization, b_γ has dimensions of time. The corresponding physical impact length is $c_{\mathrm{E}}|b_\gamma|$.

Dividing the radial equation by ω^2, one obtains

$$k_r^2 = \omega^2 \mathcal{R}_\gamma(r; b_\gamma), \tag{W.85}$$

where the radial photon potential is

$$\mathcal{R}_\gamma(r; b_\gamma) = \frac{\left[1 - b_\gamma \omega_{\mathrm{drag}}(r)\right]^2}{c_P^2(r)} - \frac{b_\gamma^2}{r^2}. \tag{W.86}$$

A circular photon orbit is a double root of this radial potential. Therefore, the photon-ring conditions are

$$\mathcal{R}_\gamma(r; b_\gamma) = 0, \tag{W.87}$$

and

$$\frac{\mathrm{d}\mathcal{R}_\gamma}{\mathrm{d}r} = 0. \tag{W.88}$$

The first condition gives zero radial motion,

$$k_r = 0. \tag{W.89}$$

The second condition requires the orbit to be stationary under radial perturbation. With the convention

$$k_r^2 = \omega^2 \mathcal{R}_\gamma, \tag{W.90}$$

the unstable photon-ring branch satisfies

$$\frac{\mathrm{d}^2\mathcal{R}_\gamma}{\mathrm{d}r^2} > 0. \tag{W.91}$$

This sign means that a small displacement away from the double root opens an allowed escape or plunge channel.

From

$$\mathcal{R}_\gamma = 0, \tag{W.92}$$

we obtain

$$\frac{[1 - b_\gamma \omega_{\mathrm{drag}}(r)]^2}{c_P^2(r)} = \frac{b_\gamma^2}{r^2}. \tag{W.93}$$

Taking the two circular-orbit branches gives

$$1 - b_\gamma \omega_{\mathrm{drag}}(r) = s_{\mathrm{br}} \frac{b_\gamma c_P(r)}{r}, \tag{W.94}$$

where

$$s_{\mathrm{br}} = +1 \tag{W.95}$$

labels the prograde branch and

$$s_{\mathrm{br}} = -1 \tag{W.96}$$

labels the retrograde branch.

Solving for the branch impact parameter gives

$$b_{\gamma,s_{\mathrm{br}}}(r) = \frac{1}{\omega_{\mathrm{drag}}(r) + s_{\mathrm{br}} \frac{c_P(r)}{r}}. \tag{W.97}$$

The circular photon-ring radius is obtained by requiring this impact parameter to be stationary with respect to radius:

$$\frac{\mathrm{d}b_{\gamma,s_{\mathrm{br}}}}{\mathrm{d}r} = 0. \tag{W.98}$$

Equivalently,

$$\frac{\mathrm{d}}{\mathrm{d}r}\left[\omega_{\mathrm{drag}}(r) + s_{\mathrm{br}} \frac{c_P(r)}{r}\right] = 0. \tag{W.99}$$

Thus, the general TFT equatorial photon-ring condition is

$$\boxed{\omega'_{\mathrm{drag}}(r) + s_{\mathrm{br}}\left[\frac{c'_P(r)}{r} - \frac{c_P(r)}{r^2}\right] = 0.} \tag{W.100}$$

This is the central result of the section. A circular photon orbit is not imposed by importing the Kerr photon-sphere condition. It occurs where the radial gradient of the torsional Soft-Floor dragging rate balances the radial gradient of the local optical propagation term.

The corresponding photon-ring impact parameter is

$$\boxed{b_{\gamma,s_{\mathrm{br}}} = \frac{1}{\omega_{\mathrm{drag}}(r_{\gamma,s_{\mathrm{br}}}) + s_{\mathrm{br}} \frac{c_P(r_{\gamma,s_{\mathrm{br}}})}{r_{\gamma,s_{\mathrm{br}}}}}.} \tag{W.101}$$

Here $r_{\gamma,s_{\mathrm{br}}}$ is the photon-ring radius of the prograde or retrograde branch.

In the nonrotating case,

$$\omega_{\mathrm{drag}}(r) = 0. \tag{W.102}$$

The photon-ring equation reduces to

$$\frac{c_P'(r)}{r} - \frac{c_P(r)}{r^2} = 0. \tag{W.103}$$

Equivalently,

$$r c_P'(r) = c_P(r). \tag{W.104}$$

Using the static TFT optical propagation law

$$c_P(r) = c_{\mathrm{E}} \left(1 - \frac{R_{\mathrm{QG}}}{r}\right)^2, \tag{W.105}$$

we have

$$c_P'(r) = 2c_{\mathrm{E}} \left(1 - \frac{R_{\mathrm{QG}}}{r}\right) \frac{R_{\mathrm{QG}}}{r^2}. \tag{W.106}$$

Substituting into the photon-ring condition gives

$$2\frac{R_{\mathrm{QG}}}{r} \left(1 - \frac{R_{\mathrm{QG}}}{r}\right) = \left(1 - \frac{R_{\mathrm{QG}}}{r}\right)^2. \tag{W.107}$$

For the exterior region

$$r > R_{\mathrm{QG}}, \tag{W.108}$$

the factor

$$1 - \frac{R_{\mathrm{QG}}}{r} \tag{W.109}$$

is nonzero and may be divided out. This leaves

$$2\frac{R_{\mathrm{QG}}}{r} = 1 - \frac{R_{\mathrm{QG}}}{r}. \tag{W.110}$$

Therefore,

$$3\frac{R_{\mathrm{QG}}}{r} = 1, \tag{W.111}$$

and the nonrotating TFT photon-ring radius is

$$\boxed{r_{\gamma,0} = 3R_{\mathrm{QG}}.} \tag{W.112}$$

Now include the weak-field matched rotational dragging law derived in the previous section:

$$\omega_{\mathrm{drag}}(r) = \frac{2G\mathcal{J}_{\mathrm{BH}}}{c_{\mathrm{E}}^2 r^3}. \tag{W.113}$$

Using

$$a_* = \frac{c_{\mathrm{E}}\mathcal{J}_{\mathrm{BH}}}{GM^2}, \tag{W.114}$$

and

$$R_{\mathrm{QG}} = \frac{GM}{c_{\mathrm{E}}^2}, \tag{W.115}$$

this becomes

$$\omega_{\rm drag}(r) = 2a_* c_{\rm E} \frac{R_{\rm QG}^2}{r^3}. \tag{W.116}$$

The static propagation speed remains

$$c_P(r) = c_{\rm E}\left(1 - \frac{R_{\rm QG}}{r}\right)^2. \tag{W.117}$$

Define the dimensionless inverse radius

$$x = \frac{R_{\rm QG}}{r}. \tag{W.118}$$

The photon-ring condition

$$\omega'_{\rm drag}(r) + s_{\rm br}\left[\frac{c'_P(r)}{r} - \frac{c_P(r)}{r^2}\right] = 0 \tag{W.119}$$

then becomes

$$\boxed{s_{\rm br}(1-x)(3x-1) = 6a_* x^2.} \tag{W.120}$$

This is the leading rotating TFT photon-ring equation in dimensionless form.
For small spin,

$$a_* \ll 1, \tag{W.121}$$

write

$$x_{s_{\rm br}} = \frac{1}{3} + \delta x_{s_{\rm br}}. \tag{W.122}$$

Keeping only first order in a_*, the solution is

$$\delta x_{s_{\rm br}} = s_{\rm br}\frac{a_*}{3}. \tag{W.123}$$

Therefore,

$$x_{s_{\rm br}} = \frac{1 + s_{\rm br}a_*}{3} + \mathcal{O}(a_*^2). \tag{W.124}$$

Since

$$r_{\gamma,s_{\rm br}} = \frac{R_{\rm QG}}{x_{s_{\rm br}}}, \tag{W.125}$$

the weak-spin photon-ring radius becomes

$$\boxed{r_{\gamma,s_{\rm br}} = 3R_{\rm QG}\left(1 - s_{\rm br}a_*\right) + \mathcal{O}(a_*^2).} \tag{W.126}$$

Thus, for the prograde branch,

$$s_{\rm br} = +1, \tag{W.127}$$

one has

$$\boxed{r_{\gamma,+} = 3R_{\rm QG}(1 - a_*) + \mathcal{O}(a_*^2),} \tag{W.128}$$

while for the retrograde branch,

$$s_{\rm br} = -1, \tag{W.129}$$

one has

$$\boxed{r_{\gamma,-} = 3R_{\rm QG}(1 + a_*) + \mathcal{O}(a_*^2).} \tag{W.130}$$

The physical interpretation is direct: torsional Soft-Floor dragging pulls the prograde photon ring inward and pushes the retrograde photon ring outward.

This is the correct qualitative behavior expected of a rotating black-hole exterior. However, this weak-spin splitting should be understood as a baseline result. It uses the weak-field matched angular-drag law and the static optical propagation law evaluated in the photon-ring region. A completed strong-field treatment must determine whether nonlinear saturation corrections modify the photon-ring and shadow map near the FCC/SC phase boundary.

The present section therefore establishes the baseline photon-ring condition for the rotating TFT exterior. The photon ring is obtained as a stationary impact-parameter orbit of the rotating Soft-Floor Hamiltonian, not by importing the Kerr photon-sphere condition. In the nonrotating limit, the static TFT optical law gives

$$r_{\gamma,0} = 3R_{\mathrm{QG}}. \tag{W.131}$$

In the weak-spin, weak-field-matched exterior, torsional Soft-Floor dragging shifts the prograde branch inward and the retrograde branch outward. These results establish the circular photon-orbit condition, while the final strong-field shadow prediction remains a separate problem involving the saturation-corrected dragging field, the capacity surface, and the observational shadow radius.

W.4 Spin-Induced Quadrupole Closure: $Q_{\mathrm{TFT}}(M, \mathcal{J}_{\mathrm{BH}})$

The next requirement for replacing the Kerr exterior is not only frame dragging and photon-ring formation. A rotating black hole also carries a mass quadrupole. In the Kerr exterior, that quadrupole is not an independent parameter; it is fixed entirely by the mass and angular momentum of the black hole.

For TFT, this is a serious structural test. A mechanical FCC/SC boundary could, in principle, carry arbitrary surface deformations. If those arbitrary deformations survived into the exterior field, then TFT would describe a generic rotating elastic object rather than a black-hole exterior. Therefore, the next closure is the TFT no-hair quadrupole relation:

$$Q_{\mathrm{TFT}}(M, \mathcal{J}_{\mathrm{BH}}). \tag{W.132}$$

The goal of this section is to derive the leading spin-induced quadrupole that the relaxed rotating TFT boundary must produce in the far exterior. Appendix U establishes the live FCC/SC boundary as the mechanical carrier of black-hole spin, while Appendix V constructs the torsional Soft-Floor exterior and Kerr-correspondence structure for rotating TFT black holes. The present section closes the next multipole level: the spin-induced quadrupole.

W.4.1 Exterior Quadrupole Definition

In the far exterior, the strained Soft-Floor potential can be expanded into spherical multipoles. The leading monopole term is the ordinary radial mass field:

$$\Phi_\tau^{(0)}(r) = -\frac{GM}{r}. \tag{W.133}$$

For a stationary axisymmetric rotating black hole, the first allowed nonspherical mass multipole is the quadrupole term. We define the TFT quadrupole Q_{TFT} through the far-field potential expansion

$$\Phi_\tau(r,\theta) = -\frac{GM}{r} + \frac{GQ_{\mathrm{TFT}}}{r^3} P_2(\cos\theta) + \mathcal{O}(r^{-4}), \tag{W.134}$$

where

$$P_2(\cos\theta) = \frac{1}{2}\left(3\cos^2\theta - 1\right). \tag{W.135}$$

The sign convention is chosen so that a negative quadrupole corresponds to the oblate rotating black-hole exterior. The structural strain variable is

$$\alpha_{\mathrm{G}}(r,\theta) = -\frac{\Phi_\tau(r,\theta)}{c_{\mathrm{E}}^2}. \tag{W.136}$$

Therefore,

$$\alpha_{\mathrm{G}}(r,\theta) = \frac{GM}{c_{\mathrm{E}}^2 r} + \frac{GQ_{\mathrm{TFT}}}{c_{\mathrm{E}}^2 r^3} P_2(\cos\theta) + \mathcal{O}(r^{-4}). \tag{W.137}$$

Using

$$R_{\mathrm{QG}} = \frac{GM}{c_{\mathrm{E}}^2}, \tag{W.138}$$

this becomes

$$\alpha_{\mathrm{G}}(r,\theta) = \frac{R_{\mathrm{QG}}}{r} + \frac{GQ_{\mathrm{TFT}}}{c_{\mathrm{E}}^2 r^3} P_2(\cos\theta) + \mathcal{O}(r^{-4}). \tag{W.139}$$

This equation defines how the spin-induced quadrupole modifies the local Soft-Floor strain field.

W.4.2 Symmetry and Dimensional Constraints

The quadrupole relation is strongly constrained before any detailed boundary model is introduced.

First, the relaxed rotating black hole is axisymmetric. Therefore, the exterior cannot depend on the azimuthal angle ϕ.

Second, the center-of-mass frame removes the dipole term. Therefore, the first nontrivial mass multipole is the $\ell = 2$ quadrupole.

Third, reversing the spin direction,

$$\mathcal{J}_{\mathrm{BH}} \to -\mathcal{J}_{\mathrm{BH}}, \tag{W.140}$$

does not change the mass distribution. It changes the direction of frame dragging, but not whether the boundary is oblate or prolate. Therefore, the mass quadrupole must be even in angular momentum:

$$Q_{\mathrm{TFT}}(M, -\mathcal{J}_{\mathrm{BH}}) = Q_{\mathrm{TFT}}(M, \mathcal{J}_{\mathrm{BH}}). \tag{W.141}$$

Thus, the leading spin-induced quadrupole must scale as

$$Q_{\mathrm{TFT}} \propto \mathcal{J}_{\mathrm{BH}}^2. \tag{W.142}$$

Fourth, the quadrupole must vanish when the black hole is nonrotating:

$$\mathcal{J}_{\mathrm{BH}} = 0 \quad \Rightarrow \quad Q_{\mathrm{TFT}} = 0. \tag{W.143}$$

Fifth, the dimensional form is fixed. A mass quadrupole has units

$$[Q] = \mathrm{kg}\cdot\mathrm{m}^2. \tag{W.144}$$

The only combination of M, $\mathcal{J}_{\mathrm{BH}}$, and c_{E} with these units is

$$\frac{\mathcal{J}_{\mathrm{BH}}^2}{M c_{\mathrm{E}}^2}. \tag{W.145}$$

Therefore, the most general leading-order TFT quadrupole closure is

$$Q_{\mathrm{TFT}} = -\lambda_Q \frac{\mathcal{J}_{\mathrm{BH}}^2}{M c_{\mathrm{E}}^2} + \mathcal{O}(\mathcal{J}_{\mathrm{BH}}^4), \tag{W.146}$$

where λ_Q is a dimensionless quadrupole coefficient. The negative sign corresponds to the oblate deformation expected from rotation.

W.4.3 Kerr-Correspondence Closure

A generic mechanical boundary would permit arbitrary values of λ_Q. But a black-hole exterior cannot carry arbitrary quadrupole hair if it is to reproduce the successful weak-field Kerr phenomenology.

Therefore, the relaxed TFT boundary must satisfy a no-hair selection rule:

$$\text{relaxed exterior} \quad \Rightarrow \quad Q_{\mathrm{TFT}} = Q_{\mathrm{TFT}}(M, \mathcal{J}_{\mathrm{BH}}), \tag{W.147}$$

not

$$Q_{\mathrm{TFT}} = Q_{\mathrm{TFT}}(M, \mathcal{J}_{\mathrm{BH}}, \text{arbitrary boundary history}). \tag{W.148}$$

The weak-field Kerr-correspondence limit fixes

$$\lambda_Q = 1. \tag{W.149}$$

The value $\lambda_Q = 1$ is a Kerr-correspondence closure, not yet a microscopic derivation from FCC/SC boundary stress balance. A future first-principles derivation must obtain this coefficient from the rotating boundary energy functional. In the present appendix, $\lambda_Q = 1$ is imposed as the no-hair condition required for weak-field Kerr correspondence.

Thus, the baseline TFT quadrupole closure is

$$\boxed{Q_{\mathrm{TFT}}(M, \mathcal{J}_{\mathrm{BH}}) = -\frac{\mathcal{J}_{\mathrm{BH}}^2}{M c_{\mathrm{E}}^2}.} \tag{W.150}$$

Using

$$a_* = \frac{c_{\mathrm{E}} \mathcal{J}_{\mathrm{BH}}}{G M^2}, \tag{W.151}$$

we have

$$\mathcal{J}_{\mathrm{BH}} = a_* \frac{G M^2}{c_{\mathrm{E}}}. \tag{W.152}$$

Therefore,

$$Q_{\mathrm{TFT}} = -\frac{1}{M c_{\mathrm{E}}^2} \left(a_*^2 \frac{G^2 M^4}{c_{\mathrm{E}}^2} \right). \tag{W.153}$$

So,

$$Q_{\mathrm{TFT}} = -a_*^2 \frac{G^2 M^3}{c_{\mathrm{E}}^4}. \tag{W.154}$$

Using

$$R_{\mathrm{QG}} = \frac{GM}{c_{\mathrm{E}}^2}, \tag{W.155}$$

we obtain

$$\boxed{Q_{\mathrm{TFT}} = -a_*^2 M R_{\mathrm{QG}}^2.} \tag{W.156}$$

This is the leading no-hair quadrupole closure for the rotating TFT exterior.

W.4.4 Strain-Field Form of the Quadrupole Closure

Substituting

$$Q_{\mathrm{TFT}} = -a_*^2 M R_{\mathrm{QG}}^2 \tag{W.157}$$

into the strain expansion gives

$$\alpha_{\mathrm{G}}(r,\theta) = \frac{R_{\mathrm{QG}}}{r} - \frac{G}{c_{\mathrm{E}}^2 r^3}\left(a_*^2 M R_{\mathrm{QG}}^2\right) P_2(\cos\theta) + \mathcal{O}(a_*^4). \tag{W.158}$$

Since

$$\frac{GM}{c_{\mathrm{E}}^2} = R_{\mathrm{QG}}, \tag{W.159}$$

this becomes

$$\alpha_{\mathrm{G}}(r,\theta) = \frac{R_{\mathrm{QG}}}{r} - a_*^2 \frac{R_{\mathrm{QG}}^3}{r^3} P_2(\cos\theta) + \mathcal{O}(a_*^4). \tag{W.160}$$

Therefore,

$$\boxed{\alpha_{\mathrm{G}}(r,\theta) = \frac{R_{\mathrm{QG}}}{r} - a_*^2 \left(\frac{R_{\mathrm{QG}}}{r}\right)^3 P_2(\cos\theta) + \mathcal{O}(a_*^4).} \tag{W.161}$$

This is the quadrupole-corrected TFT strain field.

At the equator,

$$\theta = \frac{\pi}{2}, \tag{W.162}$$

so

$$P_2(0) = -\frac{1}{2}. \tag{W.163}$$

Therefore, the equatorial strain becomes

$$\boxed{\alpha_{\mathrm{G,eq}}(r) = \frac{R_{\mathrm{QG}}}{r} + \frac{1}{2} a_*^2 \left(\frac{R_{\mathrm{QG}}}{r}\right)^3 + \mathcal{O}(a_*^4).} \tag{W.164}$$

Along the polar axis,

$$\theta = 0, \tag{W.165}$$

so

$$P_2(1) = 1. \tag{W.166}$$

Therefore, the polar strain becomes

$$\boxed{\alpha_{\mathrm{G,pole}}(r) = \frac{R_{\mathrm{QG}}}{r} - a_*^2 \left(\frac{R_{\mathrm{QG}}}{r}\right)^3 + \mathcal{O}(a_*^4).} \tag{W.167}$$

This is physically consistent with an oblate rotating exterior: the equatorial strain is enhanced, while the polar strain is reduced.

W.4.5 Effect on the Photon-Orbit Equations

The previous section derived the circular photon-orbit condition from the Hamiltonian

$$\mathcal{H}_\gamma = 0. \tag{W.168}$$

For equatorial circular photon orbits, the central condition was

$$\frac{\mathrm{d}}{\mathrm{d}r}\left[\omega_{\mathrm{drag}}(r) + s_{\mathrm{br}}\frac{c_P(r)}{r}\right] = 0, \tag{W.169}$$

where $s_{\mathrm{br}} = +1$ labels the prograde branch and $s_{\mathrm{br}} = -1$ labels the retrograde branch.

The quadrupole closure does not change this Hamiltonian structure. It changes the strain-dependent propagation speed through

$$c_P(r,\theta) = c_{\mathrm{E}}\left[1 - \alpha_{\mathrm{G}}(r,\theta)\right]^2. \tag{W.170}$$

For equatorial photon rings, this becomes

$$c_{P,\mathrm{eq}}(r) = c_{\mathrm{E}}\left[1 - \alpha_{\mathrm{G,eq}}(r)\right]^2. \tag{W.171}$$

Using the quadrupole-corrected equatorial strain,

$$\alpha_{\mathrm{G,eq}}(r) = \frac{R_{\mathrm{QG}}}{r} + \frac{1}{2}a_*^2\left(\frac{R_{\mathrm{QG}}}{r}\right)^3, \tag{W.172}$$

we obtain

$$\boxed{c_{P,\mathrm{eq}}(r) = c_{\mathrm{E}}\left[1 - \frac{R_{\mathrm{QG}}}{r} - \frac{1}{2}a_*^2\left(\frac{R_{\mathrm{QG}}}{r}\right)^3\right]^2}. \tag{W.173}$$

Therefore, the quadrupole-corrected equatorial photon-ring condition is

$$\boxed{\frac{\mathrm{d}}{\mathrm{d}r}\left[\omega_{\mathrm{drag}}(r) + s_{\mathrm{br}}\frac{c_{P,\mathrm{eq}}(r)}{r}\right] = 0.} \tag{W.174}$$

With the weak-field matched dragging law,

$$\omega_{\mathrm{drag}}(r) = \frac{2G\mathcal{J}_{\mathrm{BH}}}{c_{\mathrm{E}}^2 r^3} = 2a_* c_{\mathrm{E}}\frac{R_{\mathrm{QG}}^2}{r^3}, \tag{W.175}$$

the full baseline equatorial circular photon-orbit equation is

$$\boxed{\frac{\mathrm{d}}{\mathrm{d}r}\left[2a_* c_{\mathrm{E}}\frac{R_{\mathrm{QG}}^2}{r^3} + s_{\mathrm{br}}\frac{c_{\mathrm{E}}}{r}\left[1 - \frac{R_{\mathrm{QG}}}{r} - \frac{1}{2}a_*^2\left(\frac{R_{\mathrm{QG}}}{r}\right)^3\right]^2\right] = 0.} \tag{W.176}$$

This is the circular photon-orbit equation including both the torsional frame-dragging term and the no-hair quadrupole correction.

In dimensionless form, define

$$x = \frac{R_{\mathrm{QG}}}{r}. \tag{W.177}$$

Then

$$\omega_{\rm drag}(r) = \frac{c_{\rm E}}{R_{\rm QG}} 2a_* x^3, \tag{W.178}$$

and

$$\frac{c_{P,\rm eq}(r)}{r} = \frac{c_{\rm E}}{R_{\rm QG}} x \left[1 - x - \frac{1}{2} a_*^2 x^3\right]^2. \tag{W.179}$$

The circular photon-orbit equation becomes

$$\boxed{\frac{\rm d}{{\rm d}x}\left\{2a_* x^3 + s_{\rm br} x \left[1 - x - \frac{1}{2} a_*^2 x^3\right]^2\right\} = 0.} \tag{W.180}$$

Expanding to second order in spin gives

$$\boxed{6a_* x^2 + s_{\rm br}\left[(1-x)(1-3x) - a_*^2 x^3 (4-5x)\right] = 0.} \tag{W.181}$$

Equivalently,

$$\boxed{s_{\rm br}(1-x)(3x-1) + s_{\rm br} a_*^2 x^3 (4-5x) = 6a_* x^2.} \tag{W.182}$$

This is the baseline quadrupole-corrected circular photon-orbit equation.

W.4.6 Interpretation

The quadrupole enters at order

$$a_*^2. \tag{W.183}$$

This is expected because reversing the spin direction should not reverse the mass deformation. Frame dragging is odd in spin:

$$\omega_{\rm drag} \propto a_*, \tag{W.184}$$

while the quadrupole is even in spin:

$$Q_{\rm TFT} \propto -a_*^2. \tag{W.185}$$

Thus, the rotating TFT photon-ring structure has two distinct spin corrections:

$$\boxed{\text{order } a_* : \text{ torsional Soft-Floor frame dragging,}} \tag{W.186}$$

and

$$\boxed{\text{order } a_*^2 : \text{ spin-induced quadrupolar strain.}} \tag{W.187}$$

The quadrupole closure

$$Q_{\rm TFT} = -\frac{\mathcal{J}_{\rm BH}^2}{M c_{\rm E}^2} \tag{W.188}$$

should be interpreted as the leading weak-field no-hair selection rule for the relaxed rotating TFT boundary. It does not mean that TFT imports the Kerr interior. It means that the exterior multipole measured far from the black hole must match the successful Kerr quadrupole relation if TFT is to replace Kerr without breaking established weak-field phenomenology.

A deviation may be parametrized as

$$Q_{\rm TFT} = -(1+\delta_Q)\frac{\mathcal{J}_{\rm BH}^2}{M c_{\rm E}^2}. \tag{W.189}$$

The baseline Kerr-correspondence limit is

$$\delta_Q = 0. \tag{W.190}$$

A nonzero δ_Q would be a direct observational deviation from Kerr-like no-hair behavior. Therefore, the conservative replacement strategy is

$$\boxed{\delta_Q = 0 \quad \text{in the weak-field correspondence limit,}} \tag{W.191}$$

while any TFT-specific deviations should be reserved for the strong-field saturation regime near the FCC/SC phase boundary.

W.4.7 Baseline Conclusion

The relaxed rotating TFT exterior must carry the no-hair quadrupole

$$\boxed{Q_{\mathrm{TFT}}(M, \mathcal{J}_{\mathrm{BH}}) = -\frac{\mathcal{J}_{\mathrm{BH}}^2}{M c_{\mathrm{E}}^2} = -a_*^2 M R_{\mathrm{QG}}^2.} \tag{W.192}$$

This gives the quadrupole-corrected strain field

$$\boxed{\alpha_{\mathrm{G}}(r,\theta) = \frac{R_{\mathrm{QG}}}{r} - a_*^2 \left(\frac{R_{\mathrm{QG}}}{r}\right)^3 P_2(\cos\theta) + \mathcal{O}(a_*^4).} \tag{W.193}$$

It also gives the equatorial circular photon-orbit equation

$$\boxed{\frac{\mathrm{d}}{\mathrm{d}x}\left\{2a_* x^3 + s_{\mathrm{br}} x \left[1 - x - \frac{1}{2}a_*^2 x^3\right]^2\right\} = 0, \qquad x = \frac{R_{\mathrm{QG}}}{r}.} \tag{W.194}$$

The present section therefore fixes the leading no-hair quadrupole sector of the rotating TFT exterior. Frame dragging supplies the odd-in-spin correction, while the relaxed boundary quadrupole supplies the even-in-spin correction. Together, they determine the baseline circular photon-orbit structure through second order in spin.

W.5 Massive-Particle Orbits and the ISCO Map ($r_{\mathrm{ISCO}}(a_*)$)

The preceding sections derived the optical Hamiltonian for massless propagation and used it to obtain the photon-ring and shadow-impact map. However, a complete rotating black-hole phenomenology also requires massive-particle orbits. This is essential because accretion-disk observations, X-ray reflection spectroscopy, and continuum-fitting spin estimates are tied not primarily to the photon ring, but to the innermost stable circular orbit, or ISCO.

Therefore, the rotating TFT exterior must also provide a massive-particle Hamiltonian and an ISCO map,

$$r_{\mathrm{ISCO},s_{\mathrm{br}}}(a_*), \tag{W.195}$$

where $s_{\mathrm{br}} = +1$ labels the prograde branch and $s_{\mathrm{br}} = -1$ labels the retrograde branch.

The purpose of this section is to formulate the massive-particle orbital problem in the same Soft-Floor language used for photon propagation.

W.5.1 Massive-Particle Hamiltonian

The photon Hamiltonian used earlier follows from the local massless dispersion relation in the dragged Soft-Floor frame. For a massive particle, the corresponding local dispersion relation must include the rest-mass term.

Let

$$k_0 = \frac{m_0 c_{\mathrm{E}}}{\hbar} \tag{W.196}$$

be the inverse Compton length of a particle of rest mass m_0. The massive Soft-Floor Hamiltonian is then

$$\mathcal{H}_m = \frac{1}{2}\left[-\frac{(\omega - m_\phi \omega_{\mathrm{drag}}(r,\theta))^2}{c_P^2(r,\theta)} + k_r^2 + \frac{k_\theta^2}{r^2} + \frac{m_\phi^2}{r^2 \sin^2\theta} + k_0^2\right] = 0. \tag{W.197}$$

Here ω is the conserved wave frequency, m_ϕ is the azimuthal angular mode number, k_r and k_θ are radial and polar wave numbers, and ω_{drag} is the torsional Soft-Floor dragging rate.

The massless photon Hamiltonian is recovered by setting

$$k_0 = 0. \tag{W.198}$$

Thus, the massive Hamiltonian is not an independent construction. It is the massive extension of the same dragged Soft-Floor dispersion law used for photon propagation.

Dimensionally, every term in $\mathcal{H}_m$ has units of inverse length squared. The term

$$\frac{(\omega - m_\phi \omega_{\mathrm{drag}})^2}{c_P^2} \tag{W.199}$$

has units

$$\frac{\mathrm{s}^{-2}}{\mathrm{m}^2\mathrm{s}^{-2}} = \mathrm{m}^{-2}, \tag{W.200}$$

and the rest term k_0^2 also has units m^{-2}. Therefore, the Hamiltonian is dimensionally consistent.

W.5.2 Equatorial Massive-Particle Radial Potential

For equatorial circular orbits, set

$$\theta = \frac{\pi}{2}, \tag{W.201}$$

and

$$k_\theta = 0. \tag{W.202}$$

The Hamiltonian becomes

$$\mathcal{H}_m = \frac{1}{2}\left[-\frac{(\omega - m_\phi \omega_{\mathrm{drag}}(r))^2}{c_P^2(r)} + k_r^2 + \frac{m_\phi^2}{r^2} + k_0^2\right] = 0. \tag{W.203}$$

Solving for the radial wave number gives

$$k_r^2 = \frac{(\omega - m_\phi \omega_{\mathrm{drag}}(r))^2}{c_P^2(r)} - \frac{m_\phi^2}{r^2} - k_0^2. \tag{W.204}$$

Now define the dimensionless specific energy

$$\varepsilon = \frac{\omega}{k_0 c_{\mathrm{E}}}, \tag{W.205}$$

and the dimensionless axial angular momentum

$$j_z = \frac{m_\phi}{k_0 R_{\rm QG}}. \tag{W.206}$$

Also define

$$x = \frac{R_{\rm QG}}{r}, \tag{W.207}$$

and the dimensionless dragging rate

$$\widehat{\omega}(x) = \frac{R_{\rm QG}}{c_{\rm E}} \omega_{\rm drag}(r). \tag{W.208}$$

Then

$$\omega - m_\phi \omega_{\rm drag} = k_0 c_{\rm E} \left[\varepsilon - j_z \widehat{\omega}(x)\right]. \tag{W.209}$$

The dimensionless propagation capacity is

$$\widehat{c}_P(x) = \frac{c_P(x)}{c_{\rm E}}. \tag{W.210}$$

Dividing the radial equation by k_0^2, one obtains

$$\frac{k_r^2}{k_0^2} = \mathcal{R}_m(x; \varepsilon, j_z), \tag{W.211}$$

where the massive-particle radial potential is

$$\boxed{\mathcal{R}_m(x; \varepsilon, j_z) = \frac{\left[\varepsilon - j_z \widehat{\omega}(x)\right]^2}{\widehat{c}_P^2(x)} - j_z^2 x^2 - 1.} \tag{W.212}$$

Allowed radial motion satisfies

$$\mathcal{R}_m \geq 0. \tag{W.213}$$

Circular massive-particle orbits are therefore determined by

$$\mathcal{R}_m = 0, \tag{W.214}$$

and

$$\frac{\partial \mathcal{R}_m}{\partial x} = 0. \tag{W.215}$$

The first condition imposes zero radial motion. The second condition imposes radial stationarity of the orbit.

W.5.3 ISCO Condition

A stable circular orbit is one for which small radial perturbations do not immediately open an allowed plunge or escape channel at the same conserved energy and angular momentum. With the convention

$$k_r^2 = k_0^2 \mathcal{R}_m, \tag{W.216}$$

the stable circular branch satisfies

$$\frac{\partial^2 \mathcal{R}_m}{\partial x^2} < 0. \tag{W.217}$$

The innermost stable circular orbit is the marginal orbit separating stable circular motion from unstable circular motion. Therefore, the ISCO is defined by

$$\boxed{\mathcal{R}_m = 0, \qquad \frac{\partial \mathcal{R}_m}{\partial x} = 0, \qquad \frac{\partial^2 \mathcal{R}_m}{\partial x^2} = 0.} \tag{W.218}$$

Solving this system gives

$$x_{\mathrm{ISCO},s_{\mathrm{br}}}(a_*), \tag{W.219}$$

and therefore

$$\boxed{r_{\mathrm{ISCO},s_{\mathrm{br}}}(a_*) = \frac{R_{\mathrm{QG}}}{x_{\mathrm{ISCO},s_{\mathrm{br}}}(a_*)}.} \tag{W.220}$$

The prograde and retrograde branches are distinguished by the sign of the orbital angular momentum relative to the black-hole spin. For $a_* > 0$, $s_{\mathrm{br}} = +1$ corresponds to $j_z > 0$, and $s_{\mathrm{br}} = -1$ corresponds to $j_z < 0$. For general spin orientation, the branch sign is determined by the sign of $a_* j_z$.

W.5.4 Nonrotating ISCO Limit

The nonrotating limit provides an important validation test.

For

$$a_* = 0, \tag{W.221}$$

one has

$$\widehat{\omega}(x) = 0. \tag{W.222}$$

The static TFT propagation law is

$$c_P(r) = c_{\mathrm{E}} \left(1 - \frac{R_{\mathrm{QG}}}{r}\right)^2. \tag{W.223}$$

Therefore,

$$\widehat{c}_P(x) = (1-x)^2. \tag{W.224}$$

The massive radial potential becomes

$$\mathcal{R}_m(x; \varepsilon, j_z) = \frac{\varepsilon^2}{(1-x)^4} - j_z^2 x^2 - 1. \tag{W.225}$$

The circular-orbit conditions are

$$\mathcal{R}_m = 0, \tag{W.226}$$

and

$$\frac{\partial \mathcal{R}_m}{\partial x} = 0. \tag{W.227}$$

Solving these two equations gives

$$\varepsilon^2 = \frac{(1-x)^5}{1-3x}, \tag{W.228}$$

and

$$j_z^2 = \frac{2}{x(1-3x)}. \tag{W.229}$$

Circular massive-particle orbits therefore require

$$1 - 3x > 0. \tag{W.230}$$

Thus,

$$x < \frac{1}{3}, \tag{W.231}$$

or equivalently,

$$r > 3R_{\rm QG}. \tag{W.232}$$

The photon ring at

$$r = 3R_{\rm QG} \tag{W.233}$$

is therefore the limiting inner boundary of circular timelike orbits, as expected.

The ISCO is obtained from the marginal-stability condition

$$\frac{\partial^2 \mathcal{R}_m}{\partial x^2} = 0. \tag{W.234}$$

Substituting the circular-orbit solution into the second derivative gives the condition

$$6x - 1 = 0. \tag{W.235}$$

Therefore,

$$x_{\rm ISCO,0} = \frac{1}{6}, \tag{W.236}$$

and hence

$$\boxed{r_{\rm ISCO,0} = 6R_{\rm QG}.} \tag{W.237}$$

This is an important result. The same static TFT optical law that gives

$$r_{\gamma,0} = 3R_{\rm QG} \tag{W.238}$$

for the photon ring also gives

$$r_{\rm ISCO,0} = 6R_{\rm QG} \tag{W.239}$$

for massive-particle orbital stability.

Thus, the baseline TFT exterior reproduces the standard nonrotating ordering:

$$\boxed{R_{\rm QG} < r_{\gamma,0} = 3R_{\rm QG} < r_{\rm ISCO,0} = 6R_{\rm QG}.} \tag{W.240}$$

This ordering is necessary for any viable accretion-disk phenomenology.

W.5.5 Rotating ISCO Equation

For a rotating black hole, the weak-field matched dragging law gives

$$\widehat{\omega}(x) = 2a_* x^3. \tag{W.241}$$

The equatorial quadrupole-corrected propagation capacity is

$$\widehat{c}_{P,\rm eq}(x) = \left[1 - x - \frac{1}{2}a_*^2 x^3\right]^2. \tag{W.242}$$

Substituting these into the massive-particle radial potential gives

$$\boxed{\mathcal{R}_{m,\mathrm{eq}}(x;\varepsilon,j_z,a_*)=\frac{\left[\varepsilon-2a_*j_zx^3\right]^2}{\left[1-x-\frac{1}{2}a_*^2x^3\right]^4}-j_z^2x^2-1.} \tag{W.243}$$

The rotating ISCO is then determined by

$$\boxed{\mathcal{R}_{m,\mathrm{eq}}=0,\qquad \frac{\partial\mathcal{R}_{m,\mathrm{eq}}}{\partial x}=0,\qquad \frac{\partial^2\mathcal{R}_{m,\mathrm{eq}}}{\partial x^2}=0.} \tag{W.244}$$

This system is solved for

$$\varepsilon_{\mathrm{ISCO},s_{\mathrm{br}}}(a_*), \tag{W.245}$$

$$j_{z,\mathrm{ISCO},s_{\mathrm{br}}}(a_*), \tag{W.246}$$

and

$$x_{\mathrm{ISCO},s_{\mathrm{br}}}(a_*). \tag{W.247}$$

The ISCO radius is then

$$\boxed{r_{\mathrm{ISCO},s_{\mathrm{br}}}(a_*)=\frac{R_{\mathrm{QG}}}{x_{\mathrm{ISCO},s_{\mathrm{br}}}(a_*)}.} \tag{W.248}$$

This equation is the TFT massive-particle counterpart of the photon-ring equation. It is the key bridge between the rotating TFT exterior and accretion-disk observables.

W.5.6 Weak-Spin Structure

The ISCO map must have the symmetry

$$r_{\mathrm{ISCO},+}(a_*)=r_{\mathrm{ISCO},-}(-a_*). \tag{W.249}$$

Therefore, for small spin, the ISCO branches must have the form

$$r_{\mathrm{ISCO},s_{\mathrm{br}}}(a_*)=6R_{\mathrm{QG}}\left[1-s_{\mathrm{br}}\kappa_{\mathrm{ISCO}}a_*+\mathcal{O}(a_*^2)\right]. \tag{W.250}$$

Here κ_{ISCO} is the dimensionless linear spin-response coefficient of the TFT massive-particle orbital closure.

The prograde branch shifts inward,

$$r_{\mathrm{ISCO},+}<6R_{\mathrm{QG}}, \tag{W.251}$$

while the retrograde branch shifts outward,

$$r_{\mathrm{ISCO},-}>6R_{\mathrm{QG}}. \tag{W.252}$$

This is the same qualitative branch splitting found for the photon ring, but it applies to massive-particle orbital stability rather than optical trapping.

For exact weak-spin Kerr-ISCO correspondence, the coefficient would have to satisfy the Kerr value

$$\kappa_{\mathrm{ISCO}}=\frac{2}{3}, \tag{W.253}$$

because the Kerr weak-spin ISCO expansion is

$$r_{\mathrm{ISCO},s_{\mathrm{br}}}^{\mathrm{Kerr}} = 6R_{\mathrm{QG}}\left[1 - \frac{2}{3}s_{\mathrm{br}}a_* + \mathcal{O}(a_*^2)\right]. \tag{W.254}$$

In the present appendix, κ_{ISCO} should be treated as a validation output of the massive-particle closure and numerical exterior solver, unless one explicitly chooses to impose Kerr-ISCO correspondence as an additional phenomenological matching condition.

This distinction is important. The photon-ring and frame-dragging sectors were matched to weak-field Kerr behavior by construction. The ISCO sector now provides an independent test of whether the same Soft-Floor dynamics reproduces the massive-particle orbital structure without an additional closure.

W.5.7 Observational Role of the ISCO

The ISCO map is essential because it connects TFT to accretion-disk observables.

The disk inner edge is modeled as

$$r_{\mathrm{in}} \approx r_{\mathrm{ISCO},s_{\mathrm{br}}}(a_*) \tag{W.255}$$

for geometrically thin, radiatively efficient disks. Therefore, X-ray reflection and continuum-fitting measurements infer spin primarily through the mapping

$$a_* \longmapsto r_{\mathrm{ISCO},s_{\mathrm{br}}}(a_*). \tag{W.256}$$

Without this map, TFT can address photon rings and shadows but cannot fully interface with standard black-hole spin measurements.

The present massive-particle Hamiltonian supplies that missing interface:

$$\boxed{(M, a_*) \longrightarrow r_{\mathrm{ISCO},s_{\mathrm{br}}}(a_*) \longrightarrow \text{disk inner edge observables.}} \tag{W.257}$$

Thus, the ISCO is not a secondary detail. It is one of the primary observational tests of the rotating TFT exterior.

W.5.8 Baseline Conclusion

The massive-particle extension of the rotating Soft-Floor Hamiltonian is

$$\boxed{\mathcal{H}_m = \frac{1}{2}\left[-\frac{(\omega - m_\phi\omega_{\mathrm{drag}})^2}{c_P^2} + k_r^2 + \frac{k_\theta^2}{r^2} + \frac{m_\phi^2}{r^2\sin^2\theta} + k_0^2\right] = 0.} \tag{W.258}$$

For equatorial orbits, this gives the radial potential

$$\boxed{\mathcal{R}_m(x;\varepsilon,j_z) = \frac{[\varepsilon - j_z\widehat{\omega}(x)]^2}{\widehat{c}_P^2(x)} - j_z^2x^2 - 1.} \tag{W.259}$$

The ISCO is defined by the triple condition

$$\boxed{\mathcal{R}_m = 0, \qquad \frac{\partial\mathcal{R}_m}{\partial x} = 0, \qquad \frac{\partial^2\mathcal{R}_m}{\partial x^2} = 0.} \tag{W.260}$$

In the nonrotating limit, the baseline TFT exterior gives

$$\boxed{r_{\mathrm{ISCO},0} = 6R_{\mathrm{QG}}.} \tag{W.261}$$

For rotating black holes, the ISCO map is obtained from

$$\boxed{\mathcal{R}_{m,\mathrm{eq}}(x;\varepsilon,j_z,a_*) = \frac{\left[\varepsilon - 2a_* j_z x^3\right]^2}{\left[1 - x - \frac{1}{2}a_*^2 x^3\right]^4} - j_z^2 x^2 - 1,} \tag{W.262}$$

with

$$\boxed{r_{\mathrm{ISCO},s_{\mathrm{br}}}(a_*) = \frac{R_{\mathrm{QG}}}{x_{\mathrm{ISCO},s_{\mathrm{br}}}(a_*)}.} \tag{W.263}$$

This completes the massive-particle orbital sector required for the rotating TFT black-hole exterior. The appendix now contains the essential observational maps for frame dragging, quadrupole structure, photon rings, shadows, ISCOs, and ringdown.

W.6 Observational Surface Map: $R_{\mathrm{obs}}(a_*)$, Capacity Surface, Photon Ring, Shadow Radius, and ISCO

The previous sections fixed the leading ingredients of the rotating TFT black-hole exterior.

The torsional stiffness closure gives

$$\tau_{\mathrm{tor}}(\alpha_{\mathrm{G}}) = \tau_{D,\mathrm{bulk}}, \tag{W.264}$$

so the leading exterior angular-drag field has the inverse-cubic radial form.

Weak-field coefficient matching fixes the exterior dragging law to

$$\omega_{\mathrm{drag}}(r) = \frac{2G\mathcal{J}_{\mathrm{BH}}}{c_{\mathrm{E}}^2 r^3} = 2a_* c_{\mathrm{E}} \frac{R_{\mathrm{QG}}^2}{r^3}. \tag{W.265}$$

The relaxed no-hair quadrupole closure gives

$$Q_{\mathrm{TFT}} = -\frac{\mathcal{J}_{\mathrm{BH}}^2}{M c_{\mathrm{E}}^2} = -a_*^2 M R_{\mathrm{QG}}^2. \tag{W.266}$$

The photon-ring section derived the massless circular-orbit structure, while the massive-particle section derived the ISCO condition from the massive Soft-Floor Hamiltonian. Together, these define the leading observational surface map of a rotating TFT black hole.

The important conceptual point is that the observed black-hole scale is not a single surface. TFT separates the physical phase boundary, the torsional co-motion surface, the photon-ring surface, the shadow-impact scale, and the massive-particle orbital stability surface. Thus the observational map is not one radius but a layered structure:

$$R_{\mathrm{obs}}(a_*) = \left\{R_{\mathrm{QG}},\, r_{\mathrm{sat}}(\theta,a_*),\, r_{\mathrm{cap}}(\theta,a_*),\, r_{\gamma,s_{\mathrm{br}}}(a_*),\, B_{\gamma,s_{\mathrm{br}}}(a_*),\, r_{\mathrm{ISCO},s_{\mathrm{br}}}(a_*)\right\}. \tag{W.267}$$

Here

$$R_{\mathrm{QG}} = \frac{GM}{c_{\mathrm{E}}^2} \tag{W.268}$$

is the mass-defined saturation scale and the nonrotating FCC/SC boundary radius.

The spin-deformed physical boundary is

$$r_{\rm sat}(\theta, a_*). \tag{W.269}$$

The torsional capacity surface is

$$r_{\rm cap}(\theta, a_*). \tag{W.270}$$

The prograde and retrograde photon-ring radii are

$$r_{\gamma,+}(a_*), \qquad r_{\gamma,-}(a_*). \tag{W.271}$$

The corresponding observed shadow-impact scales are

$$B_{\gamma,+}(a_*), \qquad B_{\gamma,-}(a_*). \tag{W.272}$$

The corresponding massive-particle orbital stability radii are

$$r_{\rm ISCO,+}(a_*), \qquad r_{\rm ISCO,-}(a_*). \tag{W.273}$$

These define the prograde and retrograde innermost stable circular orbits of the rotating TFT exterior.

This is the TFT replacement for treating the Kerr horizon, ergosurface, photon ring, shadow, and ISCO as consequences of a single geometric metric. In TFT, they are mechanically distinct surfaces or orbital maps of the strained Soft Floor.

W.6.1 Physical Boundary Versus Observational Surface

The nonrotating black-hole saturation radius is

$$R_{\rm QG} = \frac{GM}{c_{\rm E}^2}. \tag{W.274}$$

This is the radius at which the active FCC Soft Floor reaches

$$\alpha_{\rm G} = 1 \tag{W.275}$$

in the spherical limit.

For a rotating black hole, however, the physical phase boundary is not exactly spherical. It is the surface on which the strain reaches saturation:

$$\alpha_{\rm G}(r, \theta) = 1. \tag{W.276}$$

Therefore, the rotating physical boundary is defined by

$$\boxed{\alpha_{\rm G}(r_{\rm sat}(\theta, a_*), \theta) = 1.} \tag{W.277}$$

Thus,

$$R_{\rm QG} \tag{W.278}$$

is the underlying mass scale, while

$$r_{\rm sat}(\theta, a_*) \tag{W.279}$$

is the actual spin-deformed FCC/SC boundary.

An observer does not directly image this microscopic phase boundary. The observer infers the black hole through optical trapping, frame dragging, photon-ring structure, accretion emission, shadow formation, and disk orbital stability. Therefore, the observed black-hole boundary is a derived phenomenological map, not simply the physical saturation boundary.

This distinction is central:

$$\boxed{\text{physical boundary} \neq \text{capacity surface} \neq \text{photon ring} \neq \text{shadow edge} \neq \text{ISCO.}} \tag{W.280}$$

The photon ring and shadow are massless optical observables. The ISCO is a massive-particle orbital-stability observable. They probe different sectors of the rotating TFT exterior.

W.6.2 Quadrupole-Corrected Strain Field

The no-hair quadrupole closure gives the leading rotating strain field:

$$\alpha_{\mathrm{G}}(r,\theta) = \frac{R_{\mathrm{QG}}}{r} - a_*^2 \left(\frac{R_{\mathrm{QG}}}{r}\right)^3 P_2(\cos\theta) + \mathcal{O}(a_*^4), \tag{W.281}$$

where

$$P_2(\cos\theta) = \frac{1}{2}\left(3\cos^2\theta - 1\right). \tag{W.282}$$

The local Soft-Floor propagation speed is

$$c_P(r,\theta) = c_{\mathrm{E}}\left[1 - \alpha_{\mathrm{G}}(r,\theta)\right]^2. \tag{W.283}$$

Substituting the quadrupole-corrected strain gives

$$\boxed{c_P(r,\theta) = c_{\mathrm{E}}\left[1 - \frac{R_{\mathrm{QG}}}{r} + a_*^2\left(\frac{R_{\mathrm{QG}}}{r}\right)^3 P_2(\cos\theta)\right]^2.} \tag{W.284}$$

This propagation law is the optical input for the capacity surface, photon-ring condition, shadow-impact map, and massive-particle orbital stability calculation.

W.6.3 Spin-Deformed Saturation Boundary

The physical FCC/SC boundary is defined by

$$\alpha_{\mathrm{G}}(r,\theta) = 1. \tag{W.285}$$

Using the quadrupole-corrected strain field, the boundary condition becomes

$$1 = \frac{R_{\mathrm{QG}}}{r} - a_*^2\left(\frac{R_{\mathrm{QG}}}{r}\right)^3 P_2(\cos\theta). \tag{W.286}$$

Define

$$x = \frac{R_{\mathrm{QG}}}{r}. \tag{W.287}$$

Then

$$1 = x - a_*^2 x^3 P_2(\cos\theta). \tag{W.288}$$

For a perturbative rotating solution, write

$$x = 1 + \delta x, \tag{W.289}$$

where

$$\delta x = \mathcal{O}(a_*^2). \tag{W.290}$$

Keeping terms through order a_*^2 gives

$$\delta x = a_*^2 P_2(\cos\theta). \tag{W.291}$$

Since

$$r = \frac{R_{\rm QG}}{x}, \tag{W.292}$$

the spin-deformed saturation boundary is

$$\boxed{r_{\rm sat}(\theta, a_*) = R_{\rm QG}\left[1 - a_*^2 P_2(\cos\theta)\right] + \mathcal{O}(a_*^4).} \tag{W.293}$$

At the equator,

$$\theta = \frac{\pi}{2}, \qquad P_2(0) = -\frac{1}{2}, \tag{W.294}$$

so

$$\boxed{r_{\rm sat,eq} = R_{\rm QG}\left(1 + \frac{1}{2}a_*^2\right) + \mathcal{O}(a_*^4).} \tag{W.295}$$

At the pole,

$$\theta = 0, \qquad P_2(1) = 1, \tag{W.296}$$

so

$$\boxed{r_{\rm sat,pole} = R_{\rm QG}\left(1 - a_*^2\right) + \mathcal{O}(a_*^4).} \tag{W.297}$$

Thus, to leading order, rotation produces an oblate saturation boundary: the equatorial boundary expands and the polar boundary contracts.

This result should not be extrapolated to extremal spin. The expression is a perturbative quadrupole boundary map through order a_*^2. A full near-extremal solution requires the nonlinear numerical exterior solver developed later.

W.6.4 Torsional Capacity Surface

The torsional capacity surface is the surface on which the local azimuthal drift speed of the Soft Floor equals the local propagation capacity.

The defining condition is

$$\left|v_\phi^{(\rm SF)}(r,\theta)\right| = c_P(r,\theta). \tag{W.298}$$

The Soft-Floor drift speed is

$$v_\phi^{(\rm SF)}(r,\theta) = r\sin\theta\,\omega_{\rm drag}(r). \tag{W.299}$$

Using the weak-field matched dragging law,

$$\omega_{\rm drag}(r) = 2a_* c_{\rm E}\frac{R_{\rm QG}^2}{r^3}, \tag{W.300}$$

one obtains

$$v_\phi^{(\rm SF)}(r,\theta) = 2a_* c_{\rm E}\left(\frac{R_{\rm QG}}{r}\right)^2\sin\theta. \tag{W.301}$$

Therefore,

$$\left|v_\phi^{(\mathrm{SF})}\right| = 2|a_*|c_\mathrm{E}\left(\frac{R_\mathrm{QG}}{r}\right)^2 \sin\theta. \tag{W.302}$$

Equating this with the quadrupole-corrected propagation speed gives

$$2|a_*|\left(\frac{R_\mathrm{QG}}{r}\right)^2 \sin\theta = \left[1 - \frac{R_\mathrm{QG}}{r} + a_*^2\left(\frac{R_\mathrm{QG}}{r}\right)^3 P_2(\cos\theta)\right]^2. \tag{W.303}$$

In dimensionless form,

$$x = \frac{R_\mathrm{QG}}{r}, \tag{W.304}$$

the capacity-surface equation is

$$\boxed{2|a_*|x^2\sin\theta = \left[1 - x + a_*^2 x^3 P_2(\cos\theta)\right]^2.} \tag{W.305}$$

The physical capacity surface is the exterior solution satisfying

$$r_\mathrm{cap}(\theta, a_*) \geq r_\mathrm{sat}(\theta, a_*). \tag{W.306}$$

At leading order, neglect the a_*^2 quadrupole correction inside the propagation factor. Then

$$2|a_*|x^2\sin\theta = (1-x)^2. \tag{W.307}$$

For the exterior branch,

$$0 < x < 1, \tag{W.308}$$

so

$$1 - x = x\sqrt{2|a_*|\sin\theta}. \tag{W.309}$$

Therefore,

$$x = \frac{1}{1 + \sqrt{2|a_*|\sin\theta}}. \tag{W.310}$$

Thus,

$$\boxed{r_\mathrm{cap}(\theta, a_*) = R_\mathrm{QG}\left[1 + \sqrt{2|a_*|\sin\theta}\right]} \tag{W.311}$$

to leading order.

At the pole,

$$\sin\theta = 0, \tag{W.312}$$

so

$$\boxed{r_\mathrm{cap,pole} = R_\mathrm{QG}.} \tag{W.313}$$

At the equator,

$$\sin\theta = 1, \tag{W.314}$$

so

$$\boxed{r_\mathrm{cap,eq} = R_\mathrm{QG}\left[1 + \sqrt{2|a_*|}\right].} \tag{W.315}$$

This is the TFT analogue of an ergosurface, but it should not be described as a copied Kerr ergosphere. It is a mechanical co-motion surface: the surface where torsional Soft-Floor drift consumes the available local propagation capacity.

The square-root dependence is also important. The capacity surface is a near-boundary strong-field object; therefore, its leading displacement is not analytic in a_*. This occurs because the propagation capacity collapses quadratically near saturation, while the torsional drift is linear in spin.

W.6.5 Photon-Ring Radius as an Observational Surface

The photon ring is determined by the rotating Soft-Floor Hamiltonian. For equatorial circular photon orbits, the condition derived earlier is

$$\frac{\mathrm{d}}{\mathrm{d}r}\left[\omega_{\mathrm{drag}}(r)+s_{\mathrm{br}}\frac{c_{P,\mathrm{eq}}(r)}{r}\right]=0, \tag{W.316}$$

where

$$s_{\mathrm{br}}=+1 \tag{W.317}$$

labels the prograde branch, and

$$s_{\mathrm{br}}=-1 \tag{W.318}$$

labels the retrograde branch.

The quadrupole-corrected equatorial propagation speed is

$$c_{P,\mathrm{eq}}(r)=c_{\mathrm{E}}\left[1-\frac{R_{\mathrm{QG}}}{r}-\frac{1}{2}a_*^2\left(\frac{R_{\mathrm{QG}}}{r}\right)^3\right]^2. \tag{W.319}$$

Therefore, the quadrupole-corrected equatorial photon-ring condition is

$$\boxed{\frac{\mathrm{d}}{\mathrm{d}r}\left[2a_*c_{\mathrm{E}}\frac{R_{\mathrm{QG}}^2}{r^3}+s_{\mathrm{br}}\frac{c_{\mathrm{E}}}{r}\left[1-\frac{R_{\mathrm{QG}}}{r}-\frac{1}{2}a_*^2\left(\frac{R_{\mathrm{QG}}}{r}\right)^3\right]^2\right]=0.} \tag{W.320}$$

In dimensionless form,

$$x=\frac{R_{\mathrm{QG}}}{r}, \tag{W.321}$$

this becomes

$$\boxed{\frac{\mathrm{d}}{\mathrm{d}x}\left\{2a_*x^3+s_{\mathrm{br}}x\left[1-x-\frac{1}{2}a_*^2x^3\right]^2\right\}=0.} \tag{W.322}$$

This equation defines

$$x_{\gamma,s_{\mathrm{br}}}(a_*), \tag{W.323}$$

and therefore

$$\boxed{r_{\gamma,s_{\mathrm{br}}}(a_*)=\frac{R_{\mathrm{QG}}}{x_{\gamma,s_{\mathrm{br}}}(a_*)}.} \tag{W.324}$$

In the nonrotating limit,

$$a_*=0, \tag{W.325}$$

one obtains

$$\boxed{r_{\gamma,0}=3R_{\mathrm{QG}}.} \tag{W.326}$$

In the weak-spin limit, the leading branch splitting is

$$\boxed{r_{\gamma,s_{\mathrm{br}}}=3R_{\mathrm{QG}}\left(1-s_{\mathrm{br}}a_*\right)+\mathcal{O}(a_*^2).} \tag{W.327}$$

Thus, the prograde photon ring shifts inward, while the retrograde photon ring shifts outward.

W.6.6 Shadow Impact Scale

The photon ring is not itself the directly observed shadow radius. The observable shadow edge is determined by the critical impact scale of rays that asymptotically approach the circular photon orbit.

From the photon-ring derivation, the signed impact parameter is

$$b_{\gamma,s_{\rm br}} = \frac{1}{\omega_{\rm drag}(r_{\gamma,s_{\rm br}}) + s_{\rm br}\frac{c_P(r_{\gamma,s_{\rm br}})}{r_{\gamma,s_{\rm br}}}}. \tag{W.328}$$

In this normalization, $b_{\gamma,s_{\rm br}}$ has dimensions of time. The corresponding physical impact length is

$$B_{\gamma,s_{\rm br}} = c_{\rm E}\left|b_{\gamma,s_{\rm br}}\right|. \tag{W.329}$$

Therefore,

$$\boxed{B_{\gamma,s_{\rm br}}(a_*) = \frac{c_{\rm E}}{\left|\omega_{\rm drag}(r_{\gamma,s_{\rm br}}) + s_{\rm br}\frac{c_P(r_{\gamma,s_{\rm br}})}{r_{\gamma,s_{\rm br}}}\right|}.} \tag{W.330}$$

This is the baseline equatorial TFT shadow-impact scale.

In the nonrotating case,

$$r_{\gamma,0} = 3R_{\rm QG}, \tag{W.331}$$

and

$$c_P(3R_{\rm QG}) = c_{\rm E}\left(1-\frac{1}{3}\right)^2 = \frac{4}{9}c_{\rm E}. \tag{W.332}$$

Therefore,

$$B_{\gamma,0} = \frac{c_{\rm E}}{c_P/r} = \frac{c_{\rm E}}{\left(\frac{4}{9}c_{\rm E}\right)\left(\frac{1}{3R_{\rm QG}}\right)}. \tag{W.333}$$

Thus,

$$\boxed{B_{\gamma,0} = \frac{27}{4}R_{\rm QG}.} \tag{W.334}$$

This is the static TFT shadow-impact scale implied by the present optical propagation law. It should not yet be described as Kerr-matched. Rather, it is a sharp prediction of the current baseline optical closure.

For small spin, using the leading photon-ring splitting gives

$$\boxed{B_{\gamma,+} \approx \frac{27}{4}R_{\rm QG}\left(1-\frac{1}{2}a_*\right)} \tag{W.335}$$

for the prograde branch, and

$$\boxed{B_{\gamma,-} \approx \frac{27}{4}R_{\rm QG}\left(1+\frac{1}{2}a_*\right)} \tag{W.336}$$

for the retrograde branch.

Thus, frame dragging compresses the prograde shadow edge and expands the retrograde shadow edge. The leading average shadow scale remains

$$\boxed{B_{\rm sh,avg} \approx \frac{27}{4}R_{\rm QG} + \mathcal{O}(a_*^2).} \tag{W.337}$$

The leading equatorial asymmetry scale is

$$\boxed{\Delta B_{\rm sh} = B_{\gamma,-} - B_{\gamma,+} \approx \frac{27}{4} R_{\rm QG} a_*.} \tag{W.338}$$

This gives a direct observational map from spin to shadow asymmetry in the baseline rotating TFT exterior.

W.6.7 ISCO as a Massive-Particle Observational Surface

The photon ring and shadow-impact scale describe massless propagation. Accretion-disk observables, however, depend on massive-particle orbital stability. Therefore, the observational map must also include the ISCO surface derived from the massive-particle Hamiltonian.

The ISCO branches are

$$r_{\rm ISCO,+}(a_*), \qquad r_{\rm ISCO,-}(a_*), \tag{W.339}$$

where the $(+)$ branch is prograde and the $(-)$ branch is retrograde.

They are obtained from the massive-particle radial potential by the triple condition

$$\mathcal{R}_m = 0, \qquad \frac{\partial \mathcal{R}_m}{\partial x} = 0, \qquad \frac{\partial^2 \mathcal{R}_m}{\partial x^2} = 0. \tag{W.340}$$

Thus,

$$\boxed{r_{{\rm ISCO},s_{\rm br}}(a_*) = \frac{R_{\rm QG}}{x_{{\rm ISCO},s_{\rm br}}(a_*)}.} \tag{W.341}$$

In the nonrotating limit, the baseline TFT massive-particle closure gives

$$\boxed{r_{\rm ISCO,0} = 6R_{\rm QG}.} \tag{W.342}$$

Therefore, the nonrotating ordering of characteristic radii is

$$\boxed{R_{\rm QG} < r_{\gamma,0} = 3R_{\rm QG} < r_{\rm ISCO,0} = 6R_{\rm QG}.} \tag{W.343}$$

This ordering is required for viable accretion-disk phenomenology. The ISCO surface supplies the link between the rotating TFT exterior and disk-based spin measurements, while the photon ring and shadow scale supply the optical imaging observables.

The ISCO should therefore be treated as a distinct observational layer:

$$\boxed{\text{shadow} = \text{massless optical observable}, \qquad \text{ISCO} = \text{massive-particle disk observable.}} \tag{W.344}$$

W.6.8 The Observational Map

The leading observational map is therefore:

$$\boxed{R_{\rm QG} = \frac{GM}{c_{\rm E}^2}} \tag{W.345}$$

as the nonrotating saturation scale;

$$\boxed{r_{\rm sat}(\theta, a_*) = R_{\rm QG}\left[1 - a_*^2 P_2(\cos\theta)\right] + \mathcal{O}(a_*^4)} \tag{W.346}$$

as the spin-deformed physical FCC/SC boundary;

$$\boxed{r_{\rm cap}(\theta, a_*) = R_{\rm QG}\left[1 + \sqrt{2|a_*|\sin\theta}\right]} \tag{W.347}$$

as the leading torsional capacity surface;

$$\boxed{r_{\gamma,s_{\rm br}}(a_*) = \frac{R_{\rm QG}}{x_{\gamma,s_{\rm br}}(a_*)}} \tag{W.348}$$

where $x_{\gamma,s_{\rm br}}$ is determined by

$$\boxed{\frac{\mathrm{d}}{\mathrm{d}x}\left\{2a_* x^3 + s_{\rm br} x\left[1 - x - \frac{1}{2}a_*^2 x^3\right]^2\right\} = 0;} \tag{W.349}$$

$$\boxed{B_{\gamma,s_{\rm br}}(a_*) = \frac{c_{\rm E}}{\left|\omega_{\rm drag}(r_{\gamma,s_{\rm br}}) + s_{\rm br}\frac{c_P(r_{\gamma,s_{\rm br}})}{r_{\gamma,s_{\rm br}}}\right|}} \tag{W.350}$$

as the equatorial shadow-impact scale; and

$$\boxed{r_{{\rm ISCO},s_{\rm br}}(a_*) = \frac{R_{\rm QG}}{x_{{\rm ISCO},s_{\rm br}}(a_*)}} \tag{W.351}$$

as the massive-particle orbital-stability surface.

Collectively,

$$\boxed{R_{\rm obs}(a_*) = \left\{R_{\rm QG},\, r_{\rm sat},\, r_{\rm cap},\, r_{\gamma,s_{\rm br}},\, B_{\gamma,s_{\rm br}},\, r_{{\rm ISCO},s_{\rm br}}\right\}.} \tag{W.352}$$

This is the observational horizon/shadow/capacity/ISCO map for the leading rotating TFT exterior.

W.6.9 Baseline Conclusion

The observational black-hole surface in TFT is not a single Kerr coordinate horizon. It is a layered mechanical-optical-orbital map:

$$\boxed{\text{mass scale} \to \text{physical phase boundary} \to \text{torsional capacity surface} \to \text{photon ring} \to \text{shadow impact scale} \to \text{IS}} \tag{W.353}$$

The mass scale is

$$R_{\rm QG}. \tag{W.354}$$

The physical rotating FCC/SC boundary is

$$r_{\rm sat}(\theta, a_*). \tag{W.355}$$

The torsional co-motion surface is

$$r_{\rm cap}(\theta, a_*). \tag{W.356}$$

The photon-ring radius is

$$r_{\gamma,s_{\rm br}}(a_*). \tag{W.357}$$

The observed equatorial shadow edge is

$$B_{\gamma,s_{\rm br}}(a_*). \tag{W.358}$$

The massive-particle orbital stability surface is

$$r_{\mathrm{ISCO},s_{\mathrm{br}}}(a_*). \tag{W.359}$$

The ISCO connects the rotating TFT exterior to accretion-disk spin measurements and completes the observational map beyond optical shadow phenomenology.

This map is sufficient as the baseline TFT observational framework. It also identifies a critical strong-field test: the present static optical closure predicts

$$B_{\gamma,0} = \frac{27}{4} R_{\mathrm{QG}}. \tag{W.360}$$

Therefore, a final Kerr-replacement model must decide whether this value is a genuine TFT shadow-scale deviation, or whether a saturation-corrected optical law modifies the shadow-impact scale while preserving the weak-field lensing, frame-dragging, photon-ring, ISCO, and ringdown limits recovered or formulated in the preceding sections.

W.7 Numerical Exterior Solver for the Rotating TFT Black-Hole Exterior

The previous sections derived the analytic closures needed to construct the rotating TFT black-hole exterior. These closures determine the torsional stiffness, weak-field angular-drag normalization, spin-induced quadrupole, photon-ring condition, massive-particle ISCO condition, observational surface map, and ringdown scaling.

The final step is to formulate the numerical exterior solver. The purpose of the solver is to determine the coupled exterior fields

$$r_\partial(\theta, a_*), \qquad \alpha_{\mathrm{G}}(r,\theta), \qquad \omega_{\mathrm{drag}}(r,\theta), \qquad c_P(r,\theta), \tag{W.361}$$

for a rotating TFT black hole with final mass M and dimensionless spin a_*.

Here $r_\partial(\theta, a_*)$ is the spin-deformed FCC/SC phase boundary. To prevent ambiguity, we explicitly define $r_\partial(\theta, a_*) \equiv r_{\mathrm{sat}}(\theta, a_*)$ when referring to the solved FCC/SC saturation boundary. Furthermore, $\alpha_{\mathrm{G}}(r,\theta)$ is the exterior gravitational strain field, $\omega_{\mathrm{drag}}(r,\theta)$ is the torsional Soft-Floor angular-drag field, and $c_P(r,\theta)$ is the local propagation capacity of the strained Soft Floor.

The numerical solver is therefore not a metric solver in the GR sense. It is a coupled free-boundary and Soft-Floor constitutive solver.

W.7.1 Dimensionless Variables

For numerical stability, introduce the dimensionless radius

$$\bar{r} = \frac{r}{R_{\mathrm{QG}}}, \tag{W.362}$$

where

$$R_{\mathrm{QG}} = \frac{GM}{c_{\mathrm{E}}^2}. \tag{W.363}$$

The dimensionless spin is

$$a_* = \frac{c_{\mathrm{E}} \mathcal{J}_{\mathrm{BH}}}{GM^2}. \tag{W.364}$$

The dimensionless angular-drag field is

$$\widehat{\omega}(\bar{r},\theta) = \frac{R_{\mathrm{QG}}}{c_{\mathrm{E}}}\omega_{\mathrm{drag}}(r,\theta). \tag{W.365}$$

Thus,

$$\omega_{\mathrm{drag}}(r,\theta) = \frac{c_{\mathrm{E}}}{R_{\mathrm{QG}}}\widehat{\omega}(\bar{r},\theta). \tag{W.366}$$

The propagation law becomes

$$\boxed{\frac{c_P(\bar{r},\theta)}{c_{\mathrm{E}}} = \left[1-\alpha_{\mathrm{G}}(\bar{r},\theta)\right]^2.} \tag{W.367}$$

The dimensionless Soft-Floor azimuthal drift speed is

$$\frac{v_\phi^{(\mathrm{SF})}}{c_{\mathrm{E}}} = \bar{r}\sin\theta\,\widehat{\omega}(\bar{r},\theta). \tag{W.368}$$

This gives the fundamental numerical field set:

$$\boxed{\left\{\bar{r}_\partial(\theta,a_*),\ \alpha_{\mathrm{G}}(\bar{r},\theta),\ \widehat{\omega}(\bar{r},\theta),\ \frac{c_P(\bar{r},\theta)}{c_{\mathrm{E}}}\right\}.} \tag{W.369}$$

W.7.2 Exterior Strain Equation

At the baseline closure level, the exterior active FCC Soft Floor is source-free outside the saturated domain. The black-hole mass and spin-induced quadrupole are encoded through the inner phase boundary and the far-field multipole conditions.

Therefore, the exterior strain field satisfies

$$\boxed{\bar{\nabla}^2\alpha_{\mathrm{G}} = 0} \tag{W.370}$$

in the exterior domain

$$\bar{r} > \bar{r}_\partial(\theta,a_*). \tag{W.371}$$

Here $\bar{\nabla}$ denotes differentiation with respect to the dimensionless coordinates $(\bar{r},\theta,\phi)$. In axisymmetric spherical coordinates, this equation is

$$\frac{1}{\bar{r}^2}\frac{\partial}{\partial\bar{r}}\left(\bar{r}^2\frac{\partial\alpha_{\mathrm{G}}}{\partial\bar{r}}\right) + \frac{1}{\bar{r}^2\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial\alpha_{\mathrm{G}}}{\partial\theta}\right) = 0. \tag{W.372}$$

The inner boundary is the FCC/SC saturation condition:

$$\boxed{\alpha_{\mathrm{G}}(\bar{r}_\partial(\theta,a_*),\theta) = 1.} \tag{W.373}$$

The far-field condition is fixed by the mass monopole and the no-hair quadrupole closure:

$$\boxed{\alpha_{\mathrm{G}}(\bar{r},\theta) \to \frac{1}{\bar{r}} - a_*^2\frac{P_2(\cos\theta)}{\bar{r}^3} \qquad (\bar{r}\to\infty).} \tag{W.374}$$

This condition encodes

$$Q_{\mathrm{TFT}} = -a_*^2 M R_{\mathrm{QG}}^2 = -\frac{\mathcal{J}_{\mathrm{BH}}^2}{Mc_{\mathrm{E}}^2}. \tag{W.375}$$

Thus, the strain solver is the free-boundary problem

$$\boxed{\bar{\nabla}^2\alpha_{\rm G}=0,\qquad \alpha_{\rm G}(\bar{r}_\partial,\theta)=1,\qquad \alpha_{\rm G}\to\frac{1}{\bar{r}}-a_*^2\frac{P_2(\cos\theta)}{\bar{r}^3}.} \tag{W.376}$$

This is the leading exterior structural equation. A later nonlinear strong-field completion may replace $\bar{\nabla}^2\alpha_{\rm G}=0$ with a nonlinear constitutive operator, but the present equation is the baseline closure implied by the appendix.

W.7.3 Free-Boundary Update

The physical boundary is not prescribed independently. It is the level surface on which the active FCC Soft Floor reaches saturation:

$$\alpha_{\rm G}=1. \tag{W.377}$$

Therefore,

$$\boxed{\bar{r}_\partial(\theta,a_*)\text{ is determined by }\alpha_{\rm G}(\bar{r}_\partial(\theta,a_*),\theta)=1.} \tag{W.378}$$

The perturbative analytic result for the spin-deformed saturation boundary provides the initial boundary guess:

$$\bar{r}_\partial^{(0)}(\theta)=1-a_*^2P_2(\cos\theta). \tag{W.379}$$

The solver then updates the boundary iteratively. If the current boundary estimate is $\bar{r}_\partial^{(n)}(\theta)$, then the residual is

$$\mathcal{R}_\partial^{(n)}(\theta)=\alpha_{\rm G}(\bar{r}_\partial^{(n)}(\theta),\theta)-1. \tag{W.380}$$

A Newton-type level-set update has the form

$$\bar{r}_\partial^{(n+1)}(\theta)=\bar{r}_\partial^{(n)}(\theta)-\frac{\mathcal{R}_\partial^{(n)}(\theta)}{\partial_{\bar{r}}\alpha_{\rm G}(\bar{r}_\partial^{(n)}(\theta),\theta)}. \tag{W.381}$$

The iteration continues until

$$|\alpha_{\rm G}(\bar{r}_\partial(\theta),\theta)-1| \tag{W.382}$$

is below the chosen tolerance for all θ.

This turns the black-hole boundary into a solved phase-transition surface, not an imposed geometric horizon.

W.7.4 Exterior Torsional-Drag Equation

The torsional Soft-Floor field is governed by angular-momentum flux balance in the exterior FCC medium.

The cylindrical distance from the spin axis is

$$r_\perp=r\sin\theta. \tag{W.383}$$

In dimensionless variables,

$$\frac{r_\perp}{R_{\rm QG}}=\bar{r}\sin\theta. \tag{W.384}$$

The torsional energy density is proportional to the square of the angular-drag gradient weighted by the lever arm $r_\perp^2$. The corresponding exterior balance equation is

$$\boxed{\bar{\nabla}\cdot\left[\bar{r}^2\sin^2\theta\,\bar{\nabla}\widehat{\omega}\right]=0.} \tag{W.385}$$

This equation is the two-dimensional axisymmetric extension of the radial torsional equation. If

$$\widehat{\omega} = \widehat{\omega}(\bar{r}) \tag{W.386}$$

only, then it reduces to

$$\frac{\mathrm{d}}{\mathrm{d}\bar{r}}\left[\bar{r}^4 \frac{\mathrm{d}\widehat{\omega}}{\mathrm{d}\bar{r}}\right] = 0, \tag{W.387}$$

which is the dimensionless form of the analytic radial equation derived earlier.

The far-field condition is fixed by weak-field Lense–Thirring matching:

$$\boxed{\widehat{\omega}(\bar{r},\theta) \to \frac{2a_*}{\bar{r}^3} \qquad (\bar{r} \to \infty).} \tag{W.388}$$

The axis regularity condition is

$$\boxed{\frac{\partial \widehat{\omega}}{\partial \theta} = 0 \qquad \text{at} \qquad \theta = 0, \pi.} \tag{W.389}$$

For reflection-symmetric solutions, one may solve only the northern half-domain,

$$0 \le \theta \le \frac{\pi}{2}, \tag{W.390}$$

with equatorial symmetry condition

$$\boxed{\frac{\partial \widehat{\omega}}{\partial \theta} = 0 \qquad \text{at} \qquad \theta = \frac{\pi}{2}.} \tag{W.391}$$

The inner torsional boundary condition is supplied by the live FCC/SC boundary. For the baseline Kerr-correspondence solver, the inner boundary is treated as a phase-locked angular-momentum reservoir. The boundary angular-drag datum is adjusted so that the exterior satisfies the global angular-momentum normalization

$$\mathcal{J}_{\mathrm{BH}} = a_* \frac{GM^2}{c_{\mathrm{E}}} \tag{W.392}$$

and the far-field coefficient

$$\widehat{\omega} \to \frac{2a_*}{\bar{r}^3}. \tag{W.393}$$

Thus, the torsional problem is not normalized by an arbitrary local no-slip surface velocity. It is normalized by the conserved total angular momentum of the black hole.

A practical numerical implementation is to use a boundary value

$$\widehat{\omega}_\partial(\theta) = \widehat{\omega}(\bar{r}_\partial(\theta), \theta), \tag{W.394}$$

solve the exterior torsional equation, and iterate $\widehat{\omega}_\partial$ until the asymptotic coefficient satisfies

$$\boxed{\lim_{\bar{r}\to\infty} \bar{r}^3 \widehat{\omega} = 2a_*.} \tag{W.395}$$

In the spherical radial limit this gives

$$\widehat{\omega}(\bar{r}) = \frac{2a_*}{\bar{r}^3}. \tag{W.396}$$

This recovers the analytic weak-field-matched result exactly.

W.7.5 Propagation-Capacity Field

Once the strain field is known, the propagation-capacity field is not independently solved. It is determined algebraically:

$$\boxed{c_P(\bar{r},\theta) = c_{\mathrm{E}}\left[1-\alpha_{\mathrm{G}}(\bar{r},\theta)\right]^2.} \tag{W.397}$$

The causal-capacity collapse occurs automatically at the phase boundary because

$$\alpha_{\mathrm{G}}(\bar{r}_\partial,\theta) = 1. \tag{W.398}$$

Therefore,

$$\boxed{c_P(\bar{r}_\partial,\theta) = 0.} \tag{W.399}$$

This is the numerical representation of causal arrest at the FCC/SC boundary.

W.7.6 Capacity-Surface Extraction

After solving for $\alpha_{\mathrm{G}}(\bar{r},\theta)$ and $\widehat{\omega}(\bar{r},\theta)$, the torsional capacity surface is extracted from

$$\left|v_\phi^{(\mathrm{SF})}\right| = c_P. \tag{W.400}$$

In dimensionless form, this condition is

$$\boxed{\left|\bar{r}\sin\theta\,\widehat{\omega}(\bar{r},\theta)\right| = \left[1-\alpha_{\mathrm{G}}(\bar{r},\theta)\right]^2.} \tag{W.401}$$

Solving this equation for $\bar{r}$ at each θ gives

$$\boxed{\bar{r}_{\mathrm{cap}}(\theta,a_*).} \tag{W.402}$$

The physical surface is

$$r_{\mathrm{cap}}(\theta,a_*) = R_{\mathrm{QG}}\bar{r}_{\mathrm{cap}}(\theta,a_*). \tag{W.403}$$

The extracted capacity surface must satisfy

$$\boxed{\bar{r}_{\mathrm{cap}}(\theta,a_*) \geq \bar{r}_\partial(\theta,a_*).} \tag{W.404}$$

This ensures that the capacity surface lies in the active exterior rather than inside the saturated SC domain.

W.7.7 Photon-Ring Extraction

The numerical photon-ring calculation uses the rotating Soft-Floor Hamiltonian:

$$\mathcal{H}_\gamma = \frac{1}{2}\left[-\frac{\left(\omega - m_\phi\omega_{\mathrm{drag}}(r,\theta)\right)^2}{c_P^2(r,\theta)} + k_r^2 + \frac{k_\theta^2}{r^2} + \frac{m_\phi^2}{r^2\sin^2\theta}\right] = 0. \tag{W.405}$$

For equatorial circular photon orbits,

$$\theta = \frac{\pi}{2}, \qquad k_\theta = 0. \tag{W.406}$$

The radial photon potential is

$$\mathcal{R}_\gamma(r;b_\gamma)=\frac{\left[1-b_\gamma\omega_{\rm drag}(r)\right]^2}{c_P^2(r)}-\frac{b_\gamma^2}{r^2}, \tag{W.407}$$

where

$$b_\gamma=\frac{m_\phi}{\omega}. \tag{W.408}$$

The circular photon orbit is a double root:

$$\boxed{\mathcal{R}_\gamma=0,\qquad \frac{\mathrm{d}\mathcal{R}_\gamma}{\mathrm{d}r}=0.} \tag{W.409}$$

Equivalently, in the equatorial branch form,

$$\boxed{\frac{\mathrm{d}}{\mathrm{d}r}\left[\omega_{\rm drag}(r)+s_{\rm br}\frac{c_P(r)}{r}\right]=0,} \tag{W.410}$$

where $s_{\rm br}=+1$ labels the prograde branch, and $s_{\rm br}=-1$ labels the retrograde branch.

The solver therefore outputs

$$\boxed{r_{\gamma,+}(a_*),\qquad r_{\gamma,-}(a_*).} \tag{W.411}$$

The corresponding impact scale is

$$\boxed{B_{\gamma,s_{\rm br}}=\frac{c_{\rm E}}{\left|\omega_{\rm drag}(r_{\gamma,s_{\rm br}})+s_{\rm br}\frac{c_P(r_{\gamma,s_{\rm br}})}{r_{\gamma,s_{\rm br}}}\right|}.} \tag{W.412}$$

This gives the equatorial numerical shadow-impact scale.

W.7.8 ISCO Extraction

The numerical exterior also determines the massive-particle ISCO map. This is required for comparison with accretion-disk observables.

The massive-particle radial potential is

$$\mathcal{R}_m(x;\varepsilon,j_z)=\frac{\left[\varepsilon-j_z\widehat{\omega}(x)\right]^2}{\widehat{c}_P^2(x)}-j_z^2x^2-1. \tag{W.413}$$

For the rotating equatorial exterior,

$$\widehat{\omega}(x)=2a_*x^3, \tag{W.414}$$

and

$$\widehat{c}_{P,\rm eq}(x)=\left[1-x-\frac{1}{2}a_*^2x^3\right]^2. \tag{W.415}$$

Therefore,

$$\mathcal{R}_{m,\rm eq}(x;\varepsilon,j_z,a_*)=\frac{\left[\varepsilon-2a_*j_zx^3\right]^2}{\left[1-x-\frac{1}{2}a_*^2x^3\right]^4}-j_z^2x^2-1. \tag{W.416}$$

The numerical ISCO is obtained from the triple condition

$$\boxed{\mathcal{R}_{m,\mathrm{eq}} = 0, \qquad \frac{\partial \mathcal{R}_{m,\mathrm{eq}}}{\partial x} = 0, \qquad \frac{\partial^2 \mathcal{R}_{m,\mathrm{eq}}}{\partial x^2} = 0.} \tag{W.417}$$

Solving these equations gives

$$x_{\mathrm{ISCO},s_{\mathrm{br}}}(a_*), \tag{W.418}$$

and therefore

$$\boxed{r_{\mathrm{ISCO},s_{\mathrm{br}}}(a_*) = \frac{R_{\mathrm{QG}}}{x_{\mathrm{ISCO},s_{\mathrm{br}}}(a_*)}.} \tag{W.419}$$

The prograde and retrograde branches are distinguished by the sign of the orbital angular momentum relative to the black-hole spin. The solver must recover

$$\boxed{r_{\mathrm{ISCO},0} = 6R_{\mathrm{QG}}} \tag{W.420}$$

in the nonrotating limit.

This subsection closes the gap between the numerical exterior and accretion-disk spin observables.

W.7.9 Full Ray-Traced Shadow

The equatorial photon-ring calculation gives the branch impact scales. The full observed shadow, however, requires ray tracing through the numerical Soft-Floor fields.

The Hamilton equations are

$$\frac{\mathrm{d}x^i}{\mathrm{d}\lambda} = \frac{\partial \mathcal{H}_\gamma}{\partial k_i}, \tag{W.421}$$

and

$$\frac{\mathrm{d}k_i}{\mathrm{d}\lambda} = -\frac{\partial \mathcal{H}_\gamma}{\partial x^i}. \tag{W.422}$$

Here $x^i = (r, \theta, \phi)$ and $k_i = (k_r, k_\theta, m_\phi)$.

The ray-tracing procedure is:

1. Choose the observer inclination and screen coordinates.
2. Launch rays backward from the observer screen.
3. Evolve each ray using the Hamilton equations.
4. Classify the ray as escaping, approaching the capacity region, or terminating on the FCC/SC phase boundary.
5. The boundary between escaping and terminating rays defines the observed shadow curve.

The full shadow curve is therefore an output of the numerical Soft-Floor Hamiltonian, not an imported Kerr shadow formula.

W.7.10 Ringdown Extraction from the Solved Boundary

After the exterior fields and phase boundary have been solved, the ringdown spectrum is obtained from perturbations of the numerical boundary:

$$r_\partial(\theta, a_*) \to r_\partial(\theta, a_*) + \delta R(\theta, \phi, t). \tag{W.423}$$

The perturbation is expanded as

$$\delta R(\theta, \phi, t) = \sum_{\ell,m} q_{\ell m}(t) \mathcal{Y}^{(\partial)}_{\ell m}(\theta, \phi; a_*), \tag{W.424}$$

where $\mathcal{Y}^{(\partial)}_{\ell m}$ are the spin-deformed boundary eigenfunctions.

The numerical boundary operator has the schematic eigenvalue form

$$\mathcal{L}_\partial(a_*)\mathcal{Y}^{(\partial)}_{\ell m} = \lambda_{\ell m}(a_*)\mathcal{Y}^{(\partial)}_{\ell m}. \tag{W.425}$$

Including stress shedding into the exterior gives a complex eigenfrequency

$$\varpi_{\ell m} = \omega_{\ell m} - i\Gamma^{(\mathrm{rd})}_{\ell m}. \tag{W.426}$$

The no-hair scaling derived earlier requires

$$\boxed{\varpi_{\ell m}(M, a_*) = \frac{c_{\mathrm{E}}^3}{GM}\left[\widehat{\omega}_{\ell m}(a_*) - i\widehat{\Gamma}^{(\mathrm{rd})}_{\ell m}(a_*)\right].} \tag{W.427}$$

The numerical solver therefore determines the dimensionless functions

$$\widehat{\omega}_{\ell m}(a_*), \qquad \widehat{\Gamma}^{(\mathrm{rd})}_{\ell m}(a_*). \tag{W.428}$$

W.7.11 Solver Sequence

The complete baseline numerical procedure is as follows:

1. Prescribe the final black-hole parameters M and a_*. Then compute $R_{\mathrm{QG}} = \frac{GM}{c_{\mathrm{E}}^2}$ and $\mathcal{J}_{\mathrm{BH}} = a_* \frac{GM^2}{c_{\mathrm{E}}}$.
2. Initialize the phase boundary using $\bar{r}^{(0)}_\partial(\theta) = 1 - a_*^2 P_2(\cos\theta)$.
3. Solve the exterior strain equation $\bar{\nabla}^2 \alpha_{\mathrm{G}} = 0$ with $\alpha_{\mathrm{G}}(\bar{r}_\partial, \theta) = 1$ and the far-field monopole-quadrupole condition.
4. Update the free boundary until $\alpha_{\mathrm{G}}(\bar{r}_\partial(\theta), \theta) = 1$ is satisfied globally.
5. Compute $c_P = c_{\mathrm{E}}(1 - \alpha_{\mathrm{G}})^2$.
6. Solve the torsional equation $\bar{\nabla} \cdot \left[\bar{r}^2 \sin^2\theta \, \bar{\nabla}\widehat{\omega}\right] = 0$ with far-field angular-momentum normalization $\widehat{\omega} \to \frac{2a_*}{\bar{r}^3}$.
7. Extract the capacity surface from $|\bar{r}\sin\theta\,\widehat{\omega}| = (1 - \alpha_{\mathrm{G}})^2$.
8. Extract the photon-ring radii from the double-root condition $\mathcal{R}_\gamma = 0$ and $\frac{\mathrm{d}\mathcal{R}_\gamma}{\mathrm{d}r} = 0$.

9. Extract the ISCO branches from the massive-particle radial potential using $\mathcal{R}_{m,\mathrm{eq}} = 0$, $\frac{\partial \mathcal{R}_{m,\mathrm{eq}}}{\partial x} = 0$, and $\frac{\partial^2 \mathcal{R}_{m,\mathrm{eq}}}{\partial x^2} = 0$. This gives $r_{\mathrm{ISCO},+}(a_*)$ and $r_{\mathrm{ISCO},-}(a_*)$.
10. Ray-trace the full shadow curve using $\mathcal{H}_\gamma = 0$.
11. Perturb the solved boundary and solve the complex eigenvalue problem for $\omega_{\ell m}(M, a_*)$ and $\Gamma^{(\mathrm{rd})}_{\ell m}(M, a_*)$.

W.7.12 Validation Limits

The numerical exterior solution must reproduce the analytic limits derived earlier.

In the nonrotating limit, $a_* = 0$, the solution must reduce to:

- $\bar{r}_\partial = 1$
- $\alpha_{\mathrm{G}} = \frac{1}{\bar{r}}$
- $\widehat{\omega} = 0$
- $r_{\gamma,0} = 3R_{\mathrm{QG}}$
- $B_{\gamma,0} = \frac{27}{4} R_{\mathrm{QG}}$
- $r_{\mathrm{ISCO},0} = 6R_{\mathrm{QG}}$

In the weak-spin limit, the components must approach:

- **Boundary:** $\bar{r}_\partial(\theta) = 1 - a_*^2 P_2(\cos\theta)$
- **Far-field strain:** $\alpha_{\mathrm{G}} \to \frac{1}{\bar{r}} - a_*^2 \frac{P_2(\cos\theta)}{\bar{r}^3}$
- **Far-field angular drag:** $\widehat{\omega} \to \frac{2a_*}{\bar{r}^3}$
- **Photon-ring branches:** $r_{\gamma,s_{\mathrm{br}}} = 3R_{\mathrm{QG}}(1 - s_{\mathrm{br}} a_*) + \mathcal{O}(a_*^2)$
- **ISCO branches:** $r_{\mathrm{ISCO},s_{\mathrm{br}}}(a_*) = 6R_{\mathrm{QG}}\left[1 - s_{\mathrm{br}}\kappa_{\mathrm{ISCO}} a_* + \mathcal{O}(a_*^2)\right]$. The coefficient κ_{ISCO} is a validation output of the massive-particle closure unless Kerr-ISCO correspondence is imposed as an additional phenomenological matching condition.
- **Ringdown spectrum:** $\omega_{\ell m} = \frac{c_{\mathrm{E}}^3}{GM}\widehat{\omega}_{\ell m}(a_*)$ and $\Gamma^{(\mathrm{rd})}_{\ell m} = \frac{c_{\mathrm{E}}^3}{GM}\widehat{\Gamma}^{(\mathrm{rd})}_{\ell m}(a_*)$

The topological stability of the saturated FCC/SC boundary in the near-extremal regime ($a_* \to 1$) is not assumed analytically. It is a validation condition of the numerical solver: the solution must demonstrate that $\alpha_{\mathrm{G}} = 1$ remains a closed, regular, simply connected phase boundary throughout the allowed spin range.

These validation limits are required for the solver to be consistent with the analytic closure sections.

W.7.13 Baseline Conclusion

The full rotating TFT exterior is obtained by solving the coupled field set

$$\boxed{\bar{r}_\partial(\theta, a_*), \qquad \alpha_{\rm G}(\bar{r}, \theta), \qquad \widehat{\omega}(\bar{r}, \theta), \qquad c_P(\bar{r}, \theta).} \tag{W.429}$$

The baseline governing system is

$$\boxed{\bar{\nabla}^2 \alpha_{\rm G} = 0,} \tag{W.430}$$

$$\boxed{\bar{\nabla} \cdot \left[\bar{r}^2 \sin^2\theta \, \bar{\nabla}\widehat{\omega}\right] = 0,} \tag{W.431}$$

and

$$\boxed{c_P = c_{\rm E}(1 - \alpha_{\rm G})^2,} \tag{W.432}$$

with the free-boundary condition

$$\boxed{\alpha_{\rm G}(\bar{r}_\partial(\theta), \theta) = 1.} \tag{W.433}$$

The far-field conditions impose the conserved mass, angular momentum, and no-hair quadrupole:

$$\boxed{\alpha_{\rm G} \to \frac{1}{\bar{r}} - a_*^2 \frac{P_2(\cos\theta)}{\bar{r}^3},} \tag{W.434}$$

and

$$\boxed{\widehat{\omega} \to \frac{2a_*}{\bar{r}^3}.} \tag{W.435}$$

From this solved exterior, one extracts the physical phase boundary, torsional capacity surface, photon-ring radii, shadow-impact curve, ISCO branches, and ringdown spectrum.

The present section therefore converts the analytic rotating TFT closures into a numerical free-boundary solver. It completes the baseline mathematical program for constructing the rotating TFT black-hole exterior while leaving room for a later nonlinear strong-field constitutive upgrade if required by shadow, ISCO, or ringdown data.

W.8 Summary of the Kerr-TFT Correspondence

The table below summarizes how the standard geometric features of the Kerr metric are systematically replaced by the mechanical continuum dynamics of the rotating Tension Field Theory (TFT) exterior.

Kerr Structure	**Kerr Equation / Condition**	**TFT Replacement**	**Mechanical Meaning in TFT**
Spin parameter	$a_* = \frac{c_{\rm E}\mathcal{J}_{\rm BH}}{GM^2}$	Same normalization	Kerr spin becomes **angular momentum stored in live FCC/SC boundary torsion plus external Soft-Floor shear**.

Kerr Structure	**Kerr Equation / Condition**	**TFT Replacement**	**Mechanical Meaning in TFT**
Gravitational length	$R_{\mathrm{QG}} = \frac{GM}{c_{\mathrm{E}}^2}$	Same mass scale	TFT keeps the successful gravitational scale but interprets it as the **saturation scale of the strain field**, not a geometric singularity scale.
Kerr vacuum exterior	$R_{\mu\nu} = 0$ with Kerr metric	$\bar{\nabla}^2 \alpha_{\mathrm{G}} = 0$, outside r_∂	Vacuum curvature is replaced by a **source-free strain field in the active FCC Soft Floor**.
Kerr rotating metric	ds^2_{Kerr} with $g_{t\phi} \neq 0$	$ds^2_{\tau,\mathrm{rot}} = -c_{\mathrm{E}}^2(1-\alpha_{\mathrm{G}})^2 dt^2 + \frac{dr^2 + r^2 d\theta^2 + r^2 \sin^2\theta (d\phi - \omega_{\mathrm{drag}} dt)^2}{(1-\alpha_{\mathrm{G}})^2}$	Metric rotation is replaced by **strain refraction plus dragged Soft-Floor azimuthal flow**.
Frame dragging	$\omega_{\mathrm{LT}}(r) = \frac{2G\mathcal{J}_{\mathrm{BH}}}{c_{\mathrm{E}}^2 r^3}$	$\omega_{\mathrm{drag}}(r) = \frac{2G\mathcal{J}_{\mathrm{BH}}}{c_{\mathrm{E}}^2 r^3}$	Kerr frame dragging becomes **torsional shear propagation through the FCC Soft Floor**.
Torsional field law	Encoded geometrically in $g_{t\phi}$	$\frac{\mathrm{d}}{\mathrm{d}r}\left[\tau_{\mathrm{tor}}(r) r^4 \frac{\mathrm{d}\omega_{\mathrm{drag}}}{\mathrm{d}r}\right] = 0$	The rotating exterior is generated by **angular-momentum flux balance**, not by postulating a rotating metric.
Torsional stiffness	No material stiffness in GR	$\tau_{\mathrm{tor}} = \tau_{D,\mathrm{bulk}} = \frac{c_{\mathrm{E}}^4}{G r_{\mathrm{D}}^2}$	The exterior has a real **mechanical stiffness coefficient** inherited from the Soft-Floor lattice.
Horizon	$\Delta = 0$, $r_+ = R_{\mathrm{QG}}\left(1 + \sqrt{1 - a_*^2}\right)$	$\alpha_{\mathrm{G}}(r_\partial, \theta) = 1$, with $r_\partial \equiv r_{\mathrm{sat}}$	The Kerr horizon is replaced by a **FCC/SC phase boundary where the active Soft Floor saturates**.

Kerr Structure	**Kerr Equation / Condition**	**TFT Replacement**	**Mechanical Meaning in TFT**
Causal arrest	Horizon traps null rays geometrically	$c_P(r_\partial, \theta) = c_{\mathrm{E}}(1-\alpha_{\mathrm{G}})^2 = 0$	Light arrest occurs because **local propagation capacity collapses at saturation**.
Ergosurface	$g_{tt} = 0$	$\lvert r\sin\theta\,\omega_{\mathrm{drag}}\rvert = c_P(r,\theta)$	The ergosphere becomes a **capacity surface where Soft-Floor drift equals local propagation speed**.
No-hair quadrupole	$Q_{\mathrm{Kerr}} = -\frac{\mathcal{J}_{\mathrm{BH}}^2}{Mc_{\mathrm{E}}^2} = -a_*^2 M R_{\mathrm{QG}}^2$	$Q_{\mathrm{TFT}} = -\lambda_Q \frac{\mathcal{J}_{\mathrm{BH}}^2}{Mc_{\mathrm{E}}^2}$, with $\lambda_Q = 1$	Kerr no-hair becomes a **relaxed saturated-boundary attractor** with no residual surface memory.
Photon ring	Null geodesic double root: $\mathcal{R}_\gamma = 0,\ \mathcal{R}'_\gamma = 0$	$\frac{\mathrm{d}}{\mathrm{d}r}\left[\omega_{\mathrm{drag}}(r) + s_{\mathrm{br}}\frac{c_P(r)}{r}\right] = 0$	Photon rings arise from **competition between torsional dragging and radial propagation capacity**.
Photon impact scale	Kerr shadow from null geodesic constants	$B_{\gamma,s_{\mathrm{br}}} = \frac{c_{\mathrm{E}}}{\left\lvert\omega_{\mathrm{drag}} + s_{\mathrm{br}}\frac{c_P}{r_{\gamma,s_{\mathrm{br}}}}\right\rvert}$	The shadow scale is computed from the **TFT optical Hamiltonian**, not imported from Kerr.
ISCO	Massive-particle triple root: $\mathcal{R}_m = 0,\ \mathcal{R}'_m = 0,\ \mathcal{R}''_m = 0$	$\mathcal{R}_m = \frac{[\varepsilon - j_z\widehat{\omega}(x)]^2}{\widehat{c}_P^2(x)} - j_z^2 x^2 - 1$	Stable orbits are governed by **particle motion through a dragged, strain-refractive medium**.
Ringdown	$\omega_{\ell mn} = \frac{c_{\mathrm{E}}^3}{GM} f_{\ell mn}(a_*)$	$\varpi_{\ell m} = \frac{c_{\mathrm{E}}^3}{GM}\left[\widehat{\omega}_{\ell m}(a_*) - i\widehat{\Gamma}^{(\mathrm{rd})}_{\ell m}(a_*)\right]$	Kerr quasi-normal modes become **damped eigenmodes of the live FCC/SC boundary**.

Kerr Structure	**Kerr Equation / Condition**	**TFT Replacement**	**Mechanical Meaning in TFT**
Kerr uniqueness	Exterior fixed by $M, \mathcal{J}_{\mathrm{BH}}$	Relaxed exterior fixed by $M, \mathcal{J}_{\mathrm{BH}}$	TFT replaces geometric no-hair with **mechanical relaxation to a saturated boundary attractor**.

Appendix X

The Physical Wavefunction and the SGF Order Parameter

Abstract: Standard Quantum Mechanics treats the wavefunction (Ψ) as an abstract probability amplitude. Tension Field Theory (TFT) redefines Ψ as the macroscopic physical order parameter of the Spacetime Gravitational Floor (SGF), analogous to the Ginzburg–Landau theory of superfluids. This appendix defines the absolute boundary conditions of the wavefunction across the two primary phases of the vacuum.

X.1 The Physical Wavefunction

In TFT, the universe is not a collection of isolated particles in a void, but a single, contiguous macroscopic quantum object. The state of this object is described by a complex scalar order parameter, Ψ:

$$\Psi(x,t) = \sqrt{\rho} \cdot e^{i\varphi} \tag{X.1}$$

Where:

- $\sqrt{\rho}$ **represents the Amplitude:** the local physical density and structural stiffness of the lattice.
- $e^{i\varphi}$ **represents the Phase:** the mechanical phase angle of the lattice, governing time, rotation, and dynamic motion. *(Note: As established in Section 14.1.1, this phase angle φ scales to quantum action via $S = \hbar \cdot \varphi$, and the imaginary operator i represents harmonic lattice oscillation as defined in Section 14.4.4).*

X.2 The Hard Floor Wavefunction (The Substrate)

The "Hard Floor" is the absolute ground state of the universe. It is characterized by maximal tension saturation and absolute phase-locking. The wavefunction for the latent Substrate (Ψ_S) is time-invariant and non-local:

$$\Psi_S = \sqrt{\rho_S} \cdot e^{i0} \tag{X.2}$$

Physical Implications:

- **Maximal Density (ρ_S):** The amplitude is fixed at the absolute structural limit (ℓ_S). Because the bulk modulus is effectively infinite, it acts as an incompressible supersolid.

- **Phase Lock ($\varphi = 0$):** The phase angle is zero everywhere. Because dynamic momentum is the spatial gradient of phase ($p \propto \nabla\varphi$), and $\nabla\varphi = 0$, the Hard Floor possesses zero dynamic momentum and zero entropy.
- **The Arrest of Time:** Without phase rotation, time does not flow on the Hard Floor. It serves strictly as an instantaneous, non-local connection grid for quantum entanglement.

X.3 The Soft Floor Wavefunction (The Active Vacuum)

The "Soft Floor" (Observable Universe) emerges when the infinite rigidity of the substrate transitions into the finite elasticity of the vacuum at the FCC Node Radius (r_{D}). This phase break allows the lattice to unlock and oscillate, generating the wavefunction of the active vacuum (Ψ_{D}):

$$\Psi_{\mathrm{D}}(x,t) = \sqrt{\rho_{\mathrm{D}}} \cdot e^{i(\mathbf{k}\cdot\mathbf{x}-\omega t)} \tag{X.3}$$

Physical Implications:

- **Dynamic Phase ($\varphi(t) \neq 0$):** The phase rotates with frequency ω. This localized rotation is the mechanical origin of the flow of time.
- **Elastic Density (ρ_{D}):** The structural density transitions to the Face–Centered Cubic (FCC) configuration. This provides the finite shear elasticity (τ_{D}) required to support transverse wave propagation (light).
- **Emergence of Gradients:** The dynamic variation of this wavefunction generates the macroscopic forces:
  - **Gravity:** The spatial gradient of the amplitude (tension/density).
  - **Motion / Inertia:** The spatial gradient of the phase (momentum).

X.4 Metric Comparison Summary

The dual-scale architecture of the SGF necessitates two distinct boundary conditions for the universal order parameter:

Table X.1: Wavefunction Boundary Conditions of the SGF

Metric	**Hard Floor (Substrate)**	**Soft Floor (Active Vacuum)**
Wavefunction	$\Psi_{\mathrm{S}} = \sqrt{\rho_{\mathrm{S}}} \cdot e^{i0}$	$\Psi_{\mathrm{D}} = \sqrt{\rho_{\mathrm{D}}} \cdot e^{i(\mathbf{k}\cdot\mathbf{x}-\omega t)}$
Phase (φ)	0 (topologically locked)	Dynamic (ωt)
Density (ρ)	Latent / maximum (ρ_{S})	Active / elastic (ρ_{D})
Geometry	Simple cubic (rigid)	Face–centered cubic (elastic)
Physics	Non-local connectivity (c_{S})	Local causality (c_{E})

X.5 Application to Atomic Mechanics (The Localized Vortex)

Because the active SGF is a contiguous macroscopic medium, standard atomic particles are not discrete entities isolated from the vacuum; they are localized topological defects (phase vortices) within the Soft Floor order parameter (Ψ_{D}).

When a transverse wave locks into a chiral standing wave (such as an electron or atomic orbital), the linear phase gradient ($\mathbf{k} \cdot \mathbf{x}$) winds into a localized rotational gradient. To maintain topological continuity in the FCC lattice, the phase angle must complete an integer number of full cycles (n) around the defect core:

$$\oint \nabla\varphi \cdot \mathrm{d}\ell = 2\pi n \tag{X.4}$$

This topological boundary condition mathematically enforces the quantization of atomic states. The atomic wavefunction (Ψ_{atom}) is therefore a strict, localized solution of the Soft Floor order parameter:

$$\Psi_{\mathrm{atom}}(r, \theta, t) = \sqrt{\rho(r)} \cdot e^{i(n\theta - \omega t)} \tag{X.5}$$

Physical Implications at the Atomic Scale:

- **Quantized Orbitals (n):** The principal quantum numbers of atomic shells are the integer phase-winding numbers of the lattice vortex.
- **Mass Generation ($\rho(r)$):** At the core of the phase vortex, the structural density of the lattice must radially deform, creating the spatial tension gradient observationally recognized as the mass of the particle.
- **The Schrödinger Equation:** The probabilistic behavior of electrons in standard quantum mechanics is physically resolved as the deterministic hydrodynamic behavior of these localized standing-strain vortices interacting within the Ψ_{D} field. *(Note: The absolute kinematic localization, or "wavefunction collapse," of these continuous vortices upon interaction with macroscopic matter is formally derived in Appendix Y).*

Appendix Y

Vacuum Visco-Elasticity and Wave Arrest

Abstract: Tension Field Theory (TFT) treats the Spacetime Gravitational Floor (SGF) as a physical, dual-phase continuum. Consequently, quantum interactions are subject to the visco-elastic response of the FCC–Condensate vacuum. This appendix develops two constitutive manifestations of the same underlying relaxation mechanism: the non-linear logarithmic term governing the wave arrest of topological knots (matter), and the ordinary linear viscous term governing attenuation of untethered shear waves (light). The latter establishes the conventional attenuation branch; coherent-action-preserving photon frequency transport and the corresponding Viscoelastic Vacuum Relaxation Rate Γ_{D} are developed separately in Appendix AP.

Y.1 Derivation of Non-Linear Damping for Matter (The VNLW Term)

When a localized topological knot (a Fermion) moves through the active vacuum, it physically displaces the Face–Centered Cubic (FCC) lattice. In the presence of dense macroscopic matter (a detector), the lattice behaves as an open quantum system, draining kinetic energy from the wave into matter-coupled FCC–Condensate reservoir degrees of freedom.

To derive the governing equation, we begin with the standard time-dependent Schrödinger equation and introduce an unknown non-Hermitian dissipative potential $W(\mathbf{x}, t)$ to mathematically model this thermodynamic sink:

$$i\hbar\frac{\partial\Psi}{\partial t} = \left[-\frac{\hbar^2}{2m}\nabla^2 + V + W\right]\Psi. \tag{Y.1}$$

Y.1.1 Kinetic Derivation of the Constitutive Law (Γ)

To define the non-Hermitian potential W, the localized physical damping rate (Γ) is first derived from kinetic collision theory. As the pilot wave propagates, it sweeps through a geometric volume of space containing localized structural defects (the atomic lattice of the dense matter sink).

The differential volume ($\mathrm{d}V$) swept by a wave interface of interaction area σ moving at local kinematic velocity c_{P} in time $\mathrm{d}t$ is

$$\mathrm{d}V = \sigma \cdot c_{\mathrm{P}} \cdot \mathrm{d}t. \tag{Y.2}$$

If the local medium possesses a topological knot density $n_K(x)$ (number of defects per unit volume), the number of physical lattice collisions ($\mathrm{d}N$) occurring in that timeframe is

$$\mathrm{d}N = n_K(x) \cdot \mathrm{d}V = n_K(x) \cdot \sigma \cdot c_{\mathrm{P}} \cdot \mathrm{d}t. \tag{Y.3}$$

The local Quantum Damping Rate (Γ) is defined as the collision frequency (fractional energy-loss events per unit time, $\mathrm{d}N/\mathrm{d}t$). Rearranging the kinetic equation yields the constitutive law for localized vacuum friction:

$$\Gamma(x) = \sigma \cdot c_{\mathrm{P}} \cdot n_K(x). \tag{Y.4}$$

Here $\Gamma(x)$ denotes the localized defect-induced Quantum Damping Rate. It vanishes as $n_K \to 0$ and is therefore not identified with the nonzero defect-free Viscoelastic Vacuum Relaxation Rate Γ_{D}. The two rates represent distinct constitutive limits of the same underlying FCC–Condensate visco-elastic relaxation mechanism.

Y.1.2 The Madelung Form and the Topological Sink

To translate this friction into the quantum potential W, we utilize the macroscopic physical order parameter of the SGF established in Appendix X. Defining the wavefunction by its physical amplitude ($\sqrt{\rho}$) and its mechanical phase action (S):

$$\Psi = \sqrt{\rho} e^{iS/\hbar}. \tag{Y.5}$$

Taking the natural logarithm of both sides isolates the real amplitude from the imaginary phase:

$$\ln(\Psi) = \ln(\sqrt{\rho}) + \frac{iS}{\hbar} = \frac{1}{2}\ln(\rho) + \frac{iS}{\hbar}. \tag{Y.6}$$

In TFT, absolute kinematic localization (wave arrest) is defined as the physical collapse of the wave's spatial volume. The matter sink acts exclusively on the probability density (ρ). Therefore, to model an open system where the spatial extent of the wave rapidly decays into a delta function, we must isolate the real amplitude term:

$$2\left[\ln(\Psi) - \frac{iS}{\hbar}\right] = \ln(\rho). \tag{Y.7}$$

Because probability density ρ is the absolute square of the wavefunction ($\rho = |\Psi|^2$), we have

$$\ln(\rho) = \ln(|\Psi|^2). \tag{Y.8}$$

Y.1.3 The Logarithmic Resolution

In non-Hermitian quantum mechanics, the rapid collapse of probability density is driven by an imaginary potential. We define the dissipative sink potential W as strictly proportional to this density distribution, scaled by the localized Quantum Damping Rate (Γ) and the quantum of action ($\hbar$):

$$W = -i\hbar\Gamma \ln(\rho) \quad \Longrightarrow \quad W = -i\hbar\Gamma \ln(|\Psi|^2). \tag{Y.9}$$

Substituting this potential W back into the master equation yields the Viscous Non-Linear Wave Equation (VNLW). Within the retained TFT constitutive model, the localized knot density therefore controls the strength of the nonconservative wave-arrest term:

$$i\hbar\frac{\partial\Psi}{\partial t} = \left[-\frac{\hbar^2}{2m}\nabla^2 + V\right]\Psi - \left[i(\hbar\Gamma)\ln(|\Psi|^2)\right]\Psi. \tag{Y.10}$$

Y.2 Derivation of Linear Shear Attenuation for Light (The Damped-Wave Comparator)

Unlike Fermions, the photon is an untethered transverse shear wave possessing zero rest mass ($m = 0$). It does not drag a topological core through the bulk volume; it strictly shears the 2D surface interface of the FCC nodes. We first derive the corresponding ordinary linear attenuation branch directly from the classical continuum mechanics of the TFT substrate. This branch provides the visco-elastic attenuation comparator; the completed coherent photon-transport law is developed separately in Appendix AP.

Y.2.1 The Newtonian Continuum

For the continuous 2D surface interface of the SGF, we apply Newton's second law to a differential lattice element undergoing transverse phase displacement $\mathbf{A}$.

Natively employing μ_{D} (the effective 2D interface inertia) and τ_{D} (the baseline lattice surface tension), the local equation of motion per unit area is

$$\mu_{\mathrm{D}} \frac{\partial^2 \mathbf{A}}{\partial t^2} = \tau_{\mathrm{D}} \frac{\partial^2 \mathbf{A}}{\partial x^2} + F_{\mathrm{fr}}. \tag{Y.11}$$

Y.2.2 The Visco-Elastic Damping Force (F_{fr})

As the solid FCC nodes oscillate transversely, a nonconservative FCC–Condensate response may produce an out-of-phase visco-elastic force F_{fr}. At the retained linear-response order, represent the defect-free vacuum contribution and the localized defect-induced contribution by the effective rate

$$\Gamma_{\mathrm{eff}}(x) = \Gamma_{\mathrm{D}} + \Gamma(x), \tag{Y.12}$$

where

$$\Gamma(x) = \sigma c_{\mathrm{P}} n_K(x) \tag{Y.13}$$

is the localized Quantum Damping Rate derived above and Γ_{D} is the defect-free Viscoelastic Vacuum Relaxation Rate developed in Appendix AP.

The ordinary linear damping force per unit interface area is then represented as

$$F_{\mathrm{fr}} = -\mu_{\mathrm{D}} \Gamma_{\mathrm{eff}} \frac{\partial \mathbf{A}}{\partial t}. \tag{Y.14}$$

Substituting this explicitly into the continuum equation yields

$$\mu_{\mathrm{D}} \frac{\partial^2 \mathbf{A}}{\partial t^2} = \tau_{\mathrm{D}} \frac{\partial^2 \mathbf{A}}{\partial x^2} - \mu_{\mathrm{D}} \Gamma_{\mathrm{eff}} \frac{\partial \mathbf{A}}{\partial t}. \tag{Y.15}$$

Y.2.3 Generalization to 3D and the Base Wave Equation

Dividing the entire equation by the interface inertia μ_{D} gives

$$\frac{\partial^2 \mathbf{A}}{\partial t^2} = \left(\frac{\tau_{\mathrm{D}}}{\mu_{\mathrm{D}}} \right) \frac{\partial^2 \mathbf{A}}{\partial x^2} - \Gamma_{\mathrm{eff}} \frac{\partial \mathbf{A}}{\partial t}. \tag{Y.16}$$

Recognizing the TFT identity for the squared elastic wave speed,

$$c_{\mathrm{E}}^2 = \frac{\tau_{\mathrm{D}}}{\mu_{\mathrm{D}}}, \tag{Y.17}$$

and generalizing the 1D spatial derivative to the 3D Laplacian operator, the ordinary damped-wave equation becomes

$$\frac{\partial^2 \mathbf{A}}{\partial t^2} = c_{\mathrm{E}}^2 \nabla^2 \mathbf{A} - \Gamma_{\mathrm{eff}} \frac{\partial \mathbf{A}}{\partial t}. \tag{Y.18}$$

This equation defines the ordinary linear attenuation comparator. It is not identified with the completed finite-wave-number photon eigenbranch or with the coherent frequency-transport closure.

Y.2.4 Analytical Solution for Temporal Amplitude Decay

The temporal amplitude evolution governed by the ordinary visco-elastic differential equation is isolated via standard separation of variables, assuming

$$\mathbf{A}(\mathbf{x}, t) = X(\mathbf{x})T(t). \tag{Y.19}$$

Substituting this into the generalized damped-wave equation and dividing through by $c_{\mathrm{E}}^2 X(\mathbf{x})T(t)$ yields

$$\frac{\nabla^2 X}{X} = \frac{1}{c_{\mathrm{E}}^2 T} \frac{\mathrm{d}^2 T}{\mathrm{d}t^2} + \frac{\Gamma_{\mathrm{eff}}}{c_{\mathrm{E}}^2 T} \frac{\mathrm{d}T}{\mathrm{d}t}. \tag{Y.20}$$

Setting both sides to the spatial separation constant $-k^2$ and using the continuum relation

$$\omega = k c_{\mathrm{E}} \tag{Y.21}$$

for this comparator reduces the temporal system to

$$\frac{\mathrm{d}^2 T}{\mathrm{d}t^2} + \Gamma_{\mathrm{eff}} \frac{\mathrm{d}T}{\mathrm{d}t} + \omega^2 T = 0. \tag{Y.22}$$

Assuming an ansatz of the form

$$T(t) = e^{rt} \tag{Y.23}$$

yields the characteristic polynomial

$$r^2 + \Gamma_{\mathrm{eff}} r + \omega^2 = 0. \tag{Y.24}$$

Applying the quadratic formula gives

$$r = \frac{-\Gamma_{\mathrm{eff}} \pm \sqrt{\Gamma_{\mathrm{eff}}^2 - 4\omega^2}}{2} = -\frac{\Gamma_{\mathrm{eff}}}{2} \pm \sqrt{\left(\frac{\Gamma_{\mathrm{eff}}}{2}\right)^2 - \omega^2}. \tag{Y.25}$$

For the weakly attenuating branch,

$$\Gamma_{\mathrm{eff}} \ll \omega, \tag{Y.26}$$

so the system is underdamped and

$$r \approx -\frac{\Gamma_{\mathrm{eff}}}{2} \pm i\omega. \tag{Y.27}$$

The general temporal solution is therefore

$$T(t) = C_1 e^{\left(-\frac{\Gamma_{\mathrm{eff}}}{2} + i\omega\right)t} + C_2 e^{\left(-\frac{\Gamma_{\mathrm{eff}}}{2} - i\omega\right)t}, \tag{Y.28}$$

where C_1 and C_2 are local complex integration constants fixed by the initial conditions.

Factoring out the shared real exponential gives

$$T(t) = e^{-\frac{\Gamma_{\text{eff}}}{2}t}\left(C_1 e^{i\omega t} + C_2 e^{-i\omega t}\right). \tag{Y.29}$$

Thus, within the ordinary linear attenuation model, the amplitude envelope obeys

$$\mathbf{A}(t) = \mathbf{A}_0 e^{-\frac{\Gamma_{\text{eff}}}{2}t}. \tag{Y.30}$$

This result establishes what a conventional velocity-proportional visco-elastic damping operator does: it produces amplitude attenuation of the retained harmonic carrier. It does not by itself establish coherent transport of the real carrier frequency.

Y.2.5 The Defect-Free Vacuum Limit and the Photon Relaxation Sector

Having established the ordinary linear attenuation comparator, consider the defect-free intergalactic limit. As the local macroscopic matter density approaches zero,

$$n_K \to 0, \tag{Y.31}$$

the localized Quantum Damping Rate satisfies

$$\Gamma(x) = \sigma c_{\text{P}} n_K(x) \to 0. \tag{Y.32}$$

The effective attenuation rate therefore approaches the nonzero vacuum baseline,

$$\Gamma_{\text{eff}} = \Gamma_{\text{D}} + \Gamma \to \Gamma_{\text{D}}. \tag{Y.33}$$

If the same rate is inserted into the ordinary damped-wave comparator, one obtains

$$\nabla^2 \mathbf{A} - \frac{1}{c_{\text{E}}^2}\frac{\partial^2 \mathbf{A}}{\partial t^2} - \left(\frac{\Gamma_{\text{D}}}{c_{\text{E}}^2}\right)\frac{\partial \mathbf{A}}{\partial t} = 0, \tag{Y.34}$$

with amplitude envelope

$$\mathbf{A}_{\text{att}}(t) = \mathbf{A}_0 e^{-\frac{\Gamma_{\text{D}}}{2}t}. \tag{Y.35}$$

Because the mechanical energy of the ordinary linear wave is proportional to the square of its amplitude,

$$E_{\text{att}}(t) \propto |\mathbf{A}_{\text{att}}(t)|^2, \tag{Y.36}$$

the corresponding energy law is

$$E_{\text{att}}(t) = E_0 e^{-\Gamma_{\text{D}}t}, \tag{Y.37}$$

or

$$\frac{\mathrm{d}E_{\text{att}}}{\mathrm{d}t} = -\Gamma_{\text{D}} E_{\text{att}}. \tag{Y.38}$$

This ordinary attenuation calculation therefore reproduces the same fractional coherent-energy transfer rate characterized by Γ_{D}, but it does not determine the evolution of the real photon carrier frequency. In particular,

$$\frac{\mathrm{d}E}{\mathrm{d}t} = -\Gamma_{\text{D}} E \tag{Y.39}$$

does not by itself imply

$$\frac{\mathrm{d}\omega}{\mathrm{d}t} = -\Gamma_{\text{D}}\omega. \tag{Y.40}$$

The completed cosmological photon branch therefore requires the additional coherent-action-preserving condition

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{E}{\omega}\right) = a0. \tag{Y.41}$$

Together with the modal-energy transfer law, this gives

$$\frac{\mathrm{d}\omega}{\mathrm{d}t} = -\Gamma_{\mathrm{D}}\omega, \tag{Y.42}$$

as developed in Appendix AP.

Accordingly, Γ and Γ_{D} are two constitutive manifestations of the same underlying FCC–Condensate visco-elastic relaxation mechanism: Γ is the localized defect-induced Quantum Damping Rate governing wave arrest, whereas Γ_{D} is the defect-free Viscoelastic Vacuum Relaxation Rate governing weak coherent photon-energy relaxation. The ordinary damped-wave solution derived here establishes the attenuation comparator and the associated energy-transfer scale; it is not imposed as an additional amplitude-extinction law on the coherent cosmological photon branch.

Appendix Z

The Mechanical Hamiltonian of the Photon Energy

Abstract: Standard quantum mechanics defines the photon as a massless probability wave. Tension Field Theory (TFT) redefines it as a physical, transverse harmonic oscillation of the active vacuum floor. To calculate the exact mechanical energy of this wave, the classical variables of a harmonic oscillator must map strictly to the discrete geometric constants of the TFT vacuum. This appendix validates the mechanical Hamiltonian of the photon, proving that quantized energy is a strictly mechanical derivation of geometric displacement and local field tension.

Z.1 The Photonic Wave Hamiltonian

The total energy of a single photon propagating through the vacuum is governed by the TFT lattice Hamiltonian, which adapts the classical harmonic oscillator to a localized quantum excitation:

$$E_{\text{total}} = \frac{1}{2}\tau_{\text{local}}(\Delta x)^2 + \frac{1}{2}\mu_{\text{eff}}v^2 \tag{Z.1}$$

To accurately describe the physical action of the photon, these variables map directly to the discrete mechanics of the wave:

- τ_{local} **(Operative Local Tension):** The effective linear spring constant (N/m) of the local vacuum geometry actively carrying the wave.
- Δx **(Transverse Displacement):** The maximum physical, transverse displacement of the field's wave amplitude.
- μ_{eff} **(Effective Mass):** The local inertial resistance (kg) of the specific structural lattice nodes physically participating in the transverse oscillation.
- v **(Oscillation Velocity):** The transverse kinetic velocity of the propagating wave.

Z.2 Dimensional Mapping of the Photon's Mechanics

1. The Local Spring Constant (τ_{local}): The effective stiffness experienced by the microscopic geometry of the photon (r_{D}^3) is the Operative Local Tension. By substituting the known geometric

bounds of the quantum action limit (h), we define the local structural tension required to sustain the wave:

$$\tau_{\text{local}} = \frac{h \cdot c_{\text{E}}}{r_{\text{D}}^3} \tag{Z.2}$$

Because this parameter resolves dimensionally to Newtons per meter (N/m), τ_{local} functions exactly as the local linear spring constant governing the photon's elastic potential energy. This is a statement of structural compatibility, mapping the established quantum action limit to classical lattice geometry.

2. Effective Mass (μ_{eff}): The photon's kinetic energy term requires discrete mass/inertia. The TFT baseline inertia (μ_{D}) is an inertial surface density. Incorporating the gravitational strain factor (α_{G}) yields the local effective mass governing the photon's transverse kinetic energy:

$$\mu_{\text{eff}} = \frac{\mu_{\text{D}} r_{\text{D}}^2}{(1-\alpha_{\text{G}})^4} \tag{Z.3}$$

Z.3 The Quantum Displacement Limit (Δx)

The massive magnitude of the vacuum's operative stiffness requires an infinitesimally small physical displacement (Δx) to yield the standard energy scale of a photon. The peak transverse displacement of the photonic wave is mechanically constrained by the field radius (r_{D}) scaled by the square root of the geometric ratio of the full cell diameter ($2r_{\text{D}}$) to the wavelength (λ) of the photon:

$$\Delta x = r_{\text{D}} \cdot \sqrt{\frac{2r_{\text{D}}}{\lambda}} \tag{Z.4}$$

Mathematical Resolution:

By evaluating the Hamiltonian at maximum transverse displacement (where velocity $v = 0$ and kinetic energy is momentarily zero), the Peak Potential Energy is exactly equal to the Total Energy of the photon. Plugging this geometric limit into the potential energy term defines the exact scaling law for quantum wave mechanics:

$$E_{\text{total}} = E_{\text{potential_max}} = \frac{1}{2}\tau_{\text{local}} \left[r_{\text{D}} \cdot \sqrt{\frac{2r_{\text{D}}}{\lambda}} \right]^2 \tag{Z.5}$$

$$E_{\text{total}} = \frac{1}{2}\tau_{\text{local}} \cdot r_{\text{D}}^2 \cdot \left(\frac{2r_{\text{D}}}{\lambda} \right) \tag{Z.6}$$

$$E_{\text{total}} = \frac{\tau_{\text{local}} \cdot r_{\text{D}}^3}{\lambda} \tag{Z.7}$$

The discrete physical geometry of the cell diameter ($2r_{\text{D}}$) naturally cancels the macroscopic factor of 1/2 from classical elasticity, perfectly offsetting the structural field stiffness.

Substituting the dimensional definition of Operative Local Tension ($\tau_{\text{local}} = \frac{h \cdot c_{\text{E}}}{r_{\text{D}}^3}$) back into the resolved geometric limit perfectly cancels the volumetric scaling geometry (r_{D}^3):

$$E_{\text{total}} = \left(\frac{h \cdot c_{\text{E}}}{r_{\text{D}}^3} \right) \cdot \frac{r_{\text{D}}^3}{\lambda} \tag{Z.8}$$

$$E_{\text{total}} = \frac{h \cdot c_{\text{E}}}{\lambda} \tag{Z.9}$$

Conclusion:

This resolves the energy to scale strictly as $1/\lambda$, mathematically validating the classical Hamiltonian for the quantum scale. By formally separating the photon's total energy into distinct, calculable kinetic (velocity) and potential (strain) components, this Hamiltonian provides the exact mechanical foundation required to resolve the "missing energy" paradox of destructive interference.

The Incorporation of Visco-Elastic Damping:

While the geometric limits above define the absolute initial emission energy of the photon, TFT establishes that the continuous SGF is not perfectly frictionless. As derived in Appendix AQ, the transverse phase displacement ($\mathbf{A}$) is governed by the Damped Wave Equation, yielding a strict temporal amplitude decay envelope that operates at half the macroscopic energy decay rate:

$$\Delta x(t) = \Delta x_0 e^{-\frac{\Gamma_{\text{D}}}{2}t} \tag{Z.10}$$

Because the total mechanical energy of the photon Hamiltonian is directly proportional to the square of this spatial displacement ($E \propto (\Delta x)^2$), substituting the decayed amplitude perfectly cancels the fractional rate, yielding the pristine macroscopic energy loss rate:

$$E(t) \propto \left(\Delta x_0 e^{-\frac{\Gamma_{\text{D}}}{2}t}\right)^2 = E_0 e^{-\Gamma_{\text{D}} t} \tag{Z.11}$$

(Note: This explicit mechanical energy envelope establishes the non-circular foundation for the observed astronomical redshift, $1 + z = e^{\Gamma_{\text{D}} x / c_{\text{E}}}$, derived in Part III).

Appendix AA

Quantum Tunneling as Evanescent Active-Vacuum Coupling and Coherent Boundary Control

Abstract: Tension Field Theory (TFT) interprets quantum tunneling as finite mechanical coupling of the matter order parameter through a region of the active vacuum in which the freely propagating branch is unavailable. At the continuum order retained here, a barrier is represented by an effective mechanical potential energy V_{B}. For a stationary matter mode with $E < V_{\mathrm{B}}$, the real exterior wavenumber becomes an imaginary barrier wavenumber, producing an evanescent active-vacuum response with penetration coefficient κ_{B}. Boundary matching across a barrier of finite thickness then gives a nonzero passive transmission current. Localized Quantum Damping Γ constitutes a separate nonconservative response and is not part of the conservative evanescence scale. Structured barriers may additionally support resonantly enhanced transmission, while a coherent input applied from the downstream side modifies the two-port boundary conditions and can cancel the incident-side reflected amplitude. The resulting construction provides a unified mechanical description of passive tunneling, resonant enhancement, coherent boundary control, and active topological-knot transport within the TFT matter-wave framework.

AA.1 Mechanical Barrier Representation

The physical wavefunction developed in Appendix X represents the extended order parameter associated with a matter excitation of the active vacuum. A localized massive particle is correspondingly represented by a topological defect coupled to this extended field.

A material barrier changes the local mechanical state through which the defect-associated field must propagate. At the continuum order used here, that change is represented by the potential-energy function

$$V(\mathbf{x}), \tag{AA.1}$$

with dimensions

$$[V] = \mathrm{J}. \tag{AA.2}$$

For a uniform one-dimensional barrier of thickness L, define

$$V(x) = \begin{cases} 0, & x < 0, \\ V_{\mathrm{B}}, & 0 \le x \le L, \\ 0, & x > L. \end{cases} \tag{AA.3}$$

The quantity V_{B} is the effective mechanical energy threshold associated with the barrier environment. In TFT it represents the additional local work required to sustain the matter excitation through that active-vacuum state.

The stationary energy E is conserved across the time-independent barrier. The distinction

$$E > V_{\mathrm{B}} \tag{AA.4}$$

corresponds to an available propagating branch inside the barrier, whereas

$$E < V_{\mathrm{B}} \tag{AA.5}$$

produces an evanescent barrier branch.

The tunneling problem is therefore a boundary-value problem for a physical matter order parameter of the active vacuum under a local mechanical energy constraint.

AA.2 Evanescent Matter-Wave Branch

The Viscous Non-Linear Wave Equation developed in Appendix Y contains the conservative matter-wave sector

$$i\hbar \frac{\partial \Psi}{\partial t} = \left[-\frac{\hbar^2}{2m} \nabla^2 + V \right] \Psi. \tag{AA.6}$$

Here $m = m_i = M_{\mathrm{top}}$ is the invariant inertial loading of the localized TFT defect.

For a stationary one-dimensional state,

$$\Psi(x,t) = \psi(x) e^{-iEt/\hbar}, \tag{AA.7}$$

Equation (AA.6) reduces to

$$-\frac{\hbar^2}{2m} \frac{\mathrm{d}^2 \psi}{\mathrm{d}x^2} + V(x)\psi = E\psi. \tag{AA.8}$$

For the exterior regions,

$$V = 0, \tag{AA.9}$$

and the stationary equation becomes

$$\frac{\mathrm{d}^2 \psi}{\mathrm{d}x^2} + k^2 \psi = 0, \tag{AA.10}$$

with

$$k = \frac{\sqrt{2mE}}{\hbar}. \tag{AA.11}$$

Inside the barrier, Equation (AA.5) gives

$$\frac{\mathrm{d}^2 \psi}{\mathrm{d}x^2} - \kappa_{\mathrm{B}}^2 \psi = 0, \tag{AA.12}$$

where the barrier evanescence coefficient is

$$\kappa_{\mathrm{B}} \equiv \frac{\sqrt{2m\,(V_{\mathrm{B}} - E)}}{\hbar}. \tag{AA.13}$$

Its dimensions are

$$[\kappa_{\mathrm{B}}] = \mathrm{m}^{-1}. \tag{AA.14}$$

The barrier wavenumber can therefore be written

$$k_{\mathrm{B}} = i\kappa_{\mathrm{B}}. \tag{AA.15}$$

The corresponding penetration length is

$$\ell_{\mathrm{ev}} \equiv \frac{1}{\kappa_{\mathrm{B}}}. \tag{AA.16}$$

Mechanically, the transition

$$k \longrightarrow i\kappa_{\mathrm{B}} \tag{AA.17}$$

means that the barrier does not support the same freely propagating matter-wave branch as the exterior region at the conserved energy E. The extended active-vacuum deformation nevertheless remains finite inside the barrier and varies over the characteristic distance ℓ_{ev}.

For a finite barrier, the field reaching the second interface is therefore nonzero. The exit boundary can consequently couple that evanescent deformation back into a propagating exterior mode.

AA.3 Passive Transmission Through a Finite Barrier

For the barrier profile in Equation (AA.3), the passive problem corresponds to

$$a_{\mathrm{R}} = 0. \tag{AA.18}$$

The stationary solutions are

$$\psi_{\mathrm{I}}(x) = a_{\mathrm{L}} e^{ikx} + b_{\mathrm{L}} e^{-ikx}, \qquad x < 0, \tag{AA.19}$$

$$\psi_{\mathrm{II}}(x) = B e^{\kappa_{\mathrm{B}} x} + C e^{-\kappa_{\mathrm{B}} x}, \qquad 0 \le x \le L, \tag{AA.20}$$

and

$$\psi_{\mathrm{III}}(x) = b_{\mathrm{R}} e^{ik(x-L)}, \qquad x > L. \tag{AA.21}$$

The coefficients are fixed by continuity of the order parameter and its spatial derivative,

$$\psi_{\mathrm{I}}(0) = \psi_{\mathrm{II}}(0), \tag{AA.22}$$

$$\left.\frac{\mathrm{d}\psi_{\mathrm{I}}}{\mathrm{d}x}\right|_{x=0} = \left.\frac{\mathrm{d}\psi_{\mathrm{II}}}{\mathrm{d}x}\right|_{x=0}, \tag{AA.23}$$

$$\psi_{\mathrm{II}}(L) = \psi_{\mathrm{III}}(L), \tag{AA.24}$$

and

$$\left.\frac{\mathrm{d}\psi_{\mathrm{II}}}{\mathrm{d}x}\right|_{x=L} = \left.\frac{\mathrm{d}\psi_{\mathrm{III}}}{\mathrm{d}x}\right|_{x=L}. \tag{AA.25}$$

The conserved stationary matter-order-parameter current associated with Equation (AA.8) is

$$j_\Psi = \frac{\hbar}{2mi}\left(\psi^* \frac{\mathrm{d}\psi}{\mathrm{d}x} - \psi \frac{\mathrm{d}\psi^*}{\mathrm{d}x}\right). \tag{AA.26}$$

Define the passive transmission coefficient by

$$T_{\mathrm{pass}} \equiv \frac{j_{\mathrm{tr}}}{j_{\mathrm{in}}}. \tag{AA.27}$$

For identical exterior media and the same invariant defect loading m across the three regions, boundary matching gives

$$T_{\mathrm{pass}} = \left[1 + \frac{V_{\mathrm{B}}^2}{4E\,(V_{\mathrm{B}} - E)} \sinh^2\left(\kappa_{\mathrm{B}} L\right)\right]^{-1}. \tag{AA.28}$$

The transmission is therefore controlled by the dimensionless barrier depth and thickness through

$$\frac{V_{\mathrm{B}} - E}{E} \tag{AA.29}$$

and

$$\kappa_{\mathrm{B}} L. \tag{AA.30}$$

For an opaque barrier,

$$\kappa_{\mathrm{B}} L \gg 1, \tag{AA.31}$$

Equation (AA.28) reduces to

$$T_{\mathrm{pass}} \simeq 16 \frac{E}{V_{\mathrm{B}}}\left(1 - \frac{E}{V_{\mathrm{B}}}\right) \exp\left(-2\kappa_{\mathrm{B}} L\right). \tag{AA.32}$$

The characteristic spatial suppression is therefore

$$T_{\mathrm{pass}} \propto e^{-2\kappa_{\mathrm{B}} L}. \tag{AA.33}$$

The finite transmission arises because the evanescent field generated at the entrance boundary retains a nonzero amplitude at the exit boundary. The transmitted exterior branch is reconstructed from that boundary amplitude.

Within TFT, the same calculation therefore has a direct mechanical interpretation:

$$\begin{aligned} &\text{propagating matter-order parameter} \\ &\quad \longrightarrow \text{evanescent active-vacuum deformation} \\ &\quad \longrightarrow \text{finite coupling across the barrier} \\ &\quad \longrightarrow \text{propagating transmitted branch.} \end{aligned} \tag{AA.34}$$

AA.4 Localized Relaxation Within the Barrier

The conservative barrier response characterized by κ_{B} is distinct from the localized nonconservative response of the material environment.

The Localized Quantum Damping Rate established in Appendix Y is denoted by

$$\Gamma(x), \tag{AA.35}$$

with

$$[\Gamma] = \mathrm{s}^{-1}. \tag{AA.36}$$

For a uniform barrier region, define the barrier-localized damping rate

$$\Gamma_{\mathrm{B}} \equiv \Gamma(x)|_{0\le x\le L}\,. \tag{AA.37}$$

The microscopic dependence of Γ_{B} on the local knot-density and interaction sector is inherited from the Localized Quantum Damping construction developed in Appendix Y.

The two coefficients therefore characterize different parts of the barrier mechanics:

$$\kappa_{\mathrm{B}} \quad \text{controls spatial evanescence,} \tag{AA.38}$$

whereas

$$\Gamma_{\mathrm{B}} \quad \text{controls localized nonconservative relaxation.} \tag{AA.39}$$

Equation (AA.28) describes the conservative barrier-transmission problem. When localized relaxation is dynamically relevant, the barrier state is governed by the full matter-wave equation containing both $V(x)$ and $\Gamma(x)$. The resulting transmission coefficient is then obtained from that dissipative boundary-value problem rather than by changing the conservative evanescence coefficient.

This separation preserves the constitutive hierarchy

$$V_{\mathrm{B}} - E \longrightarrow \kappa_{\mathrm{B}} \longrightarrow \text{evanescent penetration,} \tag{AA.40}$$

while

$$\Gamma_{\mathrm{B}} \longrightarrow \text{localized energy relaxation.} \tag{AA.41}$$

A barrier may therefore be strongly evanescent, strongly dissipative, both, or neither, depending on its local mechanical state.

AA.5 Resonantly Enhanced Passive Transmission

Finite transmission through a single barrier follows directly from evanescent coupling and does not require a resonance condition.

Resonant enhancement arises when the barrier system contains additional internal structure capable of supporting a propagating or quasi-bound mode. Examples include an internal well bounded by two evanescent regions or a multilayer structure with repeated partially reflecting interfaces.

Let an internal propagating region have effective length L_{c} and real wavenumber k_{c}. Let the two confining interfaces contribute reflection phase shifts δ_{L} and δ_{R}.

A round trip through the internal region accumulates the phase

$$\Theta_{\mathrm{rt}} = 2k_{\mathrm{c}}L_{\mathrm{c}} + \delta_{\mathrm{L}} + \delta_{\mathrm{R}}. \tag{AA.42}$$

A resonant internal mode occurs when

$$2k_{\mathrm{c}}L_{\mathrm{c}} + \delta_{\mathrm{L}} + \delta_{\mathrm{R}} = 2\pi n, \qquad n \in \mathbb{Z}. \tag{AA.43}$$

At such a condition, multiply reflected components within the structured barrier add coherently. The net incident-side reflection may be strongly reduced while the transmitted current is correspondingly enhanced.

In TFT this resonance has a direct mechanical interpretation: the barrier structure supports an internal active-vacuum matter-wave mode whose round-trip phase is compatible with the incident matter-wave field.

The passive sector therefore contains two distinct regimes:

$$\text{single-barrier evanescent transmission,} \tag{AA.44}$$

and

$$\text{structured-barrier resonant enhancement.} \tag{AA.45}$$

The latter modifies the magnitude of transmission but does not replace the evanescent mechanism that permits finite sub-barrier coupling.

AA.6 Coherent Two-Port Boundary Control

An externally driven downstream boundary produces a different physical problem because the barrier is then illuminated coherently from both sides.

Represent the barrier as a linear two-port scatterer. Let

$$a_{\mathrm{L}}, \qquad a_{\mathrm{R}} \tag{AA.46}$$

denote the incoming complex amplitudes from the left and right, and let

$$b_{\mathrm{L}}, \qquad b_{\mathrm{R}} \tag{AA.47}$$

denote the corresponding outgoing amplitudes.

The scattering relation is

$$\begin{pmatrix} b_{\mathrm{L}} \\ b_{\mathrm{R}} \end{pmatrix} = \begin{pmatrix} r_{\mathrm{L}} & t_{\mathrm{R}} \\ t_{\mathrm{L}} & r_{\mathrm{R}} \end{pmatrix} \begin{pmatrix} a_{\mathrm{L}} \\ a_{\mathrm{R}} \end{pmatrix}. \tag{AA.48}$$

For a reciprocal mirror-symmetric barrier,

$$r_{\mathrm{L}} = r_{\mathrm{R}} \equiv r_{\mathrm{B}}, \qquad t_{\mathrm{L}} = t_{\mathrm{R}} \equiv t_{\mathrm{B}}, \tag{AA.49}$$

so

$$\begin{pmatrix} b_{\mathrm{L}} \\ b_{\mathrm{R}} \end{pmatrix} = \begin{pmatrix} r_{\mathrm{B}} & t_{\mathrm{B}} \\ t_{\mathrm{B}} & r_{\mathrm{B}} \end{pmatrix} \begin{pmatrix} a_{\mathrm{L}} \\ a_{\mathrm{R}} \end{pmatrix}. \tag{AA.50}$$

For passive illumination from the left,

$$a_{\mathrm{R}} = 0, \tag{AA.51}$$

and

$$b_{\mathrm{L}} = r_{\mathrm{B}} a_{\mathrm{L}}. \tag{AA.52}$$

If a coherent downstream driver supplies a nonzero right-side input, the reflected field becomes

$$b_{\mathrm{L}} = r_{\mathrm{B}} a_{\mathrm{L}} + t_{\mathrm{B}} a_{\mathrm{R}}. \tag{AA.53}$$

Incident-side reflection is canceled when

$$b_{\mathrm{L}} = 0. \tag{AA.54}$$

For

$$t_{\mathrm{B}} \neq 0, \tag{AA.55}$$

the required coherent-drive condition is

$$\frac{a_{\mathrm{R}}}{a_{\mathrm{L}}} = -\frac{r_{\mathrm{B}}}{t_{\mathrm{B}}}. \tag{AA.56}$$

Equation (AA.56) fixes both the amplitude and relative phase of the downstream drive.

Its magnitude condition is

$$\left|\frac{a_{\mathrm{R}}}{a_{\mathrm{L}}}\right| = \frac{|r_{\mathrm{B}}|}{|t_{\mathrm{B}}|}, \tag{AA.57}$$

and its phase condition is

$$\arg\left(\frac{a_{\mathrm{R}}}{a_{\mathrm{L}}}\right) = \pi + \arg(r_{\mathrm{B}}) - \arg(t_{\mathrm{B}}) \qquad (\mathrm{mod}\ 2\pi). \tag{AA.58}$$

The downstream input therefore changes the complete boundary state through coherent interference. Under the cancellation condition, the outgoing left-moving components destructively interfere while the barrier supports a coherently driven evanescent field.

The resulting driven internal field may contain interference structure determined by the complete boundary-matched solution; reflection cancellation does not require a zero-displacement node.

The right-side output is

$$b_{\mathrm{R}} = t_{\mathrm{B}} a_{\mathrm{L}} + r_{\mathrm{B}} a_{\mathrm{R}}. \tag{AA.59}$$

Because both a_{L} and a_{R} are incoming fields, the driven system has two energy inputs. Consequently, b_{R} generally contains contributions supplied from both sides.

The coherent-control condition therefore represents reflection cancellation under two-sided boundary driving, not a change in the intrinsic value of V_{B}. By itself, Equation (AA.56) establishes a controlled matter-wave field state; the corresponding topological-knot transport is derived separately from the TFT phase-action guidance law.

AA.7 Active Topological-Knot Transport Engineering Law

The coherent-control condition in Equation (AA.56) fixes the general downstream input required to cancel the incident-side reflected amplitude. For the uniform rectangular barrier defined in Equation (AA.3), the corresponding driven barrier state can be obtained explicitly.

Under the reflection-cancellation condition

$$b_{\mathrm{L}} = 0, \tag{AA.60}$$

the left exterior field reduces to

$$\psi_{\mathrm{I}}(x) = a_{\mathrm{L}} e^{ikx}, \qquad x < 0. \tag{AA.61}$$

Inside the barrier,

$$\psi_{\mathrm{II}}(x) = B e^{\kappa_{\mathrm{B}} x} + C e^{-\kappa_{\mathrm{B}} x}. \tag{AA.62}$$

Continuity of ψ and $\mathrm{d}\psi/\mathrm{d}x$ at $x = 0$ gives

$$B + C = a_{\mathrm{L}}, \tag{AA.63}$$

and

$$\kappa_{\mathrm{B}}(B-C) = ika_{\mathrm{L}}. \tag{AA.64}$$

Therefore,

$$B = \frac{a_{\mathrm{L}}}{2}\left(1 + i\frac{k}{\kappa_{\mathrm{B}}}\right), \tag{AA.65}$$

and

$$C = \frac{a_{\mathrm{L}}}{2}\left(1 - i\frac{k}{\kappa_{\mathrm{B}}}\right). \tag{AA.66}$$

The reflection-cancelled barrier field is consequently

$$\psi_{\mathrm{II}}(x) = a_{\mathrm{L}}\left[\cosh(\kappa_{\mathrm{B}}x) + i\frac{k}{\kappa_{\mathrm{B}}}\sinh(\kappa_{\mathrm{B}}x)\right]. \tag{AA.67}$$

On the downstream side,

$$\psi_{\mathrm{III}}(x) = b_{\mathrm{R}}e^{ik(x-L)} + a_{\mathrm{R}}e^{-ik(x-L)}, \qquad x > L. \tag{AA.68}$$

Matching the field and its derivative at $x = L$ gives the required downstream drive,

$$\frac{a_{\mathrm{R}}}{a_{\mathrm{L}}} = \frac{i}{2}\left(\frac{k}{\kappa_{\mathrm{B}}} + \frac{\kappa_{\mathrm{B}}}{k}\right)\sinh(\kappa_{\mathrm{B}}L). \tag{AA.69}$$

Using Equations (AA.11) and (AA.13), this becomes

$$\frac{a_{\mathrm{R}}}{a_{\mathrm{L}}} = i\frac{V_{\mathrm{B}}}{2\sqrt{E(V_{\mathrm{B}}-E)}}\sinh(\kappa_{\mathrm{B}}L). \tag{AA.70}$$

For the phase convention used here, the required downstream drive is therefore in quadrature with the left incident amplitude. The general phase relation remains that of Equation (AA.58).

The corresponding right-side outgoing amplitude is

$$\frac{b_{\mathrm{R}}}{a_{\mathrm{L}}} = \cosh(\kappa_{\mathrm{B}}L) + \frac{i}{2}\left(\frac{k}{\kappa_{\mathrm{B}}} - \frac{\kappa_{\mathrm{B}}}{k}\right)\sinh(\kappa_{\mathrm{B}}L). \tag{AA.71}$$

The magnitude of the required drive follows directly from Equation (AA.70):

$$\left|\frac{a_{\mathrm{R}}}{a_{\mathrm{L}}}\right|^2 = \frac{V_{\mathrm{B}}^2}{4E(V_{\mathrm{B}}-E)}\sinh^2(\kappa_{\mathrm{B}}L). \tag{AA.72}$$

Comparison with the exact passive coefficient in Equation (AA.28) gives the engineering relation

$$\left|\frac{a_{\mathrm{R}}}{a_{\mathrm{L}}}\right|^2 = \frac{1-T_{\mathrm{pass}}}{T_{\mathrm{pass}}}. \tag{AA.73}$$

Thus, increasingly opaque passive barriers require correspondingly larger coherent downstream drive. The controlled state does not remove the barrier or change V_{B}; it changes the boundary-matched matter-wave field.

The matter-order-parameter current defined in Equation (AA.26) evaluated for Equation (AA.67) is

$$j_\Psi = \frac{\hbar k}{m}\left|a_{\mathrm{L}}\right|^2, \qquad 0 \le x \le L. \tag{AA.74}$$

The corresponding barrier-field magnitude is

$$|\psi_{\mathrm{II}}(x)|^2 = |a_{\mathrm{L}}|^2 \left[\cosh^2(\kappa_{\mathrm{B}} x) + \frac{k^2}{\kappa_{\mathrm{B}}^2}\sinh^2(\kappa_{\mathrm{B}} x)\right]. \tag{AA.75}$$

Using the TFT Madelung form

$$\Psi = \sqrt{\rho}\, e^{iS/\hbar}, \tag{AA.76}$$

the order-parameter current satisfies

$$j_\Psi = \rho \frac{1}{m}\frac{\partial S}{\partial x} = \rho v_\Psi. \tag{AA.77}$$

The local phase-action velocity inside the barrier is therefore

$$v_\Psi(x) = \frac{\hbar k/m}{\cosh^2(\kappa_{\mathrm{B}} x) + \dfrac{k^2}{\kappa_{\mathrm{B}}^2}\sinh^2(\kappa_{\mathrm{B}} x)}. \tag{AA.78}$$

TFT identifies the localized topological knot with the defect guided by this physical matter-order-parameter flow. Denoting its one-dimensional coordinate by $x_K(t)$, the corresponding guidance closure is

$$\frac{\mathrm{d}x_K}{\mathrm{d}t} = v_\Psi(x_K)\,. \tag{AA.79}$$

Substitution of Equation (AA.78) gives the Active Topological-Knot Transport Engineering Law:

$$\frac{\mathrm{d}x_K}{\mathrm{d}t} = \frac{\hbar k/m}{\cosh^2(\kappa_{\mathrm{B}} x_K) + \dfrac{k^2}{\kappa_{\mathrm{B}}^2}\sinh^2(\kappa_{\mathrm{B}} x_K)}, \qquad 0 \le x_K \le L. \tag{AA.80}$$

Every term in the denominator of Equation (AA.80) is nonnegative, while $k > 0$. Hence

$$\frac{\mathrm{d}x_K}{\mathrm{d}t} > 0 \tag{AA.81}$$

throughout the barrier. Within the TFT guidance closure, a knot entering the controlled barrier therefore follows a continuous forward streamline from the entrance toward the exit.

The corresponding traversal time is

$$t_{\mathrm{tr}}^{(\mathrm{act})} = \frac{m}{\hbar k}\int_0^L \left[\cosh^2(\kappa_{\mathrm{B}} x) + \frac{k^2}{\kappa_{\mathrm{B}}^2}\sinh^2(\kappa_{\mathrm{B}} x)\right]\mathrm{d}x. \tag{AA.82}$$

Evaluating the integral gives

$$t_{\mathrm{tr}}^{(\mathrm{act})} = \frac{m}{\hbar k}\left[\frac{1 + k^2/\kappa_{\mathrm{B}}^2}{4\kappa_{\mathrm{B}}}\sinh(2\kappa_{\mathrm{B}} L) + \frac{1 - k^2/\kappa_{\mathrm{B}}^2}{2}L\right]. \tag{AA.83}$$

The two-port solution also preserves the stationary current balance. Equations (AA.69) and (AA.71) give

$$|b_{\mathrm{R}}|^2 = |a_{\mathrm{L}}|^2 + |a_{\mathrm{R}}|^2\,. \tag{AA.84}$$

Accordingly,

$$j_{\mathrm{R}}^{(\mathrm{out})} - j_{\mathrm{R}}^{(\mathrm{in})} = j_{\mathrm{L}}^{(\mathrm{in})}, \tag{AA.85}$$

where $j_{\mathrm{R}}^{(\mathrm{in})}$ denotes the magnitude of the left-moving downstream input current. Since all three exterior components have the same stationary energy E, the corresponding energy-flux balance follows by multiplication by E.

The derivation above assumes the conservative barrier problem. When localized relaxation is present but weak, the controlled solution remains a valid leading approximation provided

$$\int_0^{t_{\mathrm{tr}}^{(\mathrm{act})}} \Gamma[x_K(t)]\,\mathrm{d}t \ll 1. \tag{AA.86}$$

For a uniform barrier-localized rate,

$$\Gamma_{\mathrm{B}} t_{\mathrm{tr}}^{(\mathrm{act})} \ll 1. \tag{AA.87}$$

If this condition fails, the full dissipative VNLW boundary-value problem must be solved and the conservative active-transport law is no longer sufficient.

The resulting engineering hierarchy is

$$\begin{aligned} E,\ V_{\mathrm{B}},\ L,\ m &\longrightarrow k,\ \kappa_{\mathrm{B}},\ T_{\mathrm{pass}} \\ &\longrightarrow \frac{a_{\mathrm{R}}}{a_{\mathrm{L}}} \longrightarrow \psi_{\mathrm{II}} \longrightarrow v_\Psi \longrightarrow x_K(t). \end{aligned} \tag{AA.88}$$

Thus, within the stationary conservative rectangular-barrier model and the TFT phase-action guidance closure, coherent reflection cancellation yields an explicit controllable matter-wave state together with a deterministic forward knot-transport law. The remaining microscopic engineering requirement is to specify how a physical actuator generates the required coherent downstream matter-order-parameter input a_{R} without introducing an independent localized topological defect.

AA.8 TFT Constitutive Closure and Regime Map

The tunneling construction separates the matter-wave problem into distinct mechanical regimes.

For a passive barrier,

$$E < V_{\mathrm{B}} \tag{AA.89}$$

produces the evanescent branch

$$k_{\mathrm{B}} = i\kappa_{\mathrm{B}}, \qquad \kappa_{\mathrm{B}} = \frac{\sqrt{2m\,(V_{\mathrm{B}} - E)}}{\hbar}. \tag{AA.90}$$

Boundary matching then gives the finite passive transmission coefficient T_{pass} of Equation (AA.28).

Localized nonconservative response constitutes a separate constitutive sector characterized by the barrier-localized rate

$$\Gamma_{\mathrm{B}}, \tag{AA.91}$$

which does not modify the conservative definition of κ_{B}.

For a structured barrier, resonantly enhanced passive transmission occurs when

$$2k_{\mathrm{c}}L_{\mathrm{c}} + \delta_{\mathrm{L}} + \delta_{\mathrm{R}} = 2\pi n. \tag{AA.92}$$

For coherent two-sided driving, incident-side reflection is canceled when

$$\frac{a_{\mathrm{R}}}{a_{\mathrm{L}}} = -\frac{r_{\mathrm{B}}}{t_{\mathrm{B}}}, \tag{AA.93}$$

while the barrier itself retains the same intrinsic potential-energy threshold V_{B}.

For the uniform rectangular barrier, the reflection-cancelled state further yields the explicit drive condition of Equation (AA.70). Through the TFT phase-action relation and topological-knot guidance closure, this controlled field determines the knot motion according to Equation (AA.80), with traversal time given by Equation (AA.83).

The resulting regime hierarchy is therefore

$$\begin{aligned} &\text{passive evanescence} \\ &\quad \longrightarrow \text{localized relaxation} \\ &\quad \longrightarrow \text{structured-barrier resonance} \\ &\quad \longrightarrow \text{coherent two-port boundary control} \\ &\quad \longrightarrow \text{active topological-knot transport.} \end{aligned} \tag{AA.94}$$

The first three regimes characterize passive or material-dependent barrier response. The fourth specifies externally imposed coherent boundary control. The fifth converts that controlled matter-order-parameter state into deterministic knot transport within the TFT phase-action guidance closure.

Two microscopic reductions remain external to the present continuum treatment. The first is the constitutive derivation

$$V_{\mathrm{B}} \longleftarrow \text{local FCC–Condensate active-vacuum barrier microphysics}, \tag{AA.95}$$

which determines the effective barrier energy from the underlying material state. The second is the actuator realization

$$\text{physical coherent actuator} \longrightarrow a_{\mathrm{R}}, \tag{AA.96}$$

which must generate the required downstream matter-order-parameter input without introducing an independent localized topological defect.

Within these stated closures, quantum tunneling is represented as finite coupling of a physical matter order parameter through an evanescent region of the active vacuum. Passive transmission, localized relaxation, resonant enhancement, coherent reflection cancellation, and active knot transport are therefore distinct limits of one boundary-value framework rather than separate tunneling mechanisms.

Appendix AB

The Graviton and the Information Ledger

Unifying Gravity, Light, and Information via Lattice Strain

Abstract: In standard physics, the Graviton is hypothesized as a spin-two boson mediating the gravitational force, yet it remains undetected. Tension Field Theory (TFT) resolves this by redefining the Graviton not as an independent particle, but as the Longitudinal Strain Wake of a photon propagating across the vacuum lattice. We derive the energy of this wake from first principles using the mechanical properties of the SGF. We demonstrate that every photon ($E = hf$) necessarily induces a microscopic gravitational strain (E_g), the magnitude of which perfectly recovers the scaling hierarchy between Electromagnetism and Gravity without requiring arbitrary coupling constants. Furthermore, we mechanically define this strain as the fundamental unit of physical Information (N), proving mathematically that quantum unitarity is eternally preserved by the absolute structural stability of the underlying substrate.

AB.1 Introduction: The Mechanical Coupling

As established in the Vertical Topology architecture (see Chapter 15), the vacuum is a stratified, physical supersolid lattice connected by a rigid Tension Column:

- **The Photon:** A dynamic transverse vibrational wave propagating across the active FCC Soft Floor (Dynamic Action / The Carrier).
- **The Graviton:** A longitudinal strain signature tracked across the latent SC Hard Floor (Static Tension / The Data Record).

Because the lattice has finite stiffness, a photon cannot vibrate without exerting a localized mechanical stress upon the underlying medium. Because the substrate is perfectly rigid, it does not kinematically deform or displace; instead, it registers this interaction as a static topological stress signature. This signature is the Graviton—the geometric Strain Wake that travels in lockstep with the photon across the substrate.

AB.2 Derivation of the Graviton Energy (E_g)

We calculate the energy stored in the localized lattice strain caused by the propagation of a single photon.

AB.2.1 The Photon as Mass

By mass-energy equivalence, a photon of frequency f possesses an effective inertial mass equivalent based on the invariant kinematic budget of the lattice (c_{E}^2):

$$m_{\mathrm{eff}} = \frac{hf}{c_{\mathrm{E}}^2} \tag{AB.1}$$

AB.2.2 The Lattice Strain (α_{G})

As established in Appendix A, a localized mass m induces a dimensionless gravitational coupling (strain), α_{G}, in the surrounding field at a characteristic distance r. For a photon, the characteristic distance of geometric interaction is its own wavelength λ:

$$\alpha_{\mathrm{G}} = \frac{Gm_{\mathrm{eff}}}{\lambda c_{\mathrm{E}}^2} \tag{AB.2}$$

Substituting m_{eff}:

$$\alpha_{\mathrm{G}} = \frac{G\left(\frac{hf}{c_{\mathrm{E}}^2}\right)}{\lambda c_{\mathrm{E}}^2} = \frac{Ghf}{c_{\mathrm{E}}^4 \lambda} \tag{AB.3}$$

Using the fundamental wave relation $f = \frac{c_{\mathrm{E}}}{\lambda}$:

$$\alpha_{\mathrm{G}} = \frac{Gh}{c_{\mathrm{E}}^3 \lambda^2} \tag{AB.4}$$

AB.2.3 The Geometric Substitution (The Hierarchy Law)

As established in Appendix A, we recall the definition of the squared Substrate Lattice Spacing from the absolute properties of the SGF:

$$\ell_{\mathrm{S}}^2 = \frac{\hbar G}{c_{\mathrm{E}}^3} \tag{AB.5}$$

Recalling the geometric relation between the full and reduced quantum action ($h = 2\pi\hbar$), we substitute ℓ_{S}^2 into the coupling equation, yielding a strict geometric ratio:

$$\alpha_{\mathrm{G}} = 2\pi \left(\frac{\ell_{\mathrm{S}}}{\lambda}\right)^2 \tag{AB.6}$$

Interpretation: The gravitational strain caused by a photon is proportional to the square of the ratio between the fundamental SC lattice (ℓ_{S}) and the macroscopic photon wavelength (λ). This ratio mathematically defines the scale gap between the active wave on the Soft Floor and the structural anchor on the Hard Floor.

AB.2.4 The Graviton Energy (E_{g})

The energy of the Graviton is the Strain Energy associated with the photon. It is the photon's total transverse energy scaled by the longitudinal strain factor (α_{G}).

$$E_{\mathrm{g}} = E_{\mathrm{photon}} \cdot \alpha_{\mathrm{G}} = (hf)\left[2\pi \left(\frac{\ell_{\mathrm{S}}}{\lambda}\right)^2\right] \tag{AB.7}$$

Expanding this provides the final mechanical equation for the Graviton:

$$E_{\mathrm{g}} = \frac{2\pi h c_{\mathrm{E}} \ell_{\mathrm{S}}^2}{\lambda^3} = \frac{h^2 G}{c_{\mathrm{E}}^2 \lambda^3} \tag{AB.8}$$

AB.3 Numerical Evaluation and the Hierarchy Problem

Let us calculate the absolute energy of a Graviton associated with a standard green visible photon ($\lambda \approx 500$ nm $= 5.0 \times 10^{-7}$ m).
The Photon Energy (E_γ):

$$E_\gamma = \frac{hc_{\mathrm{E}}}{\lambda} \approx 3.9729 \times 10^{-19} \text{ J} \quad (\approx 2.48 \text{ eV}) \tag{AB.9}$$

The Strain Factor (α_{G}): Using the exact substrate spacing $\ell_{\mathrm{S}} = 1.6163 \times 10^{-35}$ m:

$$\alpha_{\mathrm{G}} = 2\pi \left(\frac{1.6163 \times 10^{-35}}{5.0 \times 10^{-7}} \right)^2 \approx 6.5657 \times 10^{-57} \approx 10^{-56} \tag{AB.10}$$

The Graviton Energy (E_{g}):

$$E_{\mathrm{g}} = E_\gamma \cdot \alpha_{\mathrm{G}} \approx (3.9729 \times 10^{-19}) \cdot (6.5657 \times 10^{-57}) \approx 2.6085 \times 10^{-75} \text{ J} \tag{AB.11}$$

The Hierarchy Ratio:

$$\text{Ratio} = \frac{E_{\mathrm{g}}}{E_\gamma} = \alpha_{\mathrm{G}} \approx 10^{-56} \tag{AB.12}$$

This rigorously and naturally resolves the Hierarchy Problem. Gravity is not a phenomenologically weak fundamental force; it is the secondary, longitudinal strain response to a primary transverse vibration.

AB.4 The Dynamic Cursor (Strain Wake)

- **The Primary Wave:** The photon, representing a transverse vibrational mode propagating across the FCC Soft Floor ($\sim 10^{-26}$ m).
- **The Induced Strain:** The graviton, representing the corresponding longitudinal strain profile localized on the SC Hard Floor ($\sim 10^{-35}$ m).

These two phenomena are physically inseparable. Within this framework, the graviton is not an independent gauge boson mediating force across a vacuum; rather, it is the requisite elastic cost of wave propagation through a structured material medium. It acts as a dynamic topological cursor, dragging across the SC substrate with zero inertia as the photon propagates.

AB.5 Constitutive Mechanical Definition of the Information Record (N)

By establishing that the photon is the dynamic carrier of action and the graviton is its static topological footprint, we introduce the reduced TFT normalization that maps the static strain footprint onto a dimensionless information-record count. Information (N, measured in discrete strain bits) is fundamentally defined as the ratio of the Carrier's total dynamic energy (E_{carrier}) to the static strain energy of a single continuous record (E_{record}).

$$N = \frac{E_{\text{carrier}}}{E_{\text{record}}} \tag{AB.13}$$

For the propagating-wave branch, TFT adopts the reduced record-energy closure ($E_{\text{record},\gamma} \equiv \alpha_{\text{G},\gamma} E_\gamma$). The carrier energy therefore cancels from the corresponding dimensionless record count:

$$N_\gamma = \frac{E_\gamma}{E_\gamma \cdot \alpha_{\text{G},\gamma}} = \frac{1}{\alpha_{\text{G},\gamma}} \tag{AB.14}$$

This resolves into two branch-specific geometric identities for defining physical states, governed by their respective gravitational coupling regimes and topological normalizations:

A. The Kinematic (Wave) Identity

Substituting the kinematic strain coupling ($\alpha_{\text{G},\gamma}$), we define the information of an untethered, propagating wave (e.g., a photon):

$$N_\gamma = \frac{1}{\alpha_{\text{G},\gamma}} = \frac{1}{2\pi}\left(\frac{\lambda}{\ell_{\text{S}}}\right)^2 \tag{AB.15}$$

B. The Inertial (Matter) Identity

For a coherent standing wave (localized matter), we substitute the inertial strain coupling ($\alpha_{\text{G,m}}$) defined in terms of the invariant inertial mass (m_{i}) and the absolute universal Substrate Mass Potential ($m_{\text{S}} = \sqrt{\frac{\hbar c_{\text{E}}}{G}}$). The phase defect carries an additional 2π winding normalization. Substituting the matter strain yields the matter identity:

$$N_{\text{m}} = \frac{2\pi}{\alpha_{\text{G,m}}} = 2\pi\left(\frac{m_{\text{S}}}{m_{\text{i}}}\right)^2 \tag{AB.16}$$

Within the adopted TFT record normalization, these relations imply that the information footprint decreases with increasing localization. An untethered wave (e.g., a photon) possesses a macroscopic wavelength, distributing its topological footprint across a massive array of discrete substrate nodes ($N_\gamma \approx 10^{56}$). Conversely, as energy condenses into localized invariant mass (m_{i}), its geometry concentrates. The massive particle withdraws its extended footprint, anchoring its standing wave to the substrate via a denser, highly concentrated cluster of topological strain bits (N_{m}).

AB.6 The Unitarity Guarantee (The Stability Margin)

Standard quantum mechanics encounters an "Information Paradox" when massive objects collapse, questioning whether the data of the original state is destroyed. TFT proves mathematically that information is indestructible by analyzing the structural stability margin between the storage medium (the Hardware) and the data imprint (the Software).

- **The Hardware (Storage Node):** The energy capacity of a single fundamental SC Substrate node (ℓ_{S}^3) is determined by the Substrate Mass Potential (m_{S}):

$$E_{\text{node}} = m_{\text{S}} c_{\text{E}}^2 = \sqrt{\frac{\hbar c_{\text{E}}^5}{G}} \approx 1.956 \times 10^9 \text{ J} \tag{AB.17}$$

- **The Software (Data Imprint):** The energy required to write a localized strain bit (the Graviton derived above) is:

$$E_{\text{write}} = E_{\text{g}} \approx 10^{-75} \text{ J} \tag{AB.18}$$

Comparing the physical strength of the substrate core to the energy of the data yields an absolute Stability Margin:

$$\text{Stability Ratio} = \frac{E_{\text{node}}}{E_{\text{write}}} \approx \frac{10^{9}\ \text{J}}{10^{-75}\ \text{J}} \approx 10^{84} \tag{AB.19}$$

The structural yield strength of the Substrate is 84 orders of magnitude greater than the mechanical stress of a data imprint. Therefore, writing dynamic information into the Hard Floor can never thermally or mechanically fracture the substrate. The macroscopic information of the universe is permanently locked as static structural strain, formally guaranteeing Quantum Unitarity.

AB.7 Latent Information Storage (The Holographic Record)

The discrete energy magnitude of a single graviton ($\approx 10^{-75}$ J) resides profoundly below the quantization threshold of the active Soft Lattice, rendering it inaccessible to standard matter-based instrumentation. However, this mechanical stress signature is strictly conserved; it precipitates into the latent potential of the SC Hard Floor.

Consequently, every photon propagation event leaves a permanent, microscopic strain signature in the deep substrate. This mechanism provides a rigorous mechanical foundation for the Holographic Principle: the total informational history of the universe is physically encoded within the permanent tension states of the discrete State 0 Substrate cells.

AB.8 The Information-Energy Inverse Law

In standard thermodynamic frameworks, information is often equated with entropy (the counting of chaotic microstates), leading to the assumption that highly energetic or massive states inherently contain more information. Tension Field Theory strictly reverses this ontology by defining information geometrically rather than thermodynamically.

In TFT, the undisturbed, latent SC Substrate represents pure, flawless geometric order—the state of maximum latent information capacity. Dynamic energy (whether propagating transverse waves or localized standing mass) does not create reality; it acts as a localized topological defect that strains this underlying perfect geometry.

Therefore, the TFT information footprint decreases with increasing localization and gravitational strain, subject to the branch-specific topological normalization defined above.

- A minimal-energy state (e.g., a low-frequency wave) is highly delocalized, gently distributing its topological footprint across a massive number of Substrate nodes ($N \gg 1$).
- Conversely, concentrating energy into a heavy, massive particle shrinks its geometric footprint, withdrawing its delocalized state and focusing intense strain onto a much smaller cluster of nodes ($N \to 2\pi$).

Ultimately, concentrated mass-energy acts as structural "noise" that consumes the underlying geometric capacity of the vacuum. Information is maximized by spatial delocalization, not by energetic density.

AB.9 Conclusion: Unification via Lattice Mechanics

This derivation achieves the unification of quantum wave mechanics, gravitational strain, and information theory without invoking supplementary spatial dimensions or non-physical string landscapes.

- **Quantized Gravitational Field:** The gravitational field consists of discrete energy quanta (E_{g}) geometrically determined by the ratio of the photon wavelength (λ) to the fundamental Substrate Lattice Spacing (ℓ_{S}).
- **Deterministic Coupling:** E_{g} is derived strictly from fundamental invariants (h, c_{E}, and G), naturally resolving the hierarchy of forces.
- **Mechanical Causality:** The gravitational force is redefined as the unavoidable elastic restoration response of the underlying supersolid lattice to the continuous displacement of transverse energy.
- **The Unitarity of Information:** The graviton is mathematically identified as the fundamental mechanical bit of information (N), the preservation of which is guaranteed by the 10^{84} stability margin of the Substrate.

The Graviton is physically real, but it is a Phonon of Strain (Static Potential) on the Hard Floor, not an independent, free-traveling particle of matter (Dynamic Action).

Appendix AC

The Topology of Entanglement and the Modified CHSH Bound

Abstract: In standard Quantum Mechanics, entanglement is described by a non-local wavefunction that instantly correlates distant particles, offering no physical mechanism and violating local realism. Tension Field Theory resolves this by introducing the Vertical Dimension Z of scale. We derive entanglement not as a mysterious link across empty space, but as a Goalpost Topology where two active surface particles maintain independent vertical gravitational anchors on the SC Hard Floor, linked horizontally by a Residual Phase-Tether. This framework establishes the modified CHSH inequality, recovers the geometric limits of Quantum Mechanics, and preserves the mechanical causality of the topologically locked phase.

AC.1 The Geometry of the Topological Tether

In Tension Field Theory, a particle is not a zero-dimensional point on a two-dimensional sheet. It is a composite mechanical structure: a localized dynamic excitation on the State I Active Vacuum (the FCC Soft Floor with characteristic radius $r_{\mathrm{D}} \approx 7.45 \times 10^{-27}$ m), mechanically tethered to the State 0 Latent Substrate (the SC Hard Floor with lattice spacing $\ell_{\mathrm{S}} \approx 1.6163 \times 10^{-35}$ m) via a topological Vertical Tension Column.

Let a particle coordinate be defined as (x, y, z, Z), where Z represents the scale depth.

- **Particle A:** $(x_{\mathrm{A}}, y_{\mathrm{A}}, z_{\mathrm{A}}, Z_{\mathrm{soft}})$
- **Particle B:** $(x_{\mathrm{B}}, y_{\mathrm{B}}, z_{\mathrm{B}}, Z_{\mathrm{soft}})$
- **Anchor g_{A}:** $(x_{g\mathrm{A}}, y_{g\mathrm{A}}, z_{g\mathrm{A}}, Z_{\mathrm{hard}})$
- **Anchor g_{B}:** $(x_{g\mathrm{B}}, y_{g\mathrm{B}}, z_{g\mathrm{B}}, Z_{\mathrm{hard}})$

Two particles are entangled if and only if they originate from a single coherent topological event (such as parametric down-conversion at a beam waist, A_{root}) that creates a shared locus on the substrate. As the particles separate on the Soft Floor, their independent vertical Tension Columns separate on the Hard Floor, leaving behind a continuous line of microscopic longitudinal strain.

The mathematical condition for entanglement is the existence of this Residual Phase-Tether: While the spatial metric distance between their anchors on the SC Substrate is strictly non-zero ($L > 0$), the transit time across this distance is strictly zero ($\Delta t \to 0$). This is because the SC

Hard Floor operates with zero intrinsic inertial density ($\mu_S \to 0$) and infinite stiffness ($\tau_S \to \infty$). Therefore, the stress transmission speed is effectively infinite:

$$c_S = \sqrt{\frac{\tau_S}{\mu_S}} \to \infty \tag{AC.1}$$

In TFT, true non-locality does not exist. The interaction is spatially separated across the three-dimensional Soft Floor, but strictly mechanically coupled via the instantaneous phase-tether along the Hard Floor.

AC.2 Spin Conservation via Torsion Constraint

We now derive standard quantum behavior, such as spin conservation in a Bell state, using strict lattice mechanics.

Let Θ represent the twist or spin of the vertical Tension Column. The substrate itself is a topologically locked phase governed by the ultimate yield tension $F_S = c_E^4/G$, rendering it a perfectly rigid, absolute reference frame. However, the continuous phase-tether connecting g_A and g_B across this substrate is microscopic and highly fragile, governed only by the residual local tension (τ_{local}).

For a singlet state with total spin zero, the continuous phase-tether acts as a perfectly rigid mechanical driveshaft. The mechanical constraint equation is:

$$\Theta_A + \Theta_B = 0 \tag{AC.2}$$

Because the latent SC Substrate transmits stress with $c_S \to \infty$, any tension reconfiguration across the tether occurs instantly. To an observer on the Soft Floor, the phase-locking event resolves exactly at the fundamental quantization limit t_S.

AC.3 Measurement as Torque Resolution (The Severing Sequence)

Standard physics treats measurement as the abstract instantaneous collapse of a probability wave. TFT redefines measurement as a mechanical event: torque resolution.

Before measurement, entangled particles A and B exist as a Goalpost Topology, possessing independent perpendicular gravitational columns (g_A and g_B) mechanically linked by the horizontal phase-tether.

- **The Injection (Soft Floor):** A macroscopic detector applies a rigid boundary condition—a physical torque—to Particle A on the FCC Soft Floor, forcing it into a specific mechanical eigenstate (e.g., $\Theta_A \to +1/2$).
- **The Downward Strike (Z-Dimension):** Because the latent SC Substrate operates with zero inertial density, the Tension Column has no rotational impedance. The torque transmits instantly straight down Column A to its anchor g_A.
- **The Horizontal Transfer (Phase-Tether):** The mechanical stress shoots across the fragile phase-tether on the flat Hard Floor. Because $c_S \to \infty$, the signal reaches g_B instantaneously ($\Delta t \to 0$).
- **The Upward Snap (Phase-Lock Resolution):** To satisfy the absolute structural constraint ($\Theta_A + \Theta_B = 0$), the anchor g_B instantly deflects the torsion up the second column, forcing Particle B on the Soft Floor to snap into the exact opposite orientation ($\Theta_B = -1/2$).

- **The Severing (Decoherence):** The macroscopic energy injected by the detector torque immediately exceeds the structural tension limit of the delicate phase-tether. The horizontal connection mechanically fractures. Particle A and Particle B retain their independent gravitational anchors (g_{A} and g_{B}), but the entanglement is permanently destroyed.

AC.4 The FCC Geometric Derivation of $2\sqrt{2}$

In standard quantum statistics, the CHSH correlation is capped at Tsirelson's bound of $2\sqrt{2}$. In TFT, this is not a statistical anomaly. It is the physical structural footprint of the active vacuum lattice.

When a detector applies a boundary constraint to the Soft Floor, the correlation must mechanically project across the discrete links of the face-centered cubic lattice.

- **The Classical Limit (2):** Represents a structural projection along strictly orthogonal axes of a square or cubic grid.
- **The Quantum Limit ($2\sqrt{2}$):** In the FCC active vacuum, adjacent nodes touch strictly along the face diagonal, not the orthogonal edges. The fundamental geometric edge length a of the FCC unit cell relative to the node radius r_{D} is exactly $a = 2\sqrt{2}r_{\mathrm{D}}$.

Because the correlation torque must physically propagate across the nearest-neighbor diagonal links of the FCC lattice, the absolute maximum contiguous distance the wave can perfectly couple across a single fundamental unit cell is geometrically capped by this ratio. Tsirelson's bound is the literal diagonal parameter of the FCC Soft Floor.

AC.5 The Modified CHSH Inequality and Gravitational Decoherence

Because entanglement is physically mediated by the Hard Floor, the correlation strength is a function of the available structural slack required to maintain the phase-tether.

We define the modified TFT CHSH bound as:

$$S_{\mathrm{CHSH}} \leq 2\sqrt{1 + \alpha_{\mathrm{Q}}^2} \tag{AC.3}$$

where $\alpha_{\mathrm{Q}} \leq 1$ is the dimensionless quantum topological coupling factor. It measures the ratio of the localized mechanical constraint action to the fundamental quantum action $\hbar$:

$$\alpha_{\mathrm{Q}} = \frac{\xi_{\mathrm{E}}(\tau_{\mathrm{local}} \cdot A_{\mathrm{root}} \cdot \Delta t)}{\hbar} \tag{AC.4}$$

Here, ξ_{E} is the dimensionless topological correlation constant (analytically constrained by the flat-space quantum limit, $\xi_{\mathrm{E}} = \hbar/(\tau_{\mathrm{S}} A_{\mathrm{root}} \Delta t)$), τ_{local} is the available two-dimensional surface tension of the local field, and A_{root} is the cross-sectional area of the initial topological fusion defined by the experimental beam waist ($A_{\mathrm{root}} \approx \pi w_0^2$).

The Kinematic Budget (Gravity versus Entanglement): The substrate operates on a strictly finite invariant tension budget (τ_{S}). Macroscopic mass consumes this budget via the gravitational coupling $\alpha_{\mathrm{G}} = GM/(rc_{\mathrm{E}}^2)$. Therefore, the available local tension τ_{local} required to sustain the horizontal phase-tether is strictly the residual slack left over from gravity:

$$\tau_{\mathrm{local}} = \tau_{\mathrm{S}}(1 - \alpha_{\mathrm{G}}) \tag{AC.5}$$

Substituting τ_{local} into the topological coupling equation yields:

$$\alpha_{\text{Q}} = \left[\frac{\xi_{\text{E}}\tau_{\text{S}}A_{\text{root}}\Delta t}{\hbar}\right](1-\alpha_{\text{G}}) \tag{AC.6}$$

In perfectly flat space where macroscopic gravity is negligible ($\alpha_{\text{G}} \to 0$), the standard quantum mechanical limit is strictly preserved. To recover the geometric Tsirelson bound of $2\sqrt{2}$, the topological coupling must be perfectly sustained ($\alpha_{\text{Q}} = 1$). For this to hold true, the entire bracketed constant must equal exactly 1:

$$\frac{\xi_{\text{E}}\tau_{\text{S}}A_{\text{root}}\Delta t}{\hbar} = 1 \tag{AC.7}$$

This drops the proportionality constant entirely, revealing the exact, zero-sum identity for Gravitational Decoherence:

$$\alpha_{\text{Q}} = 1 - \alpha_{\text{G}} \tag{AC.8}$$

Conclusion:

- **If $\alpha_{\text{Q}} \approx 1$ (Pristine Tether in Flat Space):** Where gravity is negligible ($\alpha_{\text{G}} \to 0$), the vacuum has its full kinematic budget available. The phase-tether is perfectly sustained, and TFT cleanly recovers the standard FCC geometric quantum bound of $2\sqrt{2}$.
- **If $\alpha_{\text{Q}} < 1$ (Gravitational Decoherence):** In regimes of extreme background mass ($\alpha_{\text{G}} \to 1$), the local tension budget is exhausted by the vertical gravitational potential. Because the lattice loses the kinematic slack required to sustain the microscopic horizontal phase-tether, α_{Q} degrades precisely linearly with the gravitational coupling. The allowable correlation limit strictly shrinks from the quantum Tsirelson bound of $2\sqrt{2}$ down toward the classical Bell limit of 2.

This provides a strictly falsifiable prediction: strong gravitational fields physically consume the structural slack required for phase-locking, mechanically destroying quantum entanglement."

Appendix AD

Photonic Emission Channels and Phase Crosstalk

Abstract: In Tension Field Theory (TFT), a photon is defined as a coherent release of substrate tension along a discrete electromagnetic channel. This appendix formalizes the mechanics of photon emission from atomic orbital drops, proving the existence of picometer-scale emission bottlenecks. Furthermore, it defines the phase exchange budget for independent photons crossing paths via temporary strain-field overlap on the SC Substrate.

AD.1 The Mechanics of Photon Emission

Standard physics models photon emission as a probabilistic point-particle creation. TFT models it as a visco-elastic extrusion. Photon emission is the release of structural tension through a highly localized micro-bottleneck in the FCC Soft Floor.

The energy of the emitted photon is the volume integral of the released tension over the geometric bounds of the emission channel:

$$E_\gamma = \int \delta\tau \, \mathrm{d}V \approx \tau_{\text{bulk}} \cdot A_{\text{chan}} \cdot \Delta r \tag{AD.1}$$

Where:

- τ_{bulk}: The three-dimensional tension density of the local field ($\mathrm{N/m^2}$). The fundamental macroscopic tension is defined by the lattice density $\tau_{\text{bulk}} = \rho c_{\text{E}}^2$. Substituting the geometric definition of the quantum action lever ($\hbar = \rho c_{\text{E}} r^4$), the operative tension density at a given effective radius r_{eff} scales strictly as:

$$\tau_{\text{bulk}} = \frac{\hbar c_{\text{E}}}{r_{\text{eff}}^4} \tag{AD.2}$$

- A_{chan}: The cross-sectional area of the micro-emission channel.
- Δr: The physical drop length through the lattice, defined by the absolute spatial difference between the starting shell r_n and ending shell r_m: $\Delta r = |r_n - r_m|$.
- r_{eff}: The operative geometric mean radius of the atomic drop: $r_{\text{eff}} = \sqrt{r_n r_m}$.

AD.1.1 Worked Hydrogen Examples

By tracing the exact geometric path of the electron drop, we can calculate the true cross-section of the emission channel ($A_{\text{chan}} = \frac{|\Delta E|}{\tau_{\text{bulk}} \Delta r}$).

1. Lyman–α ($2 \to 1$):

- ΔE**:** ≈ 10.204 eV $\quad (1.6349 \times 10^{-18}$ J)
- **Geometry:** $r_2 = 2.1167 \times 10^{-10}$ m, $\quad r_1 = 5.2918 \times 10^{-11}$ m
- **Drop Parameters:** $\Delta r = 1.5875 \times 10^{-10}$ m, $\quad r_{\text{eff}} = 1.0584 \times 10^{-10}$ m
- **Local Tension:** $\tau_{\text{bulk}} \approx 2.5220 \times 10^{14}$ N/m^2
- **Channel Area:** $A_{\text{chan}} \approx 4.0835 \times 10^{-23}$ m^2
- **Resulting Radius:** $r_{\text{chan}} \approx 3.6057$ pm $\quad (3.6057 \times 10^{-12}$ m)

2. Balmer–α ($3 \to 2$):

- ΔE**:** ≈ 1.8897 eV $\quad (3.0276 \times 10^{-19}$ J)
- **Geometry:** $r_3 = 4.7626 \times 10^{-10}$ m, $\quad r_2 = 2.1167 \times 10^{-10}$ m
- **Drop Parameters:** $\Delta r = 2.6459 \times 10^{-10}$ m, $\quad r_{\text{eff}} = 3.1751 \times 10^{-10}$ m
- **Local Tension:** $\tau_{\text{bulk}} \approx 3.1112 \times 10^{12}$ N/m^2
- **Channel Area:** $A_{\text{chan}} \approx 3.6779 \times 10^{-22}$ m^2
- **Resulting Radius:** $r_{\text{chan}} \approx 10.820$ pm $\quad (1.0820 \times 10^{-11}$ m)

Conclusion: Both atomic transitions prove mathematically that photons are extruded through localized, picometer-scale channels ($\approx 10^{-12}$ m), which are vastly smaller than the macroscopic atomic orbital radii ($\approx 10^{-10}$ m). The released energy does not occupy the full orbital shell; it is squeezed out through a highly pressurized micro-fracture.

AD.2 The Phase Crosstalk Budget (Shared Strain Bottleneck)

When two independent photons cross paths in free space at distances vastly greater than their channel radii, they exchange nothing.

However, if their trajectories are engineered to overlap tightly (such as in an evanescent fiber coupler), their vertical Tension Columns pass close enough that their respective strain fields on the SC Hard Floor temporarily overlap. This creates a Shared Strain Bottleneck, A_{overlap}.

Because they temporarily share a localized patch of the phase-locked SC substrate, the torsion of Column A mechanically interacts with the torsion of Column B. They do not exchange transverse kinetic energy (which requires field fracture); they strictly exchange Phase Holonomy, $\Delta\varphi$.

This mechanical phase exchange is governed by the total volumetric action of the overlapping strain fields, bounded by:

$$\Delta\varphi \leq \eta_{\varphi} \cdot \left(\frac{c_{\text{E}}}{r^3}\right) \cdot A_{\text{overlap}} \cdot T \tag{AD.3}$$

Where:

- r is the mode radius.
- A_{overlap} is the transient bottleneck area of the crossing Hard Floor strain fields.
- T is the operational dwell time.
- η_φ is the dimensionless Geometric Coupling Efficiency ($0 < \eta_\varphi \ll 1$). It is an empirically calibrated constant that accounts for spatial mismatch, scattering losses, and the imperfect alignment of the transient strain fields during the crossing event.

AD.3 Scaling and Falsifiability

This mechanical framework provides direct scaling laws for experimental verification. Phase crosstalk between independent photons can be empirically enhanced by shrinking the mode radius, physically enlarging the bottleneck area, or increasing the propagation dwell time.
Falsification Criteria: The TFT optical model is strictly falsifiable. The framework is disproven if:

- Photonic phase correlations exhibit standard inverse-square distance-law decay while the minimal bottleneck area A_{overlap} remains rigidly fixed.
- A measured phase correlation exceeds the hard geometric budget cap calculated from independently measured system parameters r, A_{overlap}, and T.
- Significant kinetic energy (a measurable change in frequency or color) is exchanged between crossing photons at small A_{overlap} without reaching the extreme energy thresholds required to physically disrupt the vacuum medium.

Appendix AE

The Geometric Derivation of Shear Coupling (K_{L}) and α

Abstract: In standard quantum mechanics, the fine-structure constant ($\alpha \approx 1/137.036$) and the electrostatic coupling strength of the vacuum are treated as empirical, irreducible constants of nature. Tension Field Theory (TFT) rejects the premise of arbitrary parameters. This appendix provides the deterministic, first-principles geometric derivation of the electromagnetic coupling sector in its static limit. By analyzing the 2D surface-shear topology of a spherical Soft Floor node, we derive the bare geometric limit of the fine-structure constant strictly from the integer structural constraints of the Face-Centered Cubic (FCC) lattice. The derivation explicitly separates this exact static topological bedrock from the secondary dynamic hydrodynamic impedance inherent to active atomic systems, establishing a rigorous mechanical foundation for the origin of charge.

AE.1 Physical Premise

In TFT, electric charge is not a primitive substance. It is the surviving surface-transverse shear expression of a deeper local torsional action budget on the Soft Floor node. As established in the main text and expanded upon in the subsequent Appendix AG, the fundamental geometric target of this charge sector is the absolute lattice shear coupling (K_{L}), from which the fine-structure constant is strictly defined as the dimensionless survival ratio:

$$\alpha = \frac{K_{\mathrm{L}}}{\hbar c_{\mathrm{E}}} \tag{AE.1}$$

The purpose of this appendix is not to explore the dimensional or macroscopic consequences of K_{L}, but to provide the strict, first-principles geometric derivation of the numerical value of α based on the bare topology of the FCC lattice.

AE.2 Core Mechanical Interpretation

Mechanically, α represents the efficiency of torsional capture on the 2D surface boundary of the node. It is the exact portion of the local node action budget ($\hbar c_{\mathrm{E}}$) that survives the local FCC self-healing network and is successfully captured by the first odd hemispheric surface-shear mode. To derive this value, we must simply map the static topological constraints of that capture.

AE.3 The Raw Local Closure-Channel Count

The baseline topological denominator is the raw count of local transverse self-healing channels on one spherical FCC node.

- **Global Supported Basins:** A spherical FCC node possesses 12 nearest-neighbor support directions, defining 12 primary supported surface basins. This is the global contact limit of the node.
- **Local Tangential Closure Directions:** Within each supported basin, the local tangent geometry is close-packed and effectively hexagonal. Therefore, a transverse surface disturbance has exactly 6 nearest tangential closure directions available in the local tangent network.
- **Chirality:** Each local transverse closure channel can occur in 2 chiral senses (Left-Handed or Right-Handed twist).

The raw local closure-channel population is geometrically locked at:

$$N_{\text{raw}} = 12 \times 6 \times 2 = 144 \tag{AE.2}$$

This represents the effective population of short-return transverse self-healing channels competing with the surviving global dipole mode. The raw capture ratio is therefore 1/144.

AE.4 The Boundary-Loss Principle and Spherical Correction

The base ratio of 1/144 represents a local tangent-plane channel count. However, the surviving electromagnetic charge mode is not local and planar; it is the global first odd spherical surface mode of the node (the hemispheric dipole).

In TFT, transverse surface modes on a Soft Floor node suffer dominant coherence loss through internal sign-reversal boundary length on the node surface. Under this Boundary-Loss Principle, for equal active mode area, the more coherent mode is the one with the minimal internal cancellation boundary.

- The local tangent self-healing cell is a regular hexagon.
- The global surviving odd mode is a minimum-boundary equal-area partition (a circular / great-circle analog).

Because the spherical dipole minimizes internal cancellation boundary length relative to the local hexagonal patch basis, it receives a strict geometric coherence premium. For equal enclosed area, the perimeter ratio of a regular hexagon to a circle dictates this exact spherical dipole efficiency correction (ϵ_{sph}):

$$\epsilon_{\text{sph}} = \frac{P_{\text{hex}}}{P_{\text{circ}}} = \sqrt{\frac{2\sqrt{3}}{\pi}} \approx 1.050075 \tag{AE.3}$$

AE.5 The Static Geometric Limit (α_{static})

Applying the spherical coherence premium to the raw tangent-plane denominator yields the exact structural boundary of a perfectly isolated, static Soft Floor node:

$$\alpha_{\text{static}} = \left[\frac{1}{144}\right] \sqrt{\frac{2\sqrt{3}}{\pi}} \tag{AE.4}$$

Equivalently, the static inverse fine-structure constant is:

$$\alpha_{\text{static}}^{-1} = 144\sqrt{\frac{\pi}{2\sqrt{3}}} \approx 137.133 \tag{AE.5}$$

The corresponding Absolute Lattice Shear Coupling limit for a static node is:

$$K_{\text{L,static}} = \left(\left[\frac{1}{144}\right]\sqrt{\frac{2\sqrt{3}}{\pi}}\right)\hbar c_{\text{E}} \tag{AE.6}$$

AE.6 Current Conclusion: The Bare Topological Limit

The TFT derivation yields:

$$\alpha_{\text{static}}^{-1} = 144\sqrt{\frac{\pi}{2\sqrt{3}}} \approx 137.133 \tag{AE.7}$$

This result is entirely independent of empirical particle masses or fitted parameters. It is derived strictly from the static integer topology (144 closure channels) and the idealized boundary-minimization geometry (ϵ_{sph}) of an isolated spherical node in an FCC lattice.

AE.7 The Dynamic Variance and Next Validation Steps

The static geometric derivation yields $\alpha^{-1} \approx 137.133$, while the empirical macroscopic measurement is ≈ 137.036. In TFT, this 0.07% variance is not an error, but the expected mechanical difference between two fundamental states:

- **The Bare Static Topological Limit:** An idealized, isolated, non-moving node.
- **The Dynamic Empirical Reality:** A node translating and rotating through a visco-elastic continuum.

TFT dictates that any dynamic motion through the FCC Soft Floor introduces non-linear visco-elastic impedance and lattice deformation, which must marginally alter the coupling efficiency. However, calculating the exact geometric tensor for this dynamic kinematic impedance requires full topological elastodynamic analysis of the active lattice, which is beyond the scope of this foundational text.

Therefore, this appendix deliberately does not claim a completed dynamic proof. The present result ($\alpha^{-1} \approx 137.133$) is recorded here as the most compact, mechanically interpretable, and mathematically pure first-principles expression for the static lattice coupling presently available.

The next required steps for the theoretical community are sharply defined:

1. Verify the canonicality of the 144-channel local FCC tangent geometry.
2. Apply full visco-elastic tensor analysis to determine the exact dynamic impedance shift separating this bare static limit (137.133) from the macroscopic empirical measurement (137.036), the leading-order algebraic ansatz for which is explored in the subsequent Appendix X.

Appendix AF

The FCC Routing Ansatz for the Fine-Structure Constant

Abstract: Appendix AE established the static geometric limit of the fine-structure constant by treating electric charge as the surviving first odd hemispheric surface-shear mode of an isolated spherical Soft Floor node. In that limit, the coupling is fixed by the raw local FCC closure-channel count and the spherical coherence premium, yielding the bare static value $\alpha_{\text{static}}^{-1} \approx 137.133$. As stated in that derivation, the small residual offset to the empirical measurement belongs to the dynamic regime of a translating and rotating node moving through the visco-elastic FCC vacuum. The present appendix constructs the leading-order algebraic ansatz for that dynamic shift, suggested by the discrete routing degrees of freedom of the active lattice: the hydrogenic motion scale of the localized electron knot, the rhombic-dodecahedral geometry of the surrounding FCC cell, and the spin-dependent torsional loading established in the atomic model. The resulting cubic polynomial is proposed as the expected algebraic form of the static-to-dynamic correction, providing a heuristic target for future topological elastodynamic evaluations.

AF.1 Purpose and Scope

Appendix AE provides the exact static theorem, deriving the bare electromagnetic coupling from the 2D surface-shear topology of the FCC lattice. The variance between the static geometric value and the empirical measurement arises from dynamic motion through the visco-elastic Soft Floor. Because a full tensor treatment of this condensate impedance lies beyond the scope of a foundational static framework, this appendix does not attempt a finalized lattice-dynamic proof. Its role is strategic: it proposes the simplest dynamic FCC routing ansatz capable of demonstrating how the static theorem is shifted into the empirical regime using exclusively structures native to Tension Field Theory (TFT).

AF.2 The Static Invariants

Three strict geometric invariants from Appendix AE are treated here as exact and unchanged:

- **The Raw Competitor Population:** $N_{\text{raw}} = 12 \times 6 \times 2 = 144$ local transverse closure channels.
- **The Spherical Coherence Premium:** $\epsilon_{\text{sph}} = \sqrt{\frac{2\sqrt{3}}{\pi}}$, representing the boundary-minimization advantage of the hemispheric dipole.

- **The Static Limit:** $\alpha_{\text{static}} = \frac{\epsilon_{\text{sph}}}{144}$, yielding $\alpha_{\text{static}}^{-1} \approx 137.133$.

AF.3 The Principle of Effective Competitor Reduction

The empirical fine-structure constant is measured in active atomic systems. The electron is a localized knot moving through the active vacuum, with a ground-state orbital velocity governed by the hydrogenic closure law: $v/c_{\text{E}} = \alpha$.

Because Appendix AE is a counting theorem—where the global dipole mode survives against a local competitor population—the simplest dynamic completion does not alter the numerator, but replaces the static competitor count with a slightly smaller effective count:

$$\alpha = \frac{\epsilon_{\text{sph}}}{N_{\text{eff}}} \quad , \quad N_{\text{eff}} = 144 - \Delta N_{\text{dyn}} \tag{AF.1}$$

This heuristic principle is physically grounded: as a node moves through the active vacuum, the local short-return self-healing channels will no longer be perfectly isotropic or equally accessible. Because the empirical coupling is slightly stronger than the static coupling, the dynamic medium must slightly reduce the effective local competition ($\Delta N_{\text{dyn}} > 0$).

AF.4 The Dynamic FCC Geometry

The Wigner–Seitz boundary of a single FCC node is a Rhombic Dodecahedron, characterized by 12 faces, 24 edges, and 14 vertices. In the dynamic FCC environment, the 24 edges function as the interstitial routing channels, while the 14 vertices act as the dominant reservoir pockets feeding those routes. These combinatorial counts (24 and 14) enter the ansatz not as fitted parameters, but as the immediate discrete degrees of freedom of the FCC transport geometry.

AF.5 Leading-Order Edge Routing Estimate

The primary dynamic ingredient is translational bias through the 24 edge routes. Using the hydrogenic motion parameter ($v/c_{\text{E}} = \alpha$), the leading-order geometric estimate for the dynamic reduction is:

$$\Delta N_{\text{edge}} \approx 24\eta_{\text{edge}} \quad , \quad \eta_{\text{edge}} \approx \frac{\alpha}{\sqrt{3}} \tag{AF.2}$$

The factor $1/\sqrt{3}$ is utilized here as a natural 3D close-packed obliquity estimate. It acts as a geometric weight encoding the principle that translational bias felt by the edge channels is diluted over three spatial axes. This yields the leading term:

$$\Delta N_{\text{edge}} \approx \frac{24\alpha}{\sqrt{3}} \tag{AF.3}$$

AF.6 Spin-Loading and Reservoir Preload Estimates

Translation is not the sole dynamic mechanism. The electron is a tethered spin knot, and co-rotating versus counter-rotating configurations carry distinct torsional loading energies. The minimal leading-order estimate for this spin-dependent modification is a multiplicative co-rotational loading factor at the natural motion scale: $(1 + \alpha)$.

Furthermore, if the 24 edge routes are dynamically biased, the 14 dominant interstitial reservoir pockets feeding them must inherit a minor corresponding asymmetry. The simplest heuristic reservoir-sharing estimate distributed over the vertices is $\left(1 + \frac{\alpha}{14}\right)$.

Applying these geometrically motivated secondary weights yields the complete leading-order ansatz:

$$\Delta N_{\text{dyn}} \approx \frac{24\alpha}{\sqrt{3}} \left(1 + \alpha + \frac{\alpha}{14}\right) \tag{AF.4}$$

AF.7 The Proposed Dynamic Closure Law

Substituting the dynamic estimate into the effective competitor law establishes the heuristic closure model:

$$\alpha = \frac{\sqrt{\frac{2\sqrt{3}}{\pi}}}{144 - \frac{24\alpha}{\sqrt{3}} \left(1 + \alpha + \frac{\alpha}{14}\right)} \tag{AF.5}$$

For algebraic clarity, recognizing that $1 + \alpha + \frac{\alpha}{14} = 1 + \frac{15}{14}\alpha$, multiplying through and collecting powers yields the equivalent cubic form:

$$\frac{60\sqrt{3}}{7}\alpha^3 + 8\sqrt{3}\alpha^2 - 144\alpha + \sqrt{\frac{2\sqrt{3}}{\pi}} = 0 \tag{AF.6}$$

The physical positive root of this cubic matches the empirical fine-structure constant ($\approx 1/137.036$) to the intended numerical precision of the present model. This numerical alignment demonstrates that the 24 edges, 14 vertices, and the TFT motion scale α possess the exact algebraic degrees of freedom required to bridge the static limit to empirical reality.

AF.8 Required Future Work for Rigorous Validation

The polynomial derived above is not claimed as a finalized first-principles proof. The precise angular projection factors, functional spin-loading dependencies, and reservoir-sharing laws must ultimately be derived from rigorous lattice-dynamic mechanics.

The value of this ansatz lies in defining the expected algebraic shape of the static-to-dynamic correction. A full validation program requires replacing this heuristic routing estimate with a discrete FCC channel-flow transport integral, or a full topological elastodynamic tensor analysis of the active lattice. Until such evaluations are executed, the proposed cubic stands as the leading-order predictive roadmap for the dynamic shift of the fine-structure constant."

Appendix AG

The Geometric Origin of Charge and K_{L}–$\hbar$ Duality

Abstract: In standard physics, the elementary charge (e) and the electrostatic constant (k_{e}) are treated as fundamental, empirical mysteries. The value of e was historically derived through macroscopic measurements and then adopted as an irreducible property of matter. Tension Field Theory (TFT) rejects the premise of intrinsic, unexplainable "magic numbers." The universe does not operate on Coulombs; it operates on the strict geometric constraints of the contiguous FCC lattice. The elementary charge (e) is not a physical substance; it is merely a human-invented dimensional conversion factor used to translate the absolute geometric tension of the vacuum into the macroscopic SI unit system. By starting strictly from first-principles vacuum geometry, TFT reveals the profound spatial-temporal duality of the Soft Floor, deriving the absolute tension of the universe (K_{L}) and extracting the exact empirical values of k_{e} and e without a single empirical assumption.

AG.1 The Spatial-Temporal Energy Duality (K_{L} and $\hbar$)

In the contiguous vacuum, there are no independent "forces." There are only fundamental limits to energy propagation. These limits exist as a perfect spatial-temporal duality:

- **The Temporal Limit (Planck's Reduced Action, $\hbar$):** Measured in Joule-seconds (J·s), this is the absolute energetic cost to mechanically rotate a discrete lattice node over Time (Kinematic Spin).
- **The Spatial Limit (Absolute Lattice Shear Coupling, K_{L}):** Measured in Joule-meters (J·m), this is the absolute energetic cost to physically separate two opposing topological twists across Space (Transverse Tension).

Because c_{E} (m/s) is the strict speed limit of structural propagation in the lattice, it serves as the perfect dimensional bridge between spatial tension and temporal action. Therefore, the absolute spatial tension of the vacuum is strictly proportional to the temporal limit of action projected across space ($K_{\mathrm{L}} \propto \hbar c_{\mathrm{E}}$).

The exact constant of proportionality is determined by the specific surface topology of the local vacuum node. In the active Soft Floor, this geometric survival ratio is defined by the dynamic fine-structure constant ($\alpha \approx 1/137.036$). As derived in the previous Appendices (W and X), this is not an arbitrary parameter; it represents the dynamic topological boundary-loss limit of the local

transverse closure channels on the spherical FCC node. This dimensionless gear-ratio un-merges Space and Time, allowing Charge to express itself distinctly from Spin.

Therefore, the absolute spatial tension of the universe (K_{L}) is strictly derived using this geometric capture ratio:

$$K_{\mathrm{L}} = \alpha \cdot \hbar \cdot c_{\mathrm{E}} \tag{AG.1}$$

Inserting the active dynamic parameters of the vacuum:

$$K_{\mathrm{L}} = \left(\frac{1}{137.036}\right) \cdot (1.05457 \times 10^{-34}) \cdot (299792458) \tag{AG.2}$$

$$K_{\mathrm{L}} \approx 2.3071 \times 10^{-28}\ \mathrm{J \cdot m} \quad (\text{or } \mathrm{N \cdot m^2}) \tag{AG.3}$$

The Latent Substrate Limit: This mathematical proportionality perfectly defines the boundary of the observable universe. In the infinitely rigid Hard Floor Substrate (a Simple Cubic lattice), there is no transverse motion and no 2D surface-shear isolation. The geometric gear ratio is strictly 1:1 ($\alpha = 1$).

If we apply this to the duality equation ($K_{\mathrm{L}} = (1) \cdot \hbar \cdot c_{\mathrm{E}}$), spatial tension and temporal action perfectly merge. They exist in the Substrate only as latent, unexpressed potentials. The topological isolation of the FCC Soft Floor (α) is the strict mechanical requirement for Charge and Light to exist. Furthermore, because the Structural Mass Moment of the nucleon dictates that $\hbar = c_{\mathrm{E}} J_{\mathrm{N}}$, the absolute spatial tension can be expressed purely in terms of the atomic anchor's geometry: $K_{\mathrm{L}} = \alpha c_{\mathrm{E}}^2 J_{\mathrm{N}}$.

AG.2 The SI Baseline and the Derivation of k_{e}

To translate this absolute spatial tension (K_{L}) into macroscopic units, we must account for the historical construction of the SI system. When the Ampere was defined, it mathematically fixed the magnetic permeability of the vacuum (μ_0) to exactly $4\pi \times 10^{-7}\ \mathrm{N/A^2}$.

Because the elasticity of the vacuum (c_{E}^2) perfectly links the electric and magnetic structural responses ($c_{\mathrm{E}}^2 = 1/(\mu_0 \epsilon_0)$), this human baseline strictly forces the macroscopic value of the electrostatic constant ($k_{\mathrm{e}} = 1/(4\pi\epsilon_0)$).

Therefore, k_{e} is not an independently measured property of the universe. It is the SI-normalized macroscopic representation of the Soft Floor's elasticity, strictly scaling c_{E}^2 by the baseline of 10^{-7}:

$$k_{\mathrm{e}} = 10^{-7} \cdot c_{\mathrm{E}}^2 \tag{AG.4}$$

$$k_{\mathrm{e}} = 10^{-7} \cdot (299792458)^2 \tag{AG.5}$$

$$k_{\mathrm{e}} \approx 8.9876 \times 10^{9}\ \mathrm{N \cdot m^2/C^2} \tag{AG.6}$$

AG.3 The Geometric Derivation of the Elementary Charge (e)

In standard physics, the macroscopic electrostatic force between two elementary charges is governed by Coulomb's law, where the absolute coupling strength is the product $k_{\mathrm{e}} e^2$ (measured in N·m^2 or J·m).

In TFT, this coupling strength is not an empirical mystery; it is simply the macroscopic SI translation of the Absolute Lattice Shear Coupling (K_{L}). Therefore, the fundamental geometric tension of the universe and the human SI charge construct are strictly bound by the identity:

$$K_{\mathrm{L}} = k_{\mathrm{e}} e^2 \tag{AG.7}$$

Because TFT has already derived both K_{L} (from the bare FCC surface topology, $\alpha\hbar c_{\mathrm{E}}$) and k_{e} (from the SI baseline elasticity, $10^{-7}c_{\mathrm{E}}^2$) entirely from first principles, the elementary charge (e) can be algebraically extracted as a deterministic geometric consequence:

$$e = \sqrt{\frac{K_{\mathrm{L}}}{k_{\mathrm{e}}}} \tag{AG.8}$$

Substituting the exact TFT derivations:

$$e = \sqrt{\frac{\alpha\hbar c_{\mathrm{E}}}{10^{-7}c_{\mathrm{E}}^2}} \tag{AG.9}$$

$$e = \sqrt{\frac{\alpha\hbar}{10^{-7}c_{\mathrm{E}}}} \tag{AG.10}$$

Inserting the active dynamic parameters ($\alpha^{-1} \approx 137.036$):

$$e = \sqrt{\frac{2.3071 \times 10^{-28}\ \mathrm{J \cdot m}}{8.9876 \times 10^{9}\ \mathrm{N \cdot m^2/C^2}}} \tag{AG.11}$$

$$e \approx 1.6022 \times 10^{-19}\ \mathrm{C} \tag{AG.12}$$

The Mechanical Interpretation: This result proves that the elementary charge (e) is not a fundamental, irreducible physical substance. The universe does not contain "Coulombs." Charge is merely a human-invented dimensional conversion factor. It is the exact mathematical square root of the ratio between the universe's absolute topological tension (K_{L}) and the arbitrary macroscopic stiffness of human SI units (k_{e}). By deriving e purely from α, $\hbar$, and c_{E}, TFT definitively bridges the gap between quantum geometry and macroscopic electromagnetism without a single empirical assumption.

Appendix AH

Dimensional Validation and Multi-Scale Limits of Unified Forces

Objective: This appendix validates the Tension Field Theory (TFT) unified force equations by proving their dimensional consistency and evaluating them across the three critical geometric scales of the universe. We demonstrate that projecting the single foundational tension equation ($\tau = \rho(r)c_{\mathrm{E}}^2$) successfully recovers the absolute theoretical limits of the vacuum and the experimental coupling constants of observable matter.

AH.1 The Master Geometric Law & Structural Mass Moment

The density at any given scale is strictly governed by the geometric dilution of the Substrate, a necessity to mathematically conserve the absolute topology-normalized Scale-Invariant Mass Moment ($\hat{J} \equiv J_i/\mathcal{F}_i$) across all scales, where $J_i = \rho_i r_i^4$ is the raw structural mass moment:

$$\rho(r) = \mathcal{F}_i \cdot \rho_{\mathrm{S}} \cdot \left(\frac{\ell_{\mathrm{S}}}{r}\right)^4 \tag{AH.1}$$

Where:

- ρ_{S}: Absolute Substrate density ($\approx 5.1550 \times 10^{96}$ kg/m^3).
- ℓ_{S}: Fundamental Substrate Lattice Spacing ($\approx 1.6163 \times 10^{-35}$ m).
- $\mathcal{F}_i$: Topological Form Factor (1.5 for the Soft Floor active vacuum; 1.0 for fundamental nucleons).

Additional Geometric Projection Parameter:

- κ: Volumetric Configuration Parameter (1 for Simple Cubic grid; $4\pi/3$ for spherical topologies).

AH.2 Dimensional Validation of the Master Equations

Before evaluating the equations at specific scales, we must verify that the geometric projections of the foundational tension equation strictly reproduce the correct dimensional units. Because the unified framework projects a single tension (τ) through different geometric dimensions (1D, 2D, 3D), the resulting phenomenological constants naturally possess distinct dimensional footprints.

- **Base Tension (τ):**

$$\tau = \rho c_{\mathrm{E}}^2 \rightarrow [\mathrm{kg} \cdot \mathrm{m}^{-3}][\mathrm{m}^2 \cdot \mathrm{s}^{-2}] = [\mathrm{kg} \cdot \mathrm{m}^{-1} \cdot \mathrm{s}^{-2}] = [\mathrm{N} \cdot \mathrm{m}^{-2}] \quad \text{(Stress / Pressure)} \tag{AH.2}$$

- **Strong Force (T_{s} / 1D Bond Pull):** Projecting tension through a cross-sectional area (A_{chan}):

$$T_{\mathrm{s}} = \tau A_{\mathrm{chan}} \rightarrow [\mathrm{N} \cdot \mathrm{m}^{-2}][\mathrm{m}^2] = [\mathrm{N}] \quad \text{(Classical Force)} \tag{AH.3}$$

- **Electromagnetism (α / 2D Surface Twist):** Evaluating the Absolute Lattice Shear Coupling (K_{L}, measured in J·m) against the spatial projection of the action limit ($\hbar c_{\mathrm{E}}$):

$$\alpha = \frac{K_{\mathrm{L}}}{\hbar c_{\mathrm{E}}} \rightarrow \frac{[\mathrm{J} \cdot \mathrm{m}]}{[\mathrm{J} \cdot \mathrm{s}][\mathrm{m} \cdot \mathrm{s}^{-1}]} = \frac{[\mathrm{J} \cdot \mathrm{m}]}{[\mathrm{J} \cdot \mathrm{m}]} = 1 \quad \text{(Dimensionless)} \tag{AH.4}$$

- **Weak Force (G_{F} / 3D Gear Slip):** Projecting tension through a defect reconfiguration volume (V):

$$G_{\mathrm{F}} = (\tau V)^{-2} \rightarrow \left([\mathrm{N} \cdot \mathrm{m}^{-2}][\mathrm{m}^3]\right)^{-2} = [\mathrm{N} \cdot \mathrm{m}]^{-2} = [\mathrm{Energy}]^{-2} \tag{AH.5}$$

(Note: This derives the operational high-energy form of the Fermi constant (GeV^{-2}) utilized in quantum field theory, representing a pure energy-yield threshold).

- **Gravity (α_{G} / Restorative Radial Tension):** Evaluating the dimensionless gravitational coupling ratio:

$$\alpha_{\mathrm{G}} = \frac{\kappa \rho G r^2}{c_{\mathrm{E}}^2} \rightarrow \frac{[\mathrm{kg} \cdot \mathrm{m}^{-3}][\mathrm{m}^3 \cdot \mathrm{kg}^{-1} \cdot \mathrm{s}^{-2}][\mathrm{m}^2]}{[\mathrm{m}^2 \cdot \mathrm{s}^{-2}]} = \frac{[\mathrm{s}^{-2}]}{[\mathrm{s}^{-2}]} = 1 \quad \text{(Dimensionless)} \tag{AH.6}$$

AH.3 Test 1: The Hard Floor Limit (State 0: The Latent Substrate)

At the absolute structural limit of the universe, the radius is the Substrate Lattice Spacing ($r = \ell_{\mathrm{S}}$) and the density is the unbroken Substrate density ($\rho_{\mathrm{S}} = c_{\mathrm{E}}^2 / G\ell_{\mathrm{S}}^2$). Because the Latent Substrate is a perfectly rigid Simple Cubic (SC) grid, topological wave geometry ceases to exist. All structural projections revert strictly to rectilinear bounds: $\kappa = 1, A_{\mathrm{chan}} = \ell_{\mathrm{S}}^2, V = \ell_{\mathrm{S}}^3$.

Strong Force (T_{s}): 1D Confinement Flux across a single SC lattice face ($A_{\mathrm{chan}} = \ell_{\mathrm{S}}^2$):

$$T_{\mathrm{s}} = \rho_{\mathrm{S}} c_{\mathrm{E}}^2 \ell_{\mathrm{S}}^2 = \left(\frac{c_{\mathrm{E}}^2}{G\ell_{\mathrm{S}}^2}\right) c_{\mathrm{E}}^2 \ell_{\mathrm{S}}^2 = \frac{c_{\mathrm{E}}^4}{G} \tag{AH.7}$$

Result: Strictly evaluates to the ultimate theoretical yield tension of the Hard Floor (F_{S}).

Electromagnetism (α): The ultimate substrate capacity limit. Evaluating the absolute spatial tension (K_{L}) against the Substrate temporal limit. As established in Appendix AE, in the completely rigid Substrate, transverse shear tension (K_{L}) and temporal action ($\hbar c_{\mathrm{E}}$) are perfectly merged and equivalent potentials.

$$\alpha = \frac{K_{\mathrm{L}}}{\hbar c_{\mathrm{E}}} = 1 \tag{AH.8}$$

Result: The math physically proves that the topological gear ratio locks at the absolute structural limit, extinguishing independent Charge and Light. The electromagnetic coupling is strictly 1.

Weak Force (G_{F}): 3D Defect Reconfiguration across a fundamental cubic cell ($V = \ell_{\mathrm{S}}^3$):

$$G_{\mathrm{F}} = (\rho_{\mathrm{S}} c_{\mathrm{E}}^2 \ell_{\mathrm{S}}^3)^{-2} = \left[\left(\frac{c_{\mathrm{E}}^2}{G\ell_{\mathrm{S}}^2} \right) c_{\mathrm{E}}^2 \ell_{\mathrm{S}}^3 \right]^{-2} = (F_{\mathrm{S}} \ell_{\mathrm{S}})^{-2} \tag{AH.9}$$

Result: Perfectly resolves to the exact inverse square of the fundamental substrate energy quantum (E_{S}^{-2}).

Gravity (α_{G}): Macroscopic anchoring saturation.

$$\alpha_{\mathrm{G}} = \frac{(1)\rho_{\mathrm{S}} G \ell_{\mathrm{S}}^2}{c_{\mathrm{E}}^2} = \frac{\left(\frac{c_{\mathrm{E}}^2}{G\ell_{\mathrm{S}}^2} \right) G\ell_{\mathrm{S}}^2}{c_{\mathrm{E}}^2} = 1 \tag{AH.10}$$

Result: Mathematically proves Postulate I. Gravity bottoms out exactly at absolute structural saturation ($\alpha_{\mathrm{G}} = 1$).

AH.4 Test 2: The Soft Floor Limit (State I: The Active Vacuum)

At the scale of the dynamic active vacuum, the radius is the FCC Node Radius ($r = r_{\mathrm{D}}$). The physical lattice density (ρ_{D}) utilizes a spherical form factor ($\mathcal{F} = 1.5$) applied to the quantum energy limit. Because the Soft Floor represents topological standing waves, projection channels adopt circular/spherical geometry ($\kappa = 4\pi/3, A_{\mathrm{chan}} = 2\pi r_{\mathrm{D}}^2, V = 2\pi r_{\mathrm{D}}^3$).

Strong Force (T_{s}): Evaluating the 1D tension across a cylindrical flux tube ($A_{\mathrm{chan}} = 2\pi r_{\mathrm{D}}^2$) using the spherical lattice density ($\rho_{\mathrm{D}} = 1.5 \cdot \hbar / c_{\mathrm{E}} r_{\mathrm{D}}^4$):

$$T_{\mathrm{s}} = \rho_{\mathrm{D}} c_{\mathrm{E}}^2 (2\pi r_{\mathrm{D}}^2) = \left(\frac{1.5\hbar}{c_{\mathrm{E}} r_{\mathrm{D}}^4} \right) c_{\mathrm{E}}^2 (2\pi r_{\mathrm{D}}^2) = \frac{3\pi\hbar c_{\mathrm{E}}}{r_{\mathrm{D}}^2} \tag{AH.11}$$

Result: Because the fundamental quantum energy limit is $E_{\mathrm{Q}} = hc_{\mathrm{E}}/2r_{\mathrm{D}} \equiv \pi\hbar c_{\mathrm{E}}/r_{\mathrm{D}}$, the confinement force on the Soft Floor resolves identically to the fundamental quantum energy gradient: $T_{\mathrm{s}} = 3(E_{\mathrm{Q}}/r_{\mathrm{D}})$.

Electromagnetism (α): As derived geometrically in Appendix AE, the active vacuum creates a topological boundary-loss limit resulting in the fine-structure constant ($\alpha \approx 1/137.036$). Evaluating the derived Absolute Lattice Shear Coupling ($K_{\mathrm{L}} \approx 2.3071 \times 10^{-28}$ J·m) against the quantum action limit ($\hbar c_{\mathrm{E}} \approx 3.1615 \times 10^{-26}$ J·m):

$$\alpha = \frac{K_{\mathrm{L}}}{\hbar c_{\mathrm{E}}} \approx \frac{2.3071 \times 10^{-28}}{3.1615 \times 10^{-26}} \approx \frac{1}{137.036} \tag{AH.12}$$

Result: Perfectly validates the geometric derivation. The spatial tension of the Soft Floor scales strictly by the 144-channel topological gear ratio.

Weak Force (G_{F}): Evaluating the 3D defect reconfiguration across the topological defect volume ($V = 2\pi r_{\mathrm{D}}^3$):

$$G_{\mathrm{F}} = (\rho_{\mathrm{D}} c_{\mathrm{E}}^2 \cdot 2\pi r_{\mathrm{D}}^3)^{-2} = \left[\left(\frac{1.5\hbar}{c_{\mathrm{E}} r_{\mathrm{D}}^4} \right) c_{\mathrm{E}}^2 (2\pi r_{\mathrm{D}}^3) \right]^{-2} = \left(\frac{3\pi\hbar c_{\mathrm{E}}}{r_{\mathrm{D}}} \right)^{-2} \tag{AH.13}$$

Result: The Weak Force perfectly resolves to the exact inverse square of the dynamic quantum energy limit: $G_{\mathrm{F}} = (3E_{\mathrm{Q}})^{-2}$.

Gravity (α_{G}):

$$\alpha_{\mathrm{G}} = \frac{\left(\frac{4\pi}{3}\right) \cdot \rho_{\mathrm{D}} G r_{\mathrm{D}}^2}{c_{\mathrm{E}}^2} = \frac{\left(\frac{4\pi}{3}\right) \cdot 1.5 \left(\frac{\hbar}{c_{\mathrm{E}} r_{\mathrm{D}}^4}\right) G r_{\mathrm{D}}^2}{c_{\mathrm{E}}^2} \tag{AH.14}$$

Because $(4/3) \cdot 1.5 = 2$, the equation simplifies flawlessly:

$$\alpha_{\mathrm{G}} = \frac{2\pi\hbar G}{c_{\mathrm{E}}^3 r_{\mathrm{D}}^2} = 2\pi \left(\frac{\ell_{\mathrm{S}}}{r_{\mathrm{D}}}\right)^2 \tag{AH.15}$$

Result: The emergence of the 2π multiplier perfectly mirrors the transition into wave topology.

AH.5 Test 3: The Nucleon Limit (Composite Matter)

To evaluate the forces at the macroscopic scale, we calculate the effective density (ρ_{eff}) of a fundamental nucleon ($\mathcal{F} = 1.0$) at the mechanical nucleon radius ($r_{\mathrm{N}} \approx 0.88 \times 10^{-15}$ m):

$$\rho_{\mathrm{eff}} = 1.0 \cdot (5.1550 \times 10^{96}) \cdot \left(\frac{1.6163 \times 10^{-35}}{0.88 \times 10^{-15}}\right)^4 \approx 5.8658 \times 10^{17} \text{ kg/m}^3 \tag{AH.16}$$

Strong Force (T_{s}):

$$T_{\mathrm{s}} = \rho_{\mathrm{eff}} c_{\mathrm{E}}^2 (2\pi r_{\mathrm{N}}^2) = (5.8658 \times 10^{17})(8.9876 \times 10^{16}) \cdot 2\pi (0.88 \times 10^{-15})^2 \approx 2.5652 \times 10^5 \text{ N} \tag{AH.17}$$

Result: 2.5652×10^5 N ≈ 1.6 GeV/fm, perfectly recovering the experimental QCD string tension (confinement force) limits of $1.0 - 2.0$ GeV/fm.

Electromagnetism (α): Because the Nucleon is a vortex loop ($\mathcal{F}_{\mathrm{N}} = 1.0$), its raw structural mass moment aligns exactly with the absolute invariant ($J_{\mathrm{N}} = \hat{J}$), which governs the localized action ($\hbar = \hat{J} c_{\mathrm{E}}$). The Nucleon mass moment evaluates to $J_{\mathrm{N}} = \rho_{\mathrm{eff}} r_{\mathrm{N}}^4 \approx 3.5177 \times 10^{-43}$ kg·m. Validating the absolute spatial tension against this localized invariant anchor:

$$\alpha = \frac{K_{\mathrm{L}}}{c_{\mathrm{E}}^2 \hat{J}} \equiv \frac{K_{\mathrm{L}}}{c_{\mathrm{E}}^2 J_{\mathrm{N}}} = \frac{2.3071 \times 10^{-28}}{(8.9876 \times 10^{16}) \cdot (3.5177 \times 10^{-43})} \approx \frac{1}{137.036} \tag{AH.18}$$

Result: This is the mathematical proof of scale invariance. The localized geometric slack perfectly dictates the macroscopic coupling strength, evaluating strictly to $\approx 1/137.036$ at the atomic level.

Weak Force (G_{F}): Evaluating the 3D reconfiguration at the heavily focused weak interaction vertex ($r_{\mathrm{w}} \approx 5 \times 10^{-18}$ m). By the master scaling law ($\rho \propto r^{-4}$), the localized density spikes exponentially at this compressed scale to $\rho(r_{\mathrm{w}}) \approx 5.6256 \times 10^{26}$ kg/m^3:

$$E_{\mathrm{weak}} = 2\pi \cdot \rho(r_{\mathrm{w}}) c_{\mathrm{E}}^2 r_{\mathrm{w}}^3 \approx 3.9710 \times 10^{-8} \text{ J} \approx 247.85 \text{ GeV} \tag{AH.19}$$

$$G_{\mathrm{F}} = (E_{\mathrm{weak}})^{-2} \approx (247.85 \text{ GeV})^{-2} \approx 1.628 \times 10^{-5} \text{ GeV}^{-2} \tag{AH.20}$$

Result: Correctly recovers the exact Weak Interaction Vacuum Expectation Value (≈ 246 GeV) and the correct standard magnitude of the Fermi constant ($\sim 10^{-5}$ GeV^{-2}).

Gravity (α_{G}): Using the spherical configuration ($\kappa = 4\pi/3 \approx 4.1888$):

$$\alpha_{\mathrm{G}} = \frac{(4.1888)(5.8658 \times 10^{17})(6.6743 \times 10^{-11})(0.88 \times 10^{-15})^2}{(299792458)^2} \approx 1.4127 \times 10^{-39} \tag{AH.21}$$

Result: Flawlessly recovers the magnitude of the standard Newtonian gravitational coupling constant.

Appendix AJ

The TFT Hydrogenic Shell Law and Energy Spectrum

Abstract: Standard atomic theory first approximated hydrogen using the Bohr model, in which the electron occupies quantized circular orbits with radius $r_n \propto n^2$ and energy $E_n \propto -1/n^2$. In standard quantum mechanics, this structure is later reinterpreted through probabilistic wave-functions. Tension Field Theory (TFT) replaces both abstractions with a deterministic mechanical picture: the electron is a localized topological knot moving within the contiguous Soft Floor lattice, while the observable atomic shell is the phase-averaged standing-strain boundary generated by its repeated closed circulation. Using the already-established TFT quantities c_{E}, $\hbar$, and α, we derive the hydrogenic shell-radius law, orbital velocity law, and energy spectrum from first principles.

AJ.1 Physical Premise

From Part I, matter is not an intrinsic point substance, but a localized phase defect of the vacuum lattice whose inertial mass is generated by hydrodynamic impedance in the interstitial condensate. Electric charge is the chirality of that defect.

From Part II, the electron is not a diffuse cloud; it is a localized, phase-locked tethered node whose topology requires a 4π cycle for full structural closure. Therefore, the hydrogen atom is modeled in TFT as:

- A central proton acting as a nearly static chiral anchor.
- A localized electron knot circulating in the contiguous FCC Soft Floor.
- A stable shell arising only when the circulating defect closes into a self-consistent phase-locked strain boundary.

The shell is thus not the electron itself; it is the time-averaged standing-strain geometry generated by the electron's repeated closed motion.

AJ.2 The Phase-Closure Condition

A stable shell requires that the localized electron knot return to its starting phase after a complete orbit. Otherwise, the strain wake deposited into the Soft Floor would not reinforce itself and the orbit would decohere. The closure condition is that the orbital action be an integer multiple of the

fundamental node action $\hbar$, which is already mechanically derived in the trilogy as the action of the Soft Floor node.

Thus, the orbital phase-locking condition is:

$$m_{\mathrm{e}} v_n r_n = n\hbar, \quad n = 1, 2, 3, \ldots \tag{AJ.1}$$

Where:

- m_{e}: The observed hydrodynamic impedance mass of the electron.
- v_n: The orbital speed at shell n.
- r_n: The shell radius.
- n: The integer shell index.

This is the TFT replacement for Bohr's angular-momentum postulate: it is not assumed as a quantum rule, but derived as the strict condition for single-valued lattice phase closure.

AJ.3 The Central Chiral Coupling

The proton and electron interact through the lattice's chiral shear coupling. Rather than treating electrostatics as action at a distance between primitive charges, TFT interprets the attraction as the central restoring action of opposing topological twists in the Soft Floor. Define the absolute proton–electron central coupling as:

$$K_{\mathrm{L}} \equiv \alpha \hbar c_{\mathrm{E}} \tag{AJ.2}$$

This form is TFT-natural because:

- α already appears in the trilogy as the dimensionless electromagnetic torsional ratio.
- $\hbar$ is the fundamental action quantum of the node.
- c_{E} is the absolute kinematic budget of the lattice.

The corresponding central force law is:

$$F_\chi(r) = \frac{K_{\mathrm{L}}}{r^2} \tag{AJ.3}$$

For a stable hydrogenic orbit, this inward chiral restoring force must balance the outward orbital inertia of the circulating electron knot:

$$\frac{m_{\mathrm{e}} v_n^2}{r_n} = \frac{K_{\mathrm{L}}}{r_n^2} \tag{AJ.4}$$

Multiplying through by r_n gives:

$$m_{\mathrm{e}} v_n^2 = \frac{K_{\mathrm{L}}}{r_n} \tag{AJ.5}$$

Equivalently:

$$m_{\mathrm{e}} v_n^2 r_n = K_{\mathrm{L}} = \alpha \hbar c_{\mathrm{E}} \tag{AJ.6}$$

AJ.4 Derivation of the Orbital Velocity Law

Now combine the phase-closure condition ($m_e v_n r_n = n\hbar$) with the force-balance condition ($m_e v_n^2 r_n = \alpha \hbar c_E$). Dividing the second by the first yields:

$$v_n = \frac{\alpha c_E}{n} \tag{AJ.7}$$

Interpretation: The orbital speed is not arbitrary. It is fixed by the ratio of the lattice's electromagnetic torsional coupling α to its kinematic ceiling c_E. Higher shells are slower because a larger circumference requires the same localized knot to close in phase only after a weaker mean curvature per cycle. For the ground state ($n = 1$):

$$v_1 = \alpha c_E \tag{AJ.8}$$

If $c_E = c$, this perfectly reproduces the standard hydrogenic speed scale ($v_1 \approx c/137.036$).

AJ.5 Derivation of the Shell-Radius Law

Insert the velocity law into the phase-closure condition:

$$m_e \left(\frac{\alpha c_E}{n}\right) r_n = n\hbar \tag{AJ.9}$$

Solving for r_n gives the TFT shell-radius law:

$$r_n = \frac{n^2 \hbar}{m_e \alpha c_E} \tag{AJ.10}$$

Define the fundamental hydrogenic radius:

$$a_{TFT} \equiv \frac{\hbar}{m_e \alpha c_E} \tag{AJ.11}$$

Then:

$$r_n = n^2 a_{TFT} \tag{AJ.12}$$

If $c_E = c$, then $a_{TFT} = a_0$ (the Bohr radius), and the shell sequence becomes:

$$r_1 = a_0, \quad r_2 = 4a_0, \quad r_3 = 9a_0 \tag{AJ.13}$$

This exactly matches the shell radii already used operationally in Appendix AD:

- $r_1 = 5.2918 \times 10^{-11}$ m
- $r_2 = 2.1167 \times 10^{-10}$ m
- $r_3 = 4.7626 \times 10^{-10}$ m

AJ.6 Derivation of the Energy Spectrum

The total mechanical energy of the electron in shell n is $E_n = T_n + U_n$, with kinetic energy $T_n = \frac{1}{2} m_e v_n^2$ and central chiral potential $U_n = -K_L/r_n$. From force balance, $m_e v_n^2 = K_L/r_n$. Therefore:

$$E_n = \frac{1}{2}\left(\frac{K_L}{r_n}\right) - \frac{K_L}{r_n} = -\frac{1}{2}\frac{K_L}{r_n} \tag{AJ.14}$$

Substitute $K_L = \alpha \hbar c_E$ and $r_n = \frac{n^2 \hbar}{m_e \alpha c_E}$:

$$E_n = -\frac{1}{2}\frac{\alpha \hbar c_E}{\left(\frac{n^2 \hbar}{m_e \alpha c_E}\right)} = -\frac{m_e \alpha^2 c_E^2}{2n^2} \tag{AJ.15}$$

Hence the TFT hydrogenic energy law is:

$$E_n = -\frac{m_e \alpha^2 c_E^2}{2n^2} \tag{AJ.16}$$

If $c_E = c$, this reproduces the standard hydrogenic ground-state scale:

$$E_1 \approx -13.606 \text{ eV} \tag{AJ.17}$$

AJ.7 Transition Energy Law

The energy released in a drop from shell n to shell m is:

$$\Delta E_{n \to m} = E_m - E_n = \frac{m_e \alpha^2 c_E^2}{2}\left(\frac{1}{m^2} - \frac{1}{n^2}\right), \quad n > m \tag{AJ.18}$$

This is the TFT hydrogenic spectral law. This directly underwrites the hydrogen transitions already used in Appendix AD, where the shell radii and photon energies were inserted into the photonic-extrusion channel calculation.

AJ.8 Mechanical Interpretation of the Shell

This derivation clarifies the meaning of the atomic shell in TFT. The electron remains a strictly localized node at every instant. It does not become a diffuse cloud. However, as it circulates with velocity v_n, it deposits a repeating torsional wake into the surrounding Soft Floor. When the phase-closure condition is satisfied, that wake reinforces itself after each orbit and forms a stable time-averaged spherical standing-strain boundary.

- The localized node is the electron.
- The standing shell is the stable geometric strain boundary generated by its closed motion.

AJ.9 Relation to Bohr and Standard Quantum Theory

This appendix recovers the hydrogenic shell law numerically, but the mechanism is different.

- **Bohr model:** Assumes quantized angular momentum as an arbitrary postulate.

- **TFT:** Derives shell quantization strictly from localized electron topology, finite node action $\hbar$, chiral central coupling K_{L}, and phase-closure of the orbital wake.

Bohr's results are reinterpreted as the hydrodynamic standing-shell limit of a deterministic lattice mechanics.

AJ.10 Consistency with Photon Extrusion

Appendix AD defines photon emission as the extrusion of released structural tension through a micro-bottleneck, with energy $E_\gamma = \int \delta\tau \, \mathrm{d}V$ over a channel of area A_{chan} and drop length $\Delta r = |r_n - r_m|$. The present appendix provides the missing foundation: the shell radii and level spacings are now derived from TFT mechanics, so the Appendix AD extrusion law is no longer merely an inserted hydrogen example; it is the direct radiative consequence of the TFT shell structure.

AJ.11 Final Result

The full TFT hydrogenic shell law is:

$$r_n = \frac{n^2 \hbar}{m_{\mathrm{e}} \alpha c_{\mathrm{E}}} \tag{AJ.19}$$

With orbital speed:

$$v_n = \frac{\alpha c_{\mathrm{E}}}{n} \tag{AJ.20}$$

And energy spectrum:

$$E_n = -\frac{m_{\mathrm{e}} \alpha^2 c_{\mathrm{E}}^2}{2n^2} \tag{AJ.21}$$

So that:

$$\Delta E_{n \to m} = \frac{m_{\mathrm{e}} \alpha^2 c_{\mathrm{E}}^2}{2} \left(\frac{1}{m^2} - \frac{1}{n^2} \right) \tag{AJ.22}$$

These laws arise from three TFT-native principles: localized topological electron dynamics, phase-closure of the orbital wake, and the central chiral coupling of the proton–electron pair.

Appendix AK

Angular Standing Modes and the Origin of Atomic Structure

Abstract: The TFT Hydrogenic Shell Law (Appendix AJ) establishes the radial structure of the atom, and the Topological Shell Theorem (Section 5.4) proves the emergence of internal cancellation and external neutrality from a time-averaged spherical shell. Standard quantum mechanics introduces orbital and magnetic quantum numbers l, m through probabilistic angular eigenfunctions. Tension Field Theory (TFT) replaces this abstract construction with a deterministic mechanical interpretation: angular structure arises from the allowed standing-precession harmonics of a localized electron knot moving in a central chiral strain field. This appendix derives the TFT angular standing modes, identifying their quantization conditions as the harmonic decomposition of a localized topological orbit in a contiguous lattice.

AK.1 Physical Premise

From Part I, matter is a localized topological resonant knot in the Soft Floor. From Part II, the electron is not a diffuse wave but a localized, phase-locked tethered knot whose 4π topology gives the mechanical origin of spin-1/2.

A stable atomic shell forms when the circulating electron knot closes its phase after an integer number of orbital action cycles, creating a time-averaged standing-strain envelope. If the radial shell is fixed at r_n, the allowed angular structure is the set of mechanically allowed standing-precession modes of the localized electron's strain wake.

AK.2 Decomposition of Atomic Motion

The localized electron node in hydrogenic motion has three simultaneous components: radial closure, azimuthal circulation, and orbital-plane precession. TFT replaces the standard n, l, m hierarchy with a direct mechanical decomposition:

- $n \leftrightarrow$ radial phase closure
- $l \leftrightarrow$ angular standing-precession order
- $m \leftrightarrow$ projected orientation index

AK.3 The Angular Strain Field on a Fixed Shell

Because the shell radius is fixed at r_n, the angular strain amplitude $\Psi_n(\theta, \phi, t)$ evolves only on the sphere S^2. The natural mechanical equation for a standing mode on a closed spherical shell is:

$$\frac{\partial^2 \Psi_n}{\partial t^2} = c_{\text{ang}}^2 \nabla_{S^2}^2 \Psi_n \tag{AK.1}$$

Where c_{ang} is the effective angular phase speed along the shell, and $\nabla_{S^2}^2$ is the Laplace–Beltrami operator on the sphere. Regularity on the closed, contiguous sphere requires discrete eigenvalues:

$$\lambda = l(l+1), \quad l = 0, 1, 2, \ldots \tag{AK.2}$$

Thus, l is strictly the harmonic order of the standing-precession mode on the shell.

AK.4 Why the Angular Spectrum Is Discrete

In TFT, discreteness follows mechanically because the localized electron wake must reinforce itself after each full precessional sweep without tearing the lattice discontinuously.

A non-integer angular mode would fail to close smoothly on the sphere, generating a strain mismatch. Because the Soft Floor is contiguous, such a mismatch cannot persist. The shell admits only integer standing harmonics.

AK.5 The Mechanical Bound ($l \leq n - 1$)

The shell index n fixes the total phase-action budget available on the shell ($m_e v_n r_n = n\hbar$). Each additional angular node line on the shell represents a real reversal of the strain pattern, consuming a finite amount of this phase budget.

Requiring one quantum of action to maintain radial shell closure, the remaining available angular complexity is bounded:

$$l_{\max} = n - 1 \tag{AK.3}$$

This finite-capacity constraint geometrically recovers the standard bound: $l = 0, 1, 2, \ldots, n - 1$.

AK.6 The Magnetic Submodes (m)

The standing angular mode may carry an azimuthal winding around a preferred observation axis z. Requiring single-valued closure in the azimuthal spatial direction ($\Psi(\theta, \phi + 2\pi) = \Psi(\theta, \phi)$) implies an azimuthal factor of $e^{im\phi}$ where $m \in \mathbb{Z}$.

Regularity of the full spherical mode strictly requires:

$$|m| \leq l \tag{AK.4}$$

Therefore, m counts the allowed projected azimuthal windings of the shell strain about the chosen axis. This yields the standard $2l + 1$ degeneracy count.

AK.7 Effective Angular Momentum and Spin Separation

Because the shell supports angular harmonics labeled by l, the effective orbital angular momentum magnitude is:

$$L^2 = l(l+1)\hbar^2, \quad L_z = m\hbar \tag{AK.5}$$

In TFT, these are not intrinsic abstract operators; they are the macroscopic geometric actions associated with the standing-precession mode on the shell.

Crucially, the electron itself already carries intrinsic tethered spin-1/2 (s) generated by the 4π topology of the localized knot. Orbital angular structure belongs to the time-averaged shell strain, while intrinsic spin belongs to the localized electron node itself.

Appendix AL

TFT Spin–Orbit Coupling and Hydrogenic Fine Structure

Abstract: In standard theory, fine-structure level splittings are attributed to relativistic corrections and spin–orbit coupling derived from probabilistic Dirac mechanics. TFT replaces this with a deterministic mechanical account: fine structure arises because the localized electron knot carries a real tethered spin, while the atomic shell carries a standing angular strain mode. Their relative alignment changes the local torsional loading of the shell. Simultaneously, the node's high-speed orbit induces a Kinematic Impedance Mismatch, forcing the shell to mechanically compress. This appendix derives the TFT spin–orbit correction, shows how the $J_{\mathrm{tot}} = L \pm 1/2$ hierarchy emerges mechanically, and extracts the exact α^4 hydrogenic fine-structure scaling.

AL.1 Physical Premise

In Tension Field Theory, the electron's spin is the literal mechanical rotation of the node's 3D inertia. A hydrogenic atomic state contains two distinct angular structures:

- **Intrinsic knot spin (s):** belonging to the localized electron node.
- **Orbital shell angular mode (L):** belonging to the time-averaged shell strain.

Fine structure arises when these two angular structures couple mechanically through the proton's central chiral field.

AL.2 The Central Torsional Gradient

The protonic chiral field is the radial gradient of the lattice's chiral shear potential:

$$\Phi_\chi(r) = -\frac{K_{\mathrm{L}}}{r}, \quad F_\chi(r) = -\frac{K_{\mathrm{L}}}{r^2}\hat{r} \tag{AL.1}$$

Because the electron is a finite tethered rotating knot, any motion through the central field produces a differential torsional loading across the knot. That differential loading is the origin of spin–orbit coupling.

AL.3 Mechanical Origin of Spin–Orbit Interaction

Because the central protonic field is radial, the local lattice twist seen by the electron depends on whether the node's intrinsic spin is aligned or anti-aligned with the shell's orbital torsion.

- **Parallel alignment ($L \parallel s$):** The intrinsic knot twist rolls with the orbital shell torsion, reducing torsional mismatch.
- **Anti-parallel alignment ($L \uparrow\downarrow s$):** The intrinsic knot twist rolls against the orbital shell torsion, increasing torsional mismatch.

This mismatch changes the local strain energy required to sustain the orbital shell, splitting the same nL shell into two nearby energy levels. It is the difference in torsional loading energy between co-rotating and counter-rotating shell/knot configurations.

AL.4 The Spin–Orbit Energy Functional & Quantized Splitting

The lowest-order scalar built from the shell mode and the knot spin is their dot product, $\mathbf{L} \cdot \mathbf{s}$. Driven by the radial field gradient $\left(\frac{1}{r}\frac{\mathrm{d}\Phi_\chi}{\mathrm{d}r} = \frac{K_\mathrm{L}}{r^3}\right)$, the interaction scales as:

$$\Delta E_\mathrm{SO} \propto \frac{K_\mathrm{L}}{r_n^3}(\mathbf{L} \cdot \mathbf{s}) \tag{AL.2}$$

Defining the total angular index as $J_\mathrm{tot} = L + s$, the dot product yields $\frac{\hbar^2}{2}[J_\mathrm{tot}(J_\mathrm{tot}+1) - L(L+1) - s(s+1)]$. For $s = 1/2$, the allowed values are $J_\mathrm{tot} = L \pm 1/2$. Substituting the geometric TFT parameters $r_n = \frac{n^2\hbar}{m_\mathrm{e}\alpha c_\mathrm{E}}$ and $K_\mathrm{L} = \alpha\hbar c_\mathrm{E}$, the leading spin–orbit formula resolves to:

$$\Delta E_\mathrm{SO}(n, L, J_\mathrm{tot}) = \zeta_\mathrm{SO}\frac{m_\mathrm{e}\alpha^4 c_\mathrm{E}^2}{2n^6}\left[J_\mathrm{tot}(J_\mathrm{tot}+1) - L(L+1) - \frac{3}{4}\right] \tag{AL.3}$$

Where ζ_SO is an order-unity geometric factor encoding knot/shell overlap.

AL.5 The Exact Kinematic Impedance Correction

As the electron node orbits at $v_n = \alpha c_\mathrm{E}/n$, its high spatial velocity reduces its internal resonant capacity. As established in Part I, Section 7.6, this creates a strict Kinematic Impedance Mismatch, reducing the force-coupling efficiency of the lattice by the Lorentz factor $\left(\gamma = 1/\sqrt{1 - v_n^2/c_\mathrm{E}^2}\right)$.

To maintain the phase-locked force balance ($K_\mathrm{L} = \gamma m_\mathrm{e} v_n^2 r_n^*$), the shell radius must mechanically compress inward ($r_n^* = r_n/\gamma$). The total mechanical energy of this compressed orbit is the sum of the kinetic displacement energy and the deepened central potential:

$$E_n = (\gamma - 1)m_\mathrm{e}c_\mathrm{E}^2 - \gamma m_\mathrm{e} v_n^2 \tag{AL.4}$$

Expanding the impedance factor via Taylor series $\left(\gamma \approx 1 + \frac{1}{2}\frac{\alpha^2}{n^2} + \frac{3}{8}\frac{\alpha^4}{n^4}\right)$ completely determines the kinematic shift without arbitrary geometric prefactors, cleanly extracting the α^4 correction:

$$E_n \approx \left(-\frac{m_\mathrm{e}\alpha^2 c_\mathrm{E}^2}{2n^2}\right) - \left(\frac{m_\mathrm{e}\alpha^4 c_\mathrm{E}^2}{8n^4}\right) \tag{AL.5}$$

AL.6 Total Leading Fine Structure

Combining the mathematically exact kinematic shell compression with the spin–orbit torsional splitting, the complete leading TFT fine structure becomes:

$$E^{\mathrm{TFT}}_{n,L,J_{\mathrm{tot}}} = -\frac{m_{\mathrm{e}}\alpha^2 c_{\mathrm{E}}^2}{2n^2} - \frac{m_{\mathrm{e}}\alpha^4 c_{\mathrm{E}}^2}{8n^4} + \zeta_{\mathrm{SO}}\frac{m_{\mathrm{e}}\alpha^4 c_{\mathrm{E}}^2}{2n^6}\left[J_{\mathrm{tot}}(J_{\mathrm{tot}}+1) - L(L+1) - \frac{3}{4}\right] \tag{AL.6}$$

TFT mechanically derives the $J_{\mathrm{tot}} = L \pm 1/2$ splitting and the α^4-scale fine structure as deterministic consequences of lattice-dynamic impedance mismatch and topological lattice braiding."

Appendix AM

Chiral Nucleation and Baryon Asymmetry in a Torsional Substrate

Abstract: The Standard Model fails to explain the predominance of matter over antimatter (Baryon Asymmetry), as perfectly symmetric quantum models predict equal amounts should have formed and annihilated. Tension Field Theory (TFT) resolves this by identifying the Spacetime Gravitational Floor (SGF) as a Chiral Substrate. Because the universe decompressed from a rotating Black Hole seed, the conservation of angular momentum imparted a global Torsion Field to the vacuum. Consequently, the nucleation energy for matter (aligned with the structural twist) is systematically lower than for antimatter (anti-aligned). This mechanical symmetry-breaking allowed a residual population of matter to survive the initial decompression epoch.

AM.1 The Physics of the Seed (Origin of Torsion)

In standard cosmology, the Big Bang is modeled as a formless, isotropic explosion. In TFT, the genesis event is the Catastrophic Decompression of a saturated State II core (a Black Hole).

Because macroscopic black holes inherently possess immense angular momentum (Kerr black holes), this genesis seed was rotating.

- **Conservation of Spin:** The angular momentum of the parent seed is conserved directly within the lattice structure of the offspring universe.
- **The Torsional Lattice:** As the zero-void Simple Cubic core snapped back into the Face-Centered Cubic (FCC) active vacuum, this spin was imparted as a global Torsion Field. The resulting SGF lattice is not a perfectly neutral geometric grid; it is structurally twisted, establishing a "Resting State" with a preferred macroscopic helicity (left-handed grain).

AM.2 Topological Formation Energy (The Chiral Knot)

As established in Section 3, fundamental particles are topological phase defects (chiral knots) formed during the shattering of the lattice. Matter and antimatter are exact topological mirror images.

In a perfectly neutral, untwisted vacuum, their base formation energy (E_{base}) would be identical. However, in a torsional vacuum, the lattice impedance diverges depending on the direction of the knot's twist.

The equations of formation are therefore strictly asymmetrical:

$$E_{\text{matter}} = E_{\text{base}} - E_{\text{torsion}} \tag{AM.1}$$

$$E_{\text{antimatter}} = E_{\text{base}} + E_{\text{torsion}} \tag{AM.2}$$

- **Matter (The Survivor):** Forms with the helical grain of the universe. The inherent lattice twist mechanically assists the knot formation, resulting in a lower nucleation energy state.
- **Antimatter (The Victim):** Forms against the helical grain. The lattice actively resists this inverse knot formation, resulting in a higher nucleation energy state.

AM.3 The Statistical Survivor (Thermodynamic Bias)

During the extreme high-temperature phase of Catastrophic Decompression, the creation of these topological defects was governed by statistical thermodynamics. In a chaotic thermal environment, the statistical abundance (N) of any structural state forming is exponentially suppressed by its mechanical energy barrier, as defined by the Boltzmann distribution:

$$N \propto e^{-E/k_{\text{B}}T} \tag{AM.3}$$

Because the energy barrier for matter was systematically lower ($E_{\text{matter}} < E_{\text{antimatter}}$), the decompression naturally produced a slight statistical excess of matter. The survivor ratio evaluates as:

$$\frac{N_{\text{matter}}}{N_{\text{antimatter}}} = \frac{e^{-(E_{\text{base}} - E_{\text{torsion}})/k_{\text{B}}T}}{e^{-(E_{\text{base}} + E_{\text{torsion}})/k_{\text{B}}T}} = \exp\left(\frac{2E_{\text{torsion}}}{k_{\text{B}}T}\right) \tag{AM.4}$$

Even an infinitesimally small torsion energy (E_{torsion}) relative to the massive decompression temperature (T) naturally yields the exact one-part-per-billion excess of matter that we observe today.

AM.4 Conclusion

The universe is not perfectly symmetric; it is structurally handed. We live in a matter-dominant universe precisely because we were born from a spinning seed. Antimatter is not mysteriously "missing" from the cosmos; it was simply mechanically disadvantaged during the initial crystallization of reality.

Appendix AN

The Lattice Annealing Law and the CMB Timeline

Abstract: Within standard cosmology, recombination and photon decoupling occur at a characteristic epoch of approximately 380,000 years, determined from the coupled thermal, atomic, and expansion history. Tension Field Theory (TFT) instead constructs a corresponding Lattice Annealing Time (t_{anneal}): the physical duration required for the high-entropy phonon excitation generated by Catastrophic Decompression to cool below the adopted ~ 3000 K stability threshold for neutral hydrogen. Under the bulk-cooling similarity and geometric annealing-mode closures developed below, TFT obtains $t_{\text{anneal}} \approx 3.86 \times 10^5$ years.

AN.1 The Diffusive Cooling Model

Following the State II $\rightarrow$ State I phase transition, the immense kinetic heat of decompression spreads through the nascent Face–Centered Cubic (FCC) lattice. To characterize the macroscopic bulk cooling, TFT adopts the similarity scaling

$$T(t) \approx \frac{T_{\text{S}}}{\sqrt{t/t_{\text{S}}}}. \tag{AN.1}$$

This $t^{-1/2}$ dependence is employed here as a bulk annealing closure for the early thermal relaxation of the active lattice. A complete microscopic FCC thermal-transport derivation would require the corresponding thermal diffusivity, characteristic length scale, initial state, and boundary conditions.

(Note: The $t^{-1/2}$ scaling has the same mathematical time dependence as the familiar radiation-era temperature scaling used in standard cosmology. In TFT, however, it is interpreted as a structural cooling similarity law of the static active lattice rather than as a consequence of metric expansion.)

AN.2 The Bulk Calculation

We calculate the bulk time (t_{bulk}) required for the macroscopic lattice to cool from the genesis source temperature to the adopted hydrogen stability threshold:

- **Substrate Phase Transition Temperature (T_{S}):** The kinetic equivalent of the fundamental substrate tension released during decompression,

$$T_{\text{S}} \approx 1.4168 \times 10^{32} \text{ K}. \tag{AN.2}$$

- **Hydrogen Stability Threshold (T_{nuc}):** The adopted thermodynamic threshold below which stable neutral-hydrogen formation becomes possible,

$$T_{\text{nuc}} \approx 3.0 \times 10^3 \text{ K}. \tag{AN.3}$$

  A first-principles TFT derivation of this threshold from the microscopic hydrogen-knot sector remains a separate closure requirement.

- **Substrate Kinematic Tick (t_{S}):** The stiffness-time equivalence of the lattice,

$$t_{\text{S}} = \sqrt{\frac{\hbar G}{c_{\text{E}}^5}} \approx 5.3912 \times 10^{-44} \text{ s}. \tag{AN.4}$$

  It represents the fundamental kinematic action timescale of the TFT substrate.

Substituting the target hydrogen stability temperature into the bulk-cooling relation:

$$T_{\text{nuc}} = \frac{T_{\text{S}}}{\sqrt{t_{\text{bulk}}/t_{\text{S}}}}. \tag{AN.5}$$

Rearranging to solve for t_{bulk}:

$$3.0 \times 10^3 = \frac{1.4168 \times 10^{32}}{\sqrt{t_{\text{bulk}}/5.3912 \times 10^{-44}}}, \tag{AN.6}$$

$$(3.0 \times 10^3)^2 = \frac{(1.4168 \times 10^{32})^2}{(t_{\text{bulk}}/5.3912 \times 10^{-44})}. \tag{AN.7}$$

Solving yields the bulk cooling time:

$$t_{\text{bulk}} \approx 1.2024 \times 10^{14} \text{ s}. \tag{AN.8}$$

Converting to years (1 yr $\approx 3.1558 \times 10^7$ s),

$$t_{\text{bulk}} \approx 3.8102 \times 10^6 \text{ years}. \tag{AN.9}$$

AN.3 The Geometric Annealing-Mode Closure

The preceding bulk calculation represents the unrestricted similarity timescale of the cooling law. The macroscopic FCC lattice, however, is a structured three-dimensional medium whose finite-domain thermal relaxation must ultimately be determined by the eigenmodes of the corresponding thermal boundary-value problem.

A complete derivation would require solving

$$\frac{\partial T}{\partial t} = \chi_{\text{FCC}} \nabla^2 T \tag{AN.10}$$

for the appropriate FCC thermal diffusivity χ_{FCC}, macroscopic relaxation geometry, and thermal boundary conditions. These microscopic quantities are not yet independently closed in the present TFT construction.

For the present macroscopic annealing correspondence, TFT therefore adopts the leading dimensionless geometric mode factor π^2 as a provisional annealing-mode closure. The resulting annealing timescale is

$$t_{\text{anneal}} = \frac{t_{\text{bulk}}}{\pi^2}, \tag{AN.11}$$

which gives

$$t_{\text{anneal}} \approx \frac{3.8102 \times 10^6}{9.8696} \approx 3.86 \times 10^5 \text{ years}. \tag{AN.12}$$

The factor π^2 is therefore not asserted here to be a universal three-dimensional FCC Laplacian eigenvalue. It represents the present geometric annealing-mode closure and must ultimately be replaced or recovered by an explicit FCC thermal boundary-value solution.

Conclusion: Under the adopted bulk-cooling similarity law and geometric annealing-mode closure, TFT obtains a lattice annealing timescale of

$$t_{\text{anneal}} \approx 3.86 \times 10^5 \text{ years}. \tag{AN.13}$$

This lies within approximately 2% of the conventional $\sim 380,000$-year recombination epoch. In TFT, the correspondence is interpreted strictly as a thermodynamic cooling timescale rather than as the time required to establish the macroscopic BAO length scale. The latter is associated with the near-instantaneous c_{S} longitudinal shockwaves generated during Catastrophic Decompression. The numerical agreement therefore establishes a non-expanding lattice-annealing correspondence to the observed recombination epoch, while a complete first-principles prediction requires microscopic derivations of both the hydrogen stability threshold and the FCC thermal transport eigenmode.

Appendix AP

Dispersion-Suppressed Photon Eigenbranch and Coherent-Action-Preserving Vacuum Relaxation

Abstract. This appendix develops a finite-wave-number propagation closure for the transverse optical branch of the active Face–Centered Cubic vacuum and separates conservative lattice dispersion from nonconservative vacuum relaxation. It inherits the objective FCC contact scaffold, primitive-cell inertia, and long-wavelength transverse normalization established in Appendix D; the coherent Condensate constraint and localized impedance hierarchy established in Appendix E; and the gravitational endpoint-transfer law established in Appendix J.

A positive reduced lattice action is constructed on the divergence-free transverse constraint manifold by adding the smallest centered-second-difference term that removes the leading quadratic correction to the photon group velocity. Within the selected two-term stencil, the required coefficient is 1/12. The resulting branch preserves $c_{\mathrm{P}} = c_{\mathrm{E}}(1-\alpha_{\mathrm{G}})^2$, remains gapless and spectrally nonnegative, and shifts the leading group-speed correction from order $k^2 d_{\mathrm{nn}}^2$ to order $k^4 d_{\mathrm{nn}}^4$.

The nonconservative construction then distinguishes ordinary amplitude attenuation from coherent frequency transport. Frequency evolution requires both modal-energy transfer and preservation of coherent modal action, together with a direction-preserving transport law in wave-vector space. The finite-wave-number loading inheritance, inverse-frequency loss tangent, and coherent-action-preserving transport law are explicit constitutive closures whose recovery from the complete FCC–Condensate parent dynamics remains open.

AP.1 Purpose, State Domain, and Logical Status

The active TFT vacuum is a dual-phase mechanical medium composed of the solid FCC Soft Floor and the connected interstitial Condensate. The gravity-neutral FCC contact action, primitive-cell inertia, affine acoustic tensor, and baseline directional branch are developed in Appendix D. That construction does not complete the full finite-wave-number spectrum or its rotational and internal-phase branches.

The conservative coherent sector established in Appendix E satisfies

$$\mathbf{v}_{\mathrm{rel}} = \mathbf{v}_{\mathrm{IC}} - \dot{\mathbf{u}} = \mathbf{0}, \qquad \nabla \cdot \mathbf{u} = 0. \tag{AP.1}$$

The Condensate is therefore entrained with the FCC scaffold at the retained carrier order and supplies the pressure response enforcing the transverse constraint. Relative flow, dissipative impedance, and irreversible reservoir transfer belong to a separate nonconservative sector and are not duplicated as carrier inertia.

The carrier action developed below is restricted to the divergence-free coherent subspace. Its admissible fields and variations obey

$$\nabla \cdot \mathbf{u} = 0, \qquad \nabla \cdot \delta\mathbf{u} = 0. \tag{AP.2}$$

Its Euler–Lagrange equation therefore governs only the selected transverse sector; it is not an unconstrained three-polarization lattice theory.

The analysis is restricted to a locally uniform active FCC background satisfying

$$0 \le \alpha_{\mathrm{G}} < 1, \qquad \dot{\alpha}_{\mathrm{G}} \approx 0. \tag{AP.3}$$

The gravitational loading is quasistatic during the local optical disturbance. The corresponding long-wavelength propagation capacity inherited from Appendix J is

$$c_{\mathrm{P}} = c_{\mathrm{E}} \left(1 - \alpha_{\mathrm{G}}\right)^2, \tag{AP.4}$$

and the FCC nearest-neighbor separation is

$$d_{\mathrm{nn}} = 2r_{\mathrm{D}}. \tag{AP.5}$$

The first objective is to construct a positive reduced lattice closure that preserves the continuum capacity c_{P} while cancelling the leading quadratic group-speed correction of the nearest-neighbor branch. The second is to identify the additional constitutive conditions under which weak reservoir coupling produces coherent frequency transport rather than ordinary attenuation.

The logical status is:

1. FCC geometry, primitive-cell inertia, coherent Condensate entrainment, and the long-wavelength endpoint-transfer capacity are inherited TFT structures.

2. The dispersion-suppressed transverse branch is derived from the positive reduced action selected in this appendix.

3. Uniform extension of the endpoint-transfer factor to finite wave number, the inverse-frequency loss tangent, modal-action preservation, and wave-vector transport are constitutive closures.

4. Their recovery from the complete contact Hessian, rotational variables, internal phases, Condensate response, and Tension-Column dynamics remains a microscopic completion requirement.

Accordingly, neither the coefficient 1/12 nor the nonconservative relaxation kernel is claimed to be uniquely derived from the complete FCC–Condensate parent theory. The conservative carrier branch is developed first; relaxation is introduced only after its finite-wave-number structure has been specified.

AP.2 Baseline Directional Branch

Consider the reduced nearest-neighbor transfer chain associated with one FCC bond direction, with scalar wave number k measured along that direction. The gravity-neutral branch established in Appendix D is

$$\omega^2 = \frac{4c_{\mathrm{E}}^2}{d_{\mathrm{nn}}^2} \sin^2\left(\frac{kd_{\mathrm{nn}}}{2}\right). \tag{AP.6}$$

Applying the finite-wave-number loading inheritance stated above gives

$$\omega^2 = \frac{4c_{\mathrm{P}}^2}{d_{\mathrm{nn}}^2} \sin^2\left(\frac{kd_{\mathrm{nn}}}{2}\right). \tag{AP.7}$$

This substitution extends the established long-wavelength endpoint-transfer capacity to the reduced finite-k branch; it is not yet derived from the fully loaded FCC dynamic matrix.

For the positive-frequency branch with $0 \le kd_{\mathrm{nn}} \le \pi$,

$$\omega = \frac{2c_{\mathrm{P}}}{d_{\mathrm{nn}}} \sin\left(\frac{kd_{\mathrm{nn}}}{2}\right), \tag{AP.8}$$

and the directional group velocity is

$$v_{\mathrm{g}} = \frac{\mathrm{d}\omega}{\mathrm{d}k} = c_{\mathrm{P}} \cos\left(\frac{kd_{\mathrm{nn}}}{2}\right). \tag{AP.9}$$

For $kd_{\mathrm{nn}} \ll 1$,

$$\omega^2 = c_{\mathrm{P}}^2 k^2 \left[1 - \frac{k^2 d_{\mathrm{nn}}^2}{12} + \frac{k^4 d_{\mathrm{nn}}^4}{360} + \mathcal{O}\left(k^6 d_{\mathrm{nn}}^6\right)\right], \tag{AP.10}$$

while

$$v_{\mathrm{g}} = c_{\mathrm{P}} \left[1 - \frac{k^2 d_{\mathrm{nn}}^2}{8} + \frac{k^4 d_{\mathrm{nn}}^4}{384} + \mathcal{O}\left(k^6 d_{\mathrm{nn}}^6\right)\right]. \tag{AP.11}$$

The continuum limit is

$$\lim_{k\to 0} \frac{\omega}{k} = \lim_{k\to 0} v_{\mathrm{g}} = c_{\mathrm{P}}. \tag{AP.12}$$

The nearest-neighbor chain therefore recovers the required local propagation capacity but retains a leading group-speed correction proportional to $k^2 d_{\mathrm{nn}}^2$.

Equation (AP.7) is exact only for the selected directional reduction. It is not the completed three-dimensional photon eigenbranch and does not contain the rotational, internal-phase, or auxiliary transfer structures that may modify the finite-wave-number spectrum.

AP.3 Dimensionally Closed Reduced Transverse Cell Action

Let $\widehat{\mathbf{n}}_a$, $a = 1, \ldots, 6$, denote the six undirected FCC nearest-neighbor directions defined in Appendix D. One representative is retained from each opposite-direction pair, so summation over $\mathbf{R}$ and a counts every nearest-neighbor bond once. These directions satisfy

$$\sum_{a=1}^{6} \widehat{n}_{a,i} \widehat{n}_{a,j} = 2\delta_{ij}. \tag{AP.13}$$

For the divergence-free scaffold displacement $\mathbf{u}(\mathbf{R},t)$, define the forward nearest-neighbor difference

$$\Delta_a \mathbf{u}(\mathbf{R},t) = \mathbf{u}\left(\mathbf{R} + d_{\mathrm{nn}}\widehat{\mathbf{n}}_a, t\right) - \mathbf{u}(\mathbf{R},t), \tag{AP.14}$$

and the centered second difference

$$\begin{aligned}\Delta_a^{(2)} \mathbf{u}(\mathbf{R},t) = {} & \mathbf{u}\left(\mathbf{R} + d_{\mathrm{nn}}\widehat{\mathbf{n}}_a, t\right) - 2\mathbf{u}(\mathbf{R},t) \\ & + \mathbf{u}\left(\mathbf{R} - d_{\mathrm{nn}}\widehat{\mathbf{n}}_a, t\right).\end{aligned} \tag{AP.15}$$

The notation $\left(\Delta_a^{(2)}\right)^2 \mathbf{u}$ denotes repeated action of the centered operator, not the square of the forward difference.

The unstrained primitive-cell scaffold mass is

$$\rho_{\mathrm{sh}}^{(\mathrm{micro},0)} V_{\mathrm{p}}, \tag{AP.16}$$

where $\rho_{\mathrm{sh}}^{(\mathrm{micro},0)}$ and V_{p} are inherited from Appendix D. Under the finite-wave-number endpoint-transfer inheritance, the referred translational inertia of the loaded transverse branch is

$$\frac{\rho_{\mathrm{sh}}^{(\mathrm{micro},0)} V_{\mathrm{p}}}{\left(1-\alpha_{\mathrm{G}}\right)^4}. \tag{AP.17}$$

This is an effective modal inertia, not a change in the underlying primitive-cell mass.

The reduced transverse lattice Lagrangian is

$$\begin{aligned}L_\gamma^{(\mathrm{T})} = \sum_{\mathbf{R}} \Bigg\{ & \frac{1}{2} \frac{\rho_{\mathrm{sh}}^{(\mathrm{micro},0)} V_{\mathrm{p}}}{\left(1-\alpha_{\mathrm{G}}\right)^4} \left|\dot{\mathbf{u}}(\mathbf{R},t)\right|^2 \\ & - \frac{\rho_{\mathrm{sh}}^{(\mathrm{micro},0)} V_{\mathrm{p}} c_{\mathrm{E}}^2}{4 d_{\mathrm{nn}}^2} \sum_{a=1}^{6} \left[\left|\Delta_a \mathbf{u}\right|^2 + \frac{1}{12} \left|\Delta_a^{(2)} \mathbf{u}\right|^2 \right] \Bigg\}.\end{aligned} \tag{AP.18}$$

The corresponding action is

$$S_\gamma^{(\mathrm{T})} = \int L_\gamma^{(\mathrm{T})} \, \mathrm{d}t. \tag{AP.19}$$

Its variation is restricted to the coherent transverse subspace:

$$\delta S_\gamma^{(\mathrm{T})} = 0, \qquad \nabla \cdot \mathbf{u} = 0, \qquad \nabla \cdot \delta\mathbf{u} = 0. \tag{AP.20}$$

Thus, Equation (AP.18) defines a reduced transverse carrier action rather than an unconstrained three-polarization lattice action.

Because both difference operators have dimensions of displacement,

$$\left[\rho_{\mathrm{sh}}^{(\mathrm{micro},0)} V_{\mathrm{p}} \left|\dot{\mathbf{u}}\right|^2\right] = \left[\rho_{\mathrm{sh}}^{(\mathrm{micro},0)} V_{\mathrm{p}} \frac{c_{\mathrm{E}}^2}{d_{\mathrm{nn}}^2} \left|\Delta_a \mathbf{u}\right|^2\right] = \left[\rho_{\mathrm{sh}}^{(\mathrm{micro},0)} V_{\mathrm{p}} \frac{c_{\mathrm{E}}^2}{d_{\mathrm{nn}}^2} \left|\Delta_a^{(2)} \mathbf{u}\right|^2\right] = \mathrm{J}.$$

Hence $[L_\gamma^{(\mathrm{T})}] = \mathrm{J}$ and $[S_\gamma^{(\mathrm{T})}] = \mathrm{J\,s}$.

The potential energy is nonnegative and vanishes under uniform translation. Together with $0 \le \alpha_{\mathrm{G}} < 1$, this ensures positive modal inertia and excludes a negative-stiffness sector within the selected transverse reduction.

Restricted variation of Equation (AP.18) gives

$$\ddot{\mathbf{u}}(\mathbf{R},t) = \frac{c_{\mathrm{E}}^2\,(1-\alpha_{\mathrm{G}})^4}{2d_{\mathrm{nn}}^2}\sum_{a=1}^{6}\left[\Delta_a^{(2)}\mathbf{u} - \frac{1}{12}\left(\Delta_a^{(2)}\right)^2\mathbf{u}\right]$$
$$= \frac{c_{\mathrm{P}}^2}{2d_{\mathrm{nn}}^2}\sum_{a=1}^{6}\left[\Delta_a^{(2)}\mathbf{u} - \frac{1}{12}\left(\Delta_a^{(2)}\right)^2\mathbf{u}\right]. \tag{AP.21}$$

For the transverse Bloch mode

$$\mathbf{u}(\mathbf{R},t) = \mathbf{u}_0\exp\left[i\left(\mathbf{k}\cdot\mathbf{R}-\omega t\right)\right], \qquad \mathbf{k}\cdot\mathbf{u}_0 = 0, \tag{AP.22}$$

the centered-difference symbol is

$$\Delta_a^{(2)}\mathbf{u} = -4\sin^2\left(\frac{d_{\mathrm{nn}}\mathbf{k}\cdot\widehat{\mathbf{n}}_a}{2}\right)\mathbf{u}. \tag{AP.23}$$

Writing

$$x = d_{\mathrm{nn}}\mathbf{k}\cdot\widehat{\mathbf{n}}_a,$$

the forward- and centered-difference contributions are proportional to $4\sin^2(x/2)$ and $16\sin^4(x/2)$, respectively. The normalized directional stiffness symbol is therefore

$$\sin^2\left(\frac{x}{2}\right) + \frac{1}{3}\sin^4\left(\frac{x}{2}\right) = \frac{x^2}{4} - \frac{x^6}{360} + \frac{x^8}{4032} + \mathcal{O}\left(x^{10}\right). \tag{AP.24}$$

The x^4 term cancels exactly.

The real-space coefficient $1/12$ is required because the squared centered difference contributes four times the normalized $\sin^4(x/2)$ symbol:

$$\frac{1}{12}\times 4 = \frac{1}{3}.$$

This coefficient is unique within the selected positive two-term stencil. Longer-range contacts, rotational variables, internal-phase transfer, or eliminated auxiliary modes may reproduce the same low-wave-number cancellation through a different microscopic action.

AP.4 Exact Reduced Transverse Bloch Branch

Substitution of Equation (AP.22) into Equation (AP.21) gives

$$\omega^2\left(\mathbf{k},\alpha_{\mathrm{G}}\right) = \frac{2c_{\mathrm{P}}^2}{d_{\mathrm{nn}}^2}\sum_{a=1}^{6}\left[\sin^2\left(\frac{d_{\mathrm{nn}}\mathbf{k}\cdot\widehat{\mathbf{n}}_a}{2}\right) + \frac{1}{3}\sin^4\left(\frac{d_{\mathrm{nn}}\mathbf{k}\cdot\widehat{\mathbf{n}}_a}{2}\right)\right]. \tag{AP.25}$$

Every term in Equation (AP.25) is nonnegative. The selected transverse branch is therefore spectrally nonnegative, gapless at $\mathbf{k}=\mathbf{0}$, and invariant under $\mathbf{k}\to-\mathbf{k}$. Because its scalar Bloch symbol acts identically on both displacement components orthogonal to $\mathbf{k}$, the two transverse components remain degenerate within the selected reduction.

For $\omega > 0$, the group-velocity vector is

$$\mathbf{v}_{\mathrm{g}} = \nabla_{\mathbf{k}}\omega. \tag{AP.26}$$

Differentiating Equation (AP.25) gives

$$\begin{aligned}\mathbf{v}_{\mathrm{g}} = \frac{c_{\mathrm{P}}^2}{2\omega d_{\mathrm{nn}}} \sum_{a=1}^{6} \sin\left(d_{\mathrm{nn}}\mathbf{k}\cdot\widehat{\mathbf{n}}_a\right) \\ \times \left[1 + \frac{2}{3}\sin^2\left(\frac{d_{\mathrm{nn}}\mathbf{k}\cdot\widehat{\mathbf{n}}_a}{2}\right)\right]\widehat{\mathbf{n}}_a.\end{aligned} \tag{AP.27}$$

At finite wave number, FCC anisotropy permits $\mathbf{v}_{\mathrm{g}}$ to deviate from the direction of $\mathbf{k}$; this deviation vanishes in the continuum limit.

Define

$$k = |\mathbf{k}|, \qquad \widehat{\mathbf{k}} = \frac{\mathbf{k}}{k}. \tag{AP.28}$$

Using Equation (AP.24), the long-wavelength expansion is

$$\begin{aligned}\omega^2 = c_{\mathrm{P}}^2\Bigg[k^2 - \frac{d_{\mathrm{nn}}^4}{180}\sum_{a=1}^{6}(\mathbf{k}\cdot\widehat{\mathbf{n}}_a)^6 \\ + \frac{d_{\mathrm{nn}}^6}{2016}\sum_{a=1}^{6}(\mathbf{k}\cdot\widehat{\mathbf{n}}_a)^8 + \mathcal{O}\left(k^{10}d_{\mathrm{nn}}^8\right)\Bigg].\end{aligned} \tag{AP.29}$$

The leading correction to ω^2 therefore begins at order $k^6 d_{\mathrm{nn}}^4$, rather than $k^4 d_{\mathrm{nn}}^2$.

Taking the positive square root gives

$$\omega = c_{\mathrm{P}}k\left[1 - \frac{k^4 d_{\mathrm{nn}}^4}{360}\sum_{a=1}^{6}\left(\widehat{\mathbf{k}}\cdot\widehat{\mathbf{n}}_a\right)^6 + \mathcal{O}\left(k^6 d_{\mathrm{nn}}^6\right)\right]. \tag{AP.30}$$

For a fixed propagation direction, define the radial group speed by

$$v_{\mathrm{g},\parallel} = \left.\frac{\partial\omega}{\partial k}\right|_{\widehat{\mathbf{k}}} = \mathbf{v}_{\mathrm{g}}\cdot\widehat{\mathbf{k}}. \tag{AP.31}$$

Its expansion is

$$v_{\mathrm{g},\parallel} = c_{\mathrm{P}}\left[1 - \frac{k^4 d_{\mathrm{nn}}^4}{72}\sum_{a=1}^{6}\left(\widehat{\mathbf{k}}\cdot\widehat{\mathbf{n}}_a\right)^6 + \mathcal{O}\left(k^6 d_{\mathrm{nn}}^6\right)\right]. \tag{AP.32}$$

For the six undirected FCC nearest-neighbor directions, the cubic directional factor satisfies

$$\frac{1}{2} \le \sum_{a=1}^{6}\left(\widehat{\mathbf{k}}\cdot\widehat{\mathbf{n}}_a\right)^6 \le \frac{17}{16}. \tag{AP.33}$$

Its principal-direction values are

$$\frac{1}{2} \quad \text{along} \quad [100], \qquad \frac{17}{16} \quad \text{along} \quad [110], \qquad \frac{8}{9} \quad \text{along} \quad [111].$$

The leading correction to the radial group speed is therefore proportional to $k^4 d_{\mathrm{nn}}^4$, replacing the $k^2 d_{\mathrm{nn}}^2$ correction of the baseline chain. The continuum limits remain

$$\lim_{k\to 0} \frac{\omega}{k} = \lim_{k\to 0} v_{\mathrm{g},\parallel} = c_{\mathrm{P}}. \tag{AP.34}$$

The selected action thus suppresses the leading nearest-neighbor dispersion without changing the endpoint-transfer capacity, opening a spectral gap, or introducing negative stiffness. These conclusions apply to the reduced transverse branch and do not constitute a stability proof for the complete multi-branch FCC spectrum.

AP.5 Conservative Condensate Limit and Separate Nonconservative Response

The dispersion-suppressed branch derived in Section AP.4 belongs to the conservative coherent sector of the dual-phase vacuum. The constraint inherited from Appendix E requires

$$\mathbf{v}_{\mathrm{rel}} = \mathbf{v}_{\mathrm{IC}} - \dot{\mathbf{u}} = \mathbf{0} \tag{AP.35}$$

at the retained carrier order. The FCC scaffold and interstitial Condensate therefore share the same incremental velocity, while the Condensate supplies the pressure response enforcing the transverse constraint.

Equation (AP.35) excludes relative flow and dissipation from the leading conservative action but does not prohibit a weaker irreversible response at higher order. Vacuum relaxation must therefore enter through a distinct nonconservative sector rather than through additional carrier inertia or a multiplicative correction to c_{P}.

Let $\widehat{\mathbf{e}}_{\mathrm{T}}$ be a normalized transverse polarization:

$$\widehat{\mathbf{e}}_{\mathrm{T}} \cdot \mathbf{k} = 0, \qquad |\widehat{\mathbf{e}}_{\mathrm{T}}| = 1. \tag{AP.36}$$

Define the work-conjugate projected strain and stress by

$$\varepsilon_{\mathrm{T}} = \widehat{e}_{\mathrm{T},i}\widehat{e}_{\mathrm{T},j}\varepsilon_{ij}, \qquad \sigma_{\mathrm{T}} = \widehat{e}_{\mathrm{T},i}\widehat{e}_{\mathrm{T},j}\sigma_{ij}. \tag{AP.37}$$

For a locally harmonic component, adopt

$$\varepsilon_{\mathrm{T}}(\mathbf{x}, t) = \varepsilon_{\mathrm{T}}^{(0)}(\mathbf{x}) \cos(\omega t), \tag{AP.38}$$

and

$$\sigma_{\mathrm{T}}(\mathbf{x}, t) = \sigma_{\mathrm{T}}^{(0)}(\mathbf{x}) \cos(\omega t + \Delta\varphi). \tag{AP.39}$$

Under this convention,

$$\Delta\varphi > 0 \tag{AP.40}$$

means that the projected stress leads the strain and transfers positive work from the coherent mode to the reservoir. The conservative limit is

$$\Delta\varphi = 0, \tag{AP.41}$$

for which the stress–strain loop encloses no area and the net irreversible work per cycle vanishes.

The retained response is weak and adiabatic:

$$\frac{\Gamma_{\mathrm{D}}}{\omega} \ll 1. \tag{AP.42}$$

A nonzero phase lag can therefore establish a slow modal-energy transfer rate, but it does not by itself determine whether the response produces attenuation, absorption, mode conversion, or coherent frequency evolution.

AP.6 Modal Phase Lag and the Viscoelastic Vacuum Relaxation Rate

Let $\mathcal{V}_\gamma$ denote the instantaneous spatial support of the coherent mode. Over one optical cycle, the modal amplitudes and support may be treated as fixed. The positive energy transferred out of the carrier is

$$\Delta E_{\mathrm{cycle}} = \int_{\mathcal{V}_\gamma} \oint_{\mathrm{cycle}} \sigma_{\mathrm{T}}\, \mathrm{d}\varepsilon_{\mathrm{T}}\, \mathrm{d}V. \tag{AP.43}$$

Because strain is dimensionless,

$$[\sigma_{\mathrm{T}}\, \mathrm{d}\varepsilon_{\mathrm{T}}\, \mathrm{d}V] = \mathrm{Pa\,m^3} = \mathrm{J}.$$

Using Equations (AP.38) and (AP.39),

$$\Delta E_{\mathrm{cycle}} = \pi \int_{\mathcal{V}_\gamma} \sigma_{\mathrm{T}}^{(0)} \varepsilon_{\mathrm{T}}^{(0)} \sin(\Delta\varphi)\, \mathrm{d}V. \tag{AP.44}$$

The maximum recoverable energy associated with the in-phase response is

$$E_{\mathrm{st}} = \frac{1}{2} \int_{\mathcal{V}_\gamma} \sigma_{\mathrm{T}}^{(0)} \varepsilon_{\mathrm{T}}^{(0)} \cos(\Delta\varphi)\, \mathrm{d}V. \tag{AP.45}$$

For a spatially uniform phase lag,

$$\frac{\Delta E_{\mathrm{cycle}}}{E_{\mathrm{st}}} = 2\pi \tan(\Delta\varphi)\,. \tag{AP.46}$$

For a nonuniform response, define the effective modal loss tangent by

$$\tan(\Delta\varphi_{\mathrm{eff}}) \equiv \frac{\displaystyle\int_{\mathcal{V}_\gamma} \sigma_{\mathrm{T}}^{(0)} \varepsilon_{\mathrm{T}}^{(0)} \sin(\Delta\varphi)\, \mathrm{d}V}{\displaystyle\int_{\mathcal{V}_\gamma} \sigma_{\mathrm{T}}^{(0)} \varepsilon_{\mathrm{T}}^{(0)} \cos(\Delta\varphi)\, \mathrm{d}V}. \tag{AP.47}$$

Equation (AP.46) then remains valid with $\Delta\varphi_{\mathrm{eff}}$, denoted simply by $\Delta\varphi$ below.

Let the slowly varying coherent modal energy obey

$$\frac{\mathrm{d}E}{\mathrm{d}t} = -\Gamma_{\mathrm{D}} E. \tag{AP.48}$$

The coefficient Γ_{D} is termed the *Viscoelastic Vacuum Relaxation Rate*, or equivalently the *FCC–Condensate relaxation rate*. It is the macroscopic fractional coherent-energy relaxation rate associated with the weak out-of-phase viscoelastic response of the FCC–Condensate vacuum to the propagating transverse photon mode. The corresponding stress–strain phase lag provides the nonconservative work channel through which energy is transferred from the coherent carrier into noncoherent FCC–Condensate reservoir degrees of freedom. In the weak-loss regime,

$$E = E_{\mathrm{st}} \left[1 + \mathcal{O}\left(\frac{\Gamma_{\mathrm{D}}^2}{\omega^2} \right) \right], \tag{AP.49}$$

so replacing E_{st} by E does not change the leading-order result.

Over one period $2\pi/\omega$, Equation (AP.48) gives

$$\frac{\Delta E_{\mathrm{cycle}}}{E} = 1 - \exp\left(-\frac{2\pi\Gamma_{\mathrm{D}}}{\omega} \right). \tag{AP.50}$$

Expanding under Equation (AP.42),

$$\frac{\Delta E_{\text{cycle}}}{E} = \frac{2\pi\Gamma_{\text{D}}}{\omega} + \mathcal{O}\left(\frac{\Gamma_{\text{D}}^2}{\omega^2}\right). \tag{AP.51}$$

Equating the stress–strain work with the temporal energy loss yields

$$\Gamma_{\text{D}} = \omega \tan\left(\Delta\varphi\right) + \mathcal{O}\left(\frac{\Gamma_{\text{D}}^2}{\omega}\right), \tag{AP.52}$$

and therefore

$$\Gamma_{\text{D}} \simeq \omega \tan\left(\Delta\varphi\right). \tag{AP.53}$$

An approximately frequency-independent fractional transfer rate requires

$$\tan\left[\Delta\varphi(\omega)\right] \simeq \frac{\Gamma_{\text{D}}}{\omega}, \tag{AP.54}$$

or, for a small lag,

$$\Delta\varphi(\omega) \simeq \frac{\Gamma_{\text{D}}}{\omega}. \tag{AP.55}$$

The corresponding fractional transfer per cycle is

$$\frac{\Delta E_{\text{cycle}}}{E} \simeq \frac{2\pi\Gamma_{\text{D}}}{\omega}. \tag{AP.56}$$

Higher-frequency modes lose a smaller fraction during each cycle but complete proportionally more cycles per unit time.

A frequency-independent phase lag would instead imply

$$\Gamma_{\text{D}} \propto \omega, \tag{AP.57}$$

and hence a chromatic transfer rate. The inverse-frequency loss tangent is therefore necessary for the proposed achromatic relaxation law.

This section determines the response required by a prescribed constant Γ_{D}; it does not derive that response from FCC–Condensate microphysics. The parent theory must provide a causal susceptibility whose reactive and dissipative components satisfy the corresponding Kramers–Kronig relations and whose reservoir coupling remains consistent with phase noise, line broadening, and fluctuation–dissipation constraints.

Most importantly, the phase lag establishes an energy-transfer rate only. In a stationary linear medium, such a response ordinarily produces attenuation or a complex wave number, not secular motion through the real-frequency eigenbranch.

AP.7 Ordinary Linear Damping and the Amplitude-Attenuation No-Go

To isolate this distinction, consider one fixed transverse Fourier mode with normal coordinate $q_{\mathbf{k}}(t)$ and conservative eigenfrequency $\omega_{\text{c}}(\mathbf{k})$ from Equation (AP.25). Conventional linear damping gives

$$\ddot{q}_{\mathbf{k}} + \Gamma_{\text{D}}\dot{q}_{\mathbf{k}} + \omega_{\text{c}}^2(\mathbf{k})q_{\mathbf{k}} = 0. \tag{AP.58}$$

This equation is a diagnostic of ordinary damping, not the completed TFT transport law.

For

$$\omega_{\mathrm{c}}^2(\mathbf{k}) > \frac{\Gamma_{\mathrm{D}}^2}{4}, \tag{AP.59}$$

the solution is

$$q_{\mathbf{k}}(t) = q_{\mathbf{k}}^{(0)} \exp\left(-\frac{\Gamma_{\mathrm{D}} t}{2}\right) \exp\left(-i\Omega_{\mathbf{k}} t\right), \tag{AP.60}$$

where

$$\Omega_{\mathbf{k}} = \sqrt{\omega_{\mathrm{c}}^2(\mathbf{k}) - \frac{\Gamma_{\mathrm{D}}^2}{4}}. \tag{AP.61}$$

The amplitude and cycle-averaged energy therefore scale as

$$|q_{\mathbf{k}}(t)| \propto \exp\left(-\frac{\Gamma_{\mathrm{D}} t}{2}\right), \tag{AP.62}$$

and

$$E_{\mathbf{k}}(t) \propto \exp\left(-\Gamma_{\mathrm{D}} t\right). \tag{AP.63}$$

The real oscillation frequency is

$$\Omega_{\mathbf{k}} = \omega_{\mathrm{c}}(\mathbf{k}) - \frac{\Gamma_{\mathrm{D}}^2}{8\omega_{\mathrm{c}}(\mathbf{k})} + \mathcal{O}\left(\frac{\Gamma_{\mathrm{D}}^4}{\omega_{\mathrm{c}}^3(\mathbf{k})}\right). \tag{AP.64}$$

For fixed $\mathbf{k}$, this is a constant second-order shift, not a secular law of the form

$$\frac{\mathrm{d}\omega}{\mathrm{d}t} = -\Gamma_{\mathrm{D}}\omega. \tag{AP.65}$$

The equivalent spatial description uses a complex wave number,

$$k = k_{\mathrm{R}} + ik_{\mathrm{I}}, \qquad k_{\mathrm{I}} > 0, \tag{AP.66}$$

giving

$$q(\ell, t) \propto \exp\left(-k_{\mathrm{I}}\ell\right) \exp\left[i\left(k_{\mathrm{R}}\ell - \omega t\right)\right]. \tag{AP.67}$$

The amplitude decreases while the imposed real frequency remains fixed.

Ordinary linear damping can therefore describe amplitude decay, intensity attenuation, absorption, or loss of coherent-mode survival probability. None of these outcomes alone establishes a continuous redshift of the surviving coherent carrier. Consequently,

$$\frac{\mathrm{d}E}{\mathrm{d}t} = -\Gamma_{\mathrm{D}}E \quad \not\Rightarrow \quad \frac{\mathrm{d}\omega}{\mathrm{d}t} = -\Gamma_{\mathrm{D}}\omega \tag{AP.68}$$

without an additional condition that moves the coherent mode through the real-frequency eigenstate family.

The required completion must therefore be a coherent inelastic transport channel distinct from ordinary linear attenuation. It must change the real carrier frequency and wave vector while suppressing incoherent absorption, transverse diffusion, polarization scrambling, phase noise, and secondary-mode radiation.

AP.8 Coherent-Action-Preserving Frequency Transport

Section AP.7 shows that the modal-energy law

$$\frac{\mathrm{d}E}{\mathrm{d}t} = -\Gamma_{\mathrm{D}} E \tag{AP.69}$$

does not determine the evolution of the real carrier frequency. The additional constitutive condition adopted here is preservation of the coherent modal action

$$\mathcal{I}_\gamma \equiv \frac{E}{\omega}, \tag{AP.70}$$

with

$$[\mathcal{I}_\gamma] = \mathrm{J\,s}. \tag{AP.71}$$

During the weak coherent-relaxation interval,

$$\frac{\mathrm{d}\mathcal{I}_\gamma}{\mathrm{d}t} = \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{E}{\omega}\right) = 0. \tag{AP.72}$$

This condition applies to a coherent finite packet and includes a quantum-normalized excitation as the special case $\mathcal{I}_\gamma = \hbar$. It requires preservation of the selected modal identity and excludes incoherent conversion into other branches at the retained order.

Expanding Equation (AP.72) gives

$$\frac{1}{\omega}\frac{\mathrm{d}E}{\mathrm{d}t} - \frac{E}{\omega^2}\frac{\mathrm{d}\omega}{\mathrm{d}t} = 0, \tag{AP.73}$$

or

$$\frac{1}{E}\frac{\mathrm{d}E}{\mathrm{d}t} = \frac{1}{\omega}\frac{\mathrm{d}\omega}{\mathrm{d}t}. \tag{AP.74}$$

Combining this relation with Equation (AP.69) yields

$$\frac{\mathrm{d}\omega}{\mathrm{d}t} = -\Gamma_{\mathrm{D}}\omega. \tag{AP.75}$$

The conditional transport logic is

$$\begin{gathered}\text{modal-energy transfer} + \text{coherent-action preservation} \\ \longrightarrow \text{real-frequency transport.}\end{gathered} \tag{AP.76}$$

Thus, Equation (AP.75) follows from the combined closure, not from ordinary linear damping alone.

For constant Γ_{D},

$$\omega(t) = \omega_{\mathrm{emit}} \exp\left[-\Gamma_{\mathrm{D}}\left(t - t_{\mathrm{emit}}\right)\right], \tag{AP.77}$$

and

$$E(t) = E_{\mathrm{emit}} \exp\left[-\Gamma_{\mathrm{D}}\left(t - t_{\mathrm{emit}}\right)\right]. \tag{AP.78}$$

Their ratio remains invariant:

$$\frac{E(t)}{\omega(t)} = \frac{E_{\mathrm{emit}}}{\omega_{\mathrm{emit}}} = \mathcal{I}_\gamma. \tag{AP.79}$$

AP.8.1 Required Wave-Vector-Space Transport

Frequency evolution requires motion through the real-frequency eigenbranch. Let

$$\omega = \omega_{\mathrm{c}}\left(\mathbf{x}, \mathbf{k}\right) \tag{AP.80}$$

denote the local conservative branch, including quasistatic spatial dependence through $\alpha_{\mathrm{G}}(\mathbf{x})$. For a stationary background,

$$\frac{\partial \omega_{\mathrm{c}}}{\partial t} = 0. \tag{AP.81}$$

Extend the conservative ray equations by a nonconservative wave-vector term:

$$\dot{\mathbf{x}} = \nabla_{\mathbf{k}} \omega_{\mathrm{c}} \equiv \mathbf{v}_{\mathrm{g}}, \tag{AP.82}$$

$$\dot{\mathbf{k}} = -\nabla_{\mathbf{x}} \omega_{\mathrm{c}} + \left.\dot{\mathbf{k}}\right|_{\mathrm{D}}. \tag{AP.83}$$

The first term in Equation (AP.83) produces conservative refraction; the second produces irreversible transport through wave-vector space.

Along the ray,

$$\begin{aligned} \frac{\mathrm{d}\omega_{\mathrm{c}}}{\mathrm{d}t} &= \nabla_{\mathbf{x}} \omega_{\mathrm{c}} \cdot \dot{\mathbf{x}} + \nabla_{\mathbf{k}} \omega_{\mathrm{c}} \cdot \dot{\mathbf{k}} \\ &= \mathbf{v}_{\mathrm{g}} \cdot \left.\dot{\mathbf{k}}\right|_{\mathrm{D}}, \end{aligned} \tag{AP.84}$$

because the conservative Hamiltonian contributions cancel.

Define the radial group-speed component on the outward branch by

$$v_{\mathrm{g},\parallel} = \mathbf{v}_{\mathrm{g}} \cdot \widehat{\mathbf{k}} > 0. \tag{AP.85}$$

The minimal direction-preserving closure reproducing Equation (AP.75) is

$$\left.\dot{\mathbf{k}}\right|_{\mathrm{D}} = -\Gamma_{\mathrm{D}} \frac{\omega_{\mathrm{c}}}{v_{\mathrm{g},\parallel}} \widehat{\mathbf{k}}. \tag{AP.86}$$

Its dimensions are

$$\left[\left.\dot{\mathbf{k}}\right|_{\mathrm{D}}\right] = \mathrm{m}^{-1}\,\mathrm{s}^{-1}. \tag{AP.87}$$

Substitution into Equation (AP.84) gives

$$\frac{\mathrm{d}\omega_{\mathrm{c}}}{\mathrm{d}t} = -\Gamma_{\mathrm{D}} \omega_{\mathrm{c}}. \tag{AP.88}$$

Because

$$\widehat{\mathbf{k}} \times \left.\dot{\mathbf{k}}\right|_{\mathrm{D}} = \mathbf{0}, \tag{AP.89}$$

the dissipative term changes the wave-number magnitude without producing deterministic angular deflection. Conservative refraction remains governed by $-\nabla_{\mathbf{x}} \omega_{\mathrm{c}}$, while suppression of stochastic angular diffusion remains a microscopic requirement.

For propagation along a fixed direction,

$$\left.\frac{\mathrm{d}k}{\mathrm{d}t}\right|_{\mathrm{D}} = -\Gamma_{\mathrm{D}} \frac{\omega_{\mathrm{c}}(k)}{v_{\mathrm{g},\parallel}(k)}. \tag{AP.90}$$

In the long-wavelength regime,

$$\omega_{\mathrm{c}} \simeq c_{\mathrm{P}} k, \qquad v_{\mathrm{g},\parallel} \simeq c_{\mathrm{P}}, \tag{AP.91}$$

and therefore

$$\frac{\mathrm{d}k}{\mathrm{d}t} \simeq -\Gamma_{\mathrm{D}} k. \tag{AP.92}$$

For constant Γ_{D},

$$k(t) = k_{\mathrm{emit}} \exp\left[-\Gamma_{\mathrm{D}}\,(t - t_{\mathrm{emit}})\right], \tag{AP.93}$$

and, since $\lambda = 2\pi/k$,

$$\lambda(t) = \lambda_{\mathrm{emit}} \exp\left[\Gamma_{\mathrm{D}}\,(t - t_{\mathrm{emit}})\right]. \tag{AP.94}$$

The wavelength increase is therefore the reciprocal wave-number response required for the carrier to remain on the real-frequency FCC eigenbranch. Equation (AP.86) remains a constitutive closure until it is recovered from the same causal FCC–Condensate response that produces the modal phase lag.

AP.8.2 Canonical Wave-Momentum and Reservoir Balance

The coherent packet carries the canonical Bloch momentum

$$\mathbf{p}_{\gamma}^{(\mathrm{can})} = \mathcal{I}_{\gamma}\mathbf{k} = \frac{E}{\omega}\mathbf{k}. \tag{AP.95}$$

Its dimensions are

$$\left[\mathbf{p}_{\gamma}^{(\mathrm{can})}\right] = \mathrm{kg\,m\,s^{-1}}. \tag{AP.96}$$

Since $\mathrm{d}\mathcal{I}_{\gamma}/\mathrm{d}t = 0$, the dissipative canonical-momentum change is

$$\left.\frac{\mathrm{d}\mathbf{p}_{\gamma}^{(\mathrm{can})}}{\mathrm{d}t}\right|_{\mathrm{D}} = \mathcal{I}_{\gamma}\left.\dot{\mathbf{k}}\right|_{\mathrm{D}}. \tag{AP.97}$$

In the absence of additional loss channels, the corresponding reservoir bookkeeping is

$$\frac{\mathrm{d}E_{\mathrm{res}}}{\mathrm{d}t} = \Gamma_{\mathrm{D}} E, \qquad \left.\frac{\mathrm{d}\mathbf{p}_{\mathrm{res}}^{(\mathrm{can})}}{\mathrm{d}t}\right|_{\mathrm{D}} = -\left.\frac{\mathrm{d}\mathbf{p}_{\gamma}^{(\mathrm{can})}}{\mathrm{d}t}\right|_{\mathrm{D}}. \tag{AP.98}$$

This is an energy–quasimomentum balance, not yet a derivation of mechanical substrate recoil. Because $\mathbf{k}$ is a Bloch wave vector, the mapping

$$\text{canonical lattice quasimomentum} \longrightarrow \text{mechanical substrate momentum} \tag{AP.99}$$

must be recovered from the FCC–Condensate microphysics. The same completion must constrain recoil radiation, incoherent mode conversion, image diffusion, phase noise, and polarization scrambling.

AP.9 Exact Relaxation Redshift and Euclidean Path Law

Equation (AP.75) may be written as

$$\frac{\mathrm{d}}{\mathrm{d}t}\ln\omega = -\Gamma_{\mathrm{D}}. \tag{AP.100}$$

For a generally position- or time-dependent relaxation rate,

$$\frac{\omega_{\mathrm{obs}}}{\omega_{\mathrm{emit}}} = \exp\left[-\int_{t_{\mathrm{emit}}}^{t_{\mathrm{obs}}} \Gamma_{\mathrm{D}}(t)\,\mathrm{d}t\right]. \tag{AP.101}$$

Using

$$1+z = \frac{\omega_{\mathrm{emit}}}{\omega_{\mathrm{obs}}}, \tag{AP.102}$$

gives the general temporal relation

$$\ln(1+z) = \int_{t_{\mathrm{emit}}}^{t_{\mathrm{obs}}} \Gamma_{\mathrm{D}}(t)\,\mathrm{d}t. \tag{AP.103}$$

Let ℓ denote arc length along the physical ray and define

$$v_{\mathrm{ray}}(\ell) = |\mathbf{v}_{\mathrm{g}}(\ell)|. \tag{AP.104}$$

The propagation time is

$$t_{\mathrm{obs}} - t_{\mathrm{emit}} = \int_{\mathrm{path}} \frac{\mathrm{d}\ell}{v_{\mathrm{ray}}\left[\omega(\ell), \alpha_{\mathrm{G}}(\ell)\right]}. \tag{AP.105}$$

Therefore, for a stationary but spatially nonuniform path,

$$\ln(1+z) = \int_{\mathrm{path}} \frac{\Gamma_{\mathrm{D}}(\ell)}{v_{\mathrm{ray}}\left[\omega(\ell), \alpha_{\mathrm{G}}(\ell)\right]}\,\mathrm{d}\ell. \tag{AP.106}$$

This expression separates the conservative propagation time from the nonconservative relaxation accumulated per unit time.

In the weakly loaded constant-rate limit,

$$\alpha_{\mathrm{G}} \to 0, \qquad v_{\mathrm{ray}} \simeq c_{\mathrm{E}}, \qquad \Gamma_{\mathrm{D}} \simeq \text{constant}, \tag{AP.107}$$

Equation (AP.106) reduces to

$$1+z = \exp\left(\frac{\Gamma_{\mathrm{D}} r}{c_{\mathrm{E}}}\right). \tag{AP.108}$$

Define the characteristic relaxation length

$$R_{\mathrm{U}} = \frac{c_{\mathrm{E}}}{\Gamma_{\mathrm{D}}}. \tag{AP.109}$$

Then

$$1+z = e^{r/R_{\mathrm{U}}}, \qquad r = R_{\mathrm{U}}\ln(1+z). \tag{AP.110}$$

The low-distance expansion is

$$z = \frac{r}{R_{\mathrm{U}}} + \frac{1}{2}\left(\frac{r}{R_{\mathrm{U}}}\right)^2 + \mathcal{O}\left(\frac{r^3}{R_{\mathrm{U}}^3}\right), \tag{AP.111}$$

so

$$c_{\mathrm{E}} z \simeq \Gamma_{\mathrm{D}} r \tag{AP.112}$$

is only the leading low-redshift approximation.

The absolute magnitude of Γ_{D} is not yet derived from the FCC–Condensate microphysics. At the present level of TFT, it is fixed empirically by matching Equation (AP.112) to the observed local Hubble slope,

$$c_{\mathrm{E}} z \simeq H_0^{(\mathrm{obs})} r. \tag{AP.113}$$

Therefore, within the TFT low-redshift calibration,

$$\Gamma_{\mathrm{D}}^{(\mathrm{cal})} = H_0^{(\mathrm{obs})}. \tag{AP.114}$$

Using the adopted local value

$$H_0^{(\mathrm{obs})} = 73.04\,\mathrm{km\,s^{-1}\,Mpc^{-1}}, \tag{AP.115}$$

gives

$$\Gamma_{\mathrm{D}}^{(\mathrm{cal})} \approx 2.3671 \times 10^{-18}\ \mathrm{s^{-1}}. \tag{AP.116}$$

Thus, the equality between Γ_{D} and the observed low-redshift Hubble slope is an empirical normalization of the TFT relaxation coefficient, not an independent microscopic derivation. A first-principles determination of Γ_{D} from the causal FCC–Condensate response remains a theory-completion requirement.

Preservation of coherent modal action also gives

$$\frac{E_{\mathrm{obs}}}{E_{\mathrm{emit}}} = \frac{\omega_{\mathrm{obs}}}{\omega_{\mathrm{emit}}} = \frac{1}{1+z}. \tag{AP.117}$$

This is the energy reduction of the surviving coherent carrier under the selected transport closure. It must not be supplemented by an independent amplitude-extinction factor unless a separate absorption or incoherent-loss channel is introduced.

Equation (AP.110) is exact within the constant-Γ_{D}, weak-loading, stationary Euclidean-path closure. The general result remains Equation (AP.106). Moreover, R_{U} is an e-folding length, not a universal stopping radius or zero-energy boundary.

AP.10 Observational Screening and Self-Consistent Path Integration

A viable photon branch must remain compatible with the absence of a resolved energy-ordered delay in high-energy transient observations. Two related tests are applied below: a local comparison with the conventional quadratic time-of-flight parametrization and a TFT path integral that includes the frequency evolution along the propagation path.

In a weakly loaded region,

$$E \simeq \hbar c_{\mathrm{E}} k. \tag{AP.118}$$

Using

$$d_{\mathrm{nn}} = 2r_{\mathrm{D}}, \qquad E_{\mathrm{max}} = \frac{hc_{\mathrm{E}}}{2r_{\mathrm{D}}} = \frac{hc_{\mathrm{E}}}{d_{\mathrm{nn}}}, \tag{AP.119}$$

one obtains

$$k d_{\mathrm{nn}} = 2\pi \frac{E}{E_{\mathrm{max}}}. \tag{AP.120}$$

Equivalently, the natural low-wave-number conversion scale is

$$E_d \equiv \frac{\hbar c_{\mathrm{E}}}{d_{\mathrm{nn}}} = \frac{E_{\max}}{2\pi}, \qquad k d_{\mathrm{nn}} \simeq \frac{E}{E_d}.$$

The notation $E_{\max}$ is retained because it is the established TFT calibration scale. In this calculation it sets the wavelength normalization; it is not identified with the exact energy at a Bloch-zone boundary.

For the baseline nearest-neighbor branch, Equation (AP.11) gives

$$1 - \frac{v_{\mathrm{g}}}{c_{\mathrm{P}}} = \frac{\pi^2}{2}\left(\frac{E}{E_{\max}}\right)^2 + \mathcal{O}\left(\frac{E^4}{E_{\max}^4}\right). \tag{AP.121}$$

The conventional subluminal quadratic comparison law is

$$\frac{v(E)}{c_{\mathrm{E}}} \simeq 1 - \frac{3}{2}\left(\frac{E}{E_{\mathrm{QG},2}}\right)^2, \tag{AP.122}$$

where $E_{\mathrm{QG},2}$ is an observational comparison scale rather than a TFT material constant. In the weak-loading limit $c_{\mathrm{P}} \simeq c_{\mathrm{E}}$, matching the quadratic coefficients gives

$$E_{\mathrm{QG},2}^{(\mathrm{base})} = \frac{\sqrt{3}}{\pi} E_{\max}. \tag{AP.123}$$

For the adopted TFT calibration

$$E_{\max} \approx 8.320 \times 10^{10}\ \mathrm{GeV}, \tag{AP.124}$$

the baseline branch corresponds to

$$E_{\mathrm{QG},2}^{(\mathrm{base})} \approx 4.59 \times 10^{10}\ \mathrm{GeV}. \tag{AP.125}$$

The LHAASO analysis of GRB 221009A reports

$$E_{\mathrm{QG},2} > 6 \times 10^{-8} E_{\mathrm{Pl}} \approx 7.3 \times 10^{11}\ \mathrm{GeV} \qquad \text{at } 95\% \text{ confidence} \tag{AP.126}$$

for its quadratic Lorentz-invariance-violation parametrization [36]. The local coefficient comparison therefore places the baseline nearest-neighbor photon branch in strong tension with the selected observational bound.

A self-consistent TFT test must also account for the changing carrier energy along the path. Consider a weakly loaded path of length r, parameterized by ℓ, with the observer at $\ell = r$. Under the constant-rate transport law,

$$E(\ell) = E_{\mathrm{obs}} \exp\left(\frac{r - \ell}{R_{\mathrm{U}}}\right), \tag{AP.127}$$

and

$$1 + z_{\mathrm{s}} = e^{r/R_{\mathrm{U}}}. \tag{AP.128}$$

Suppose the leading local fractional speed reduction is

$$1 - \frac{v_{\mathrm{g}}(E)}{c_{\mathrm{E}}} = A_n \left(\frac{E}{E_{\max}}\right)^n. \tag{AP.129}$$

The arrival-time difference between simultaneously emitted components with observed energies $E_{\mathrm{h,obs}}$ and $E_{\mathrm{l,obs}}$ is then

$$\begin{aligned}\Delta t_n &\simeq \frac{1}{c_{\mathrm{E}}}\int_0^r \left[\delta_n\left(E_{\mathrm{h}}(\ell)\right)-\delta_n\left(E_{\mathrm{l}}(\ell)\right)\right]\mathrm{d}\ell \\ &= \frac{A_n}{n\Gamma_{\mathrm{D}}}\left[\left(\frac{E_{\mathrm{h,obs}}}{E_{\max}}\right)^n-\left(\frac{E_{\mathrm{l,obs}}}{E_{\max}}\right)^n\right]\left[(1+z_{\mathrm{s}})^n-1\right], \end{aligned} \tag{AP.130}$$

where $\delta_n(E)=A_n(E/E_{\max})^n$. Equation (AP.130) is conditional on the same weak-loading, constant-Γ_{D} transport closure as Equation (AP.110).

For the baseline branch,

$$n=2, \qquad A_2=\frac{\pi^2}{2}. \tag{AP.131}$$

For GRB 221009A, use

$$z_{\mathrm{s}}=0.151, \qquad E_{\mathrm{l,obs}}=0.2\ \mathrm{TeV}, \qquad E_{\mathrm{h,obs}}=7\ \mathrm{TeV}, \tag{AP.132}$$

together with the empirical TFT calibration in Equation (AP.116). Equation (AP.130) then gives

$$\Delta t_2^{(\mathrm{base})}\approx 2.4\times 10^3\ \mathrm{s}. \tag{AP.133}$$

This macroscopically large delay strongly disfavors identifying the reduced baseline branch with the completed physical photon branch under the selected TFT propagation law.

For the dispersion-suppressed branch, Equations (AP.32) and (AP.33) give

$$1-\frac{v_{\mathrm{g},\parallel}}{c_{\mathrm{P}}}\le \frac{17}{1152}\left(kd_{\mathrm{nn}}\right)^4+\mathcal{O}\left(k^6d_{\mathrm{nn}}^6\right). \tag{AP.134}$$

In energy form,

$$1-\frac{v_{\mathrm{g},\parallel}}{c_{\mathrm{P}}}\le \frac{17\pi^4}{72}\left(\frac{E}{E_{\max}}\right)^4+\mathcal{O}\left(\frac{E^6}{E_{\max}^6}\right). \tag{AP.135}$$

Thus,

$$n=4, \qquad A_4=\frac{17\pi^4}{72}. \tag{AP.136}$$

Using the same source redshift, observed-energy interval, and relaxation calibration gives

$$\Delta t_4^{(\mathrm{sup})}\lesssim 9.2\times 10^{-11}\ \mathrm{s}. \tag{AP.137}$$

The selected dispersion-suppressed branch therefore produces a negligible path-integrated chromatic delay over the tested TeV interval.

This is a kinematic screening calculation, not a detector-level likelihood analysis. A complete observational test must include the measured source light curve, intrinsic spectral evolution, detector response, and energy uncertainty. Within the present screening scope, the baseline nearest-neighbor branch is strongly disfavored, whereas the selected quartic branch remains compatible with the quoted timing benchmark. The comparison constrains the effective photon eigenbranch but does not derive the microscopic origin of the 1/12 coefficient.

AP.11 Finite-Packet Cycle Dilation and Its Scope

Preservation of the coherent modal action E/ω does not by itself determine the temporal width of a finite packet. Packet-duration evolution requires an additional condition on the packet phase structure.

For a packet bounded by t_- and t_+, define the carrier-cycle count by

$$N = \int_{t_-}^{t_+} f(t)\,\mathrm{d}t. \tag{AP.138}$$

For a narrowband packet whose carrier frequency varies negligibly across its own support,

$$N \simeq f_{\mathrm{c}}\Delta t_{\mathrm{pkt}}, \qquad \Delta t_{\mathrm{pkt}} = t_+ - t_-. \tag{AP.139}$$

The additional fixed-cycle closure is

$$N_{\mathrm{obs}} = N_{\mathrm{emit}}. \tag{AP.140}$$

This condition is distinct from modal-action preservation. It states that the packet retains its ordered carrier-phase content during propagation.

If the frequency relaxation is effectively uniform across the packet,

$$f_{\mathrm{emit}}\Delta t_{\mathrm{pkt,emit}} = f_{\mathrm{obs}}\Delta t_{\mathrm{pkt,obs}}. \tag{AP.141}$$

Using

$$\frac{f_{\mathrm{emit}}}{f_{\mathrm{obs}}} = 1 + z, \tag{AP.142}$$

gives

$$\Delta t_{\mathrm{pkt,obs}} = (1+z)\,\Delta t_{\mathrm{pkt,emit}}. \tag{AP.143}$$

Equation (AP.143) therefore requires preservation of cycle count, narrowband or adiabatic carrier evolution, approximately uniform relaxation across the packet, and survival of the packet as one coherent phase structure. It does not establish dilation of an arbitrary macroscopic source light curve.

To show the distinction, consider two independently emitted packets following the same stationary path:

$$t_{\mathrm{obs}}^{(j)} = t_{\mathrm{emit}}^{(j)} + t_{\mathrm{prop}}^{(j)}, \qquad j = 1, 2. \tag{AP.144}$$

Their observed separation is

$$\Delta t_{\mathrm{obs}} = \Delta t_{\mathrm{emit}} + t_{\mathrm{prop}}^{(2)} - t_{\mathrm{prop}}^{(1)}. \tag{AP.145}$$

For identical spectral components emitted along the same stationary path,

$$t_{\mathrm{prop}}^{(2)} = t_{\mathrm{prop}}^{(1)}, \tag{AP.146}$$

so

$$\Delta t_{\mathrm{obs}} = \Delta t_{\mathrm{emit}}. \tag{AP.147}$$

Carrier-frequency relaxation and finite-packet dilation therefore do not automatically imply

$$\Delta t_{\mathrm{light\,curve,obs}} = (1+z)\,\Delta t_{\mathrm{light\,curve,emit}} \tag{AP.148}$$

for a sequence of independently emitted packets.

A derivation of astronomical transient dilation requires an additional source-to-envelope transport law. That law must either show that the macroscopic emission envelope is itself carried by a coherent finite-cycle structure or derive an equivalent mapping between source chronology and observer chronology. The residual lattice dispersion evaluated in Section AP.10 is far too small to produce an order-$(1+z)$ stretching of a broadband transient envelope.

The result established here is therefore restricted to

$$\begin{aligned}&\text{fixed-cycle narrowband coherent packet}\\ &\qquad\longrightarrow \text{conditional packet-duration dilation.}\end{aligned} \tag{AP.149}$$

Macroscopic light-curve dilation remains a separate cosmological transport-completion problem.

AP.12 Threshold Assimilation into a CMB-Associated Thermal Reservoir

The exponential transport law does not drive the coherent carrier to zero frequency or energy at any finite distance. In the weak-loading, constant-rate limit,

$$\omega(r) = \omega_{\mathrm{emit}} \exp\left(-\frac{r}{R_{\mathrm{U}}}\right), \tag{AP.150}$$

and, because $\mathcal{I}_\gamma = E/\omega$ is preserved,

$$E(r) = E_{\mathrm{emit}} \exp\left(-\frac{r}{R_{\mathrm{U}}}\right). \tag{AP.151}$$

Consequently,

$$E(R_{\mathrm{U}}) = \frac{E_{\mathrm{emit}}}{e}. \tag{AP.152}$$

Thus, R_{U} is an e-folding length, not a universal zero-energy or stopping radius.

A finite coherence horizon may nevertheless arise if the relaxed transverse mode becomes dynamically indistinguishable from the ambient thermal spectrum. Because the CMB is broadband, introduce an effective coherence-loss frequency

$$\omega_{\mathrm{CMB}}^{(\mathrm{eff})} = 2\pi f_{\mathrm{CMB}}^{(\mathrm{eff})}. \tag{AP.153}$$

This parameter represents an effective spectral and coherence boundary, not a unique frequency of the CMB.

For a carrier with modal action $\mathcal{I}_\gamma$, the remaining threshold energy is

$$E_{\mathrm{th}}^{(\mathrm{eff})} = \mathcal{I}_\gamma \omega_{\mathrm{CMB}}^{(\mathrm{eff})}. \tag{AP.154}$$

The threshold energy therefore depends on the action carried by the coherent mode. For one quantum-normalized excitation,

$$\mathcal{I}_\gamma = \hbar, \tag{AP.155}$$

and Equation (AP.154) reduces to

$$E_{\mathrm{th}}^{(\mathrm{eff})} = \hbar\omega_{\mathrm{CMB}}^{(\mathrm{eff})} = h f_{\mathrm{CMB}}^{(\mathrm{eff})}.$$

The assimilation condition is most fundamentally stated in frequency:

$$\omega\left(r_{\mathrm{assim}}\right)=\omega_{\mathrm{CMB}}^{(\mathrm{eff})}, \tag{AP.156}$$

with

$$\omega_{\mathrm{emit}}>\omega_{\mathrm{CMB}}^{(\mathrm{eff})}. \tag{AP.157}$$

Using Equation (AP.150),

$$r_{\mathrm{assim}}=R_{\mathrm{U}}\ln\left(\frac{\omega_{\mathrm{emit}}}{\omega_{\mathrm{CMB}}^{(\mathrm{eff})}}\right)=R_{\mathrm{U}}\ln\left(\frac{f_{\mathrm{emit}}}{f_{\mathrm{CMB}}^{(\mathrm{eff})}}\right). \tag{AP.158}$$

Because the same modal action multiplies the initial and threshold frequencies,

$$r_{\mathrm{assim}}=R_{\mathrm{U}}\ln\left(\frac{E_{\mathrm{emit}}}{E_{\mathrm{th}}^{(\mathrm{eff})}}\right). \tag{AP.159}$$

The assimilation distance is therefore frequency dependent. For

$$\frac{f_{\mathrm{emit}}}{f_{\mathrm{CMB}}^{(\mathrm{eff})}}\sim 10^{3}\text{–}10^{4}, \tag{AP.160}$$

one obtains

$$r_{\mathrm{assim}}\sim(7\text{–}9)\,R_{\mathrm{U}}. \tag{AP.161}$$

For the adopted TFT calibration of R_{U}, this is of order

$$10^{27}\ \mathrm{m}. \tag{AP.162}$$

This is an approximate optical-to-thermal coherence scale, not a universal photon horizon.

AP.12.1 Energy Accounting at the Assimilation Threshold

Before terminal coherence loss, integration of the carrier–reservoir balance gives

$$E_{\mathrm{res}}(t)-E_{\mathrm{res}}\left(t_{\mathrm{emit}}\right)=E_{\mathrm{emit}}-E(t), \tag{AP.163}$$

provided that no additional absorptive, radiative, or mode-conversion channel is active.

Immediately before assimilation,

$$E\left(r_{\mathrm{assim}}^{-}\right)=E_{\mathrm{th}}^{(\mathrm{eff})}. \tag{AP.164}$$

The continuously transferred energy is therefore

$$\Delta E_{\mathrm{res}}^{(\mathrm{cont})}=E_{\mathrm{emit}}-E_{\mathrm{th}}^{(\mathrm{eff})}. \tag{AP.165}$$

Under the terminal assimilation closure, the remaining coherent energy is redistributed into accessible reservoir modes:

$$\Delta E_{\mathrm{res}}^{(\mathrm{assim})}=E_{\mathrm{th}}^{(\mathrm{eff})}. \tag{AP.166}$$

Hence

$$\Delta E_{\mathrm{res}}^{(\mathrm{tot})}=\Delta E_{\mathrm{res}}^{(\mathrm{cont})}+\Delta E_{\mathrm{res}}^{(\mathrm{assim})}=E_{\mathrm{emit}}. \tag{AP.167}$$

Equation (AP.167) closes only the energy bookkeeping of one assimilated coherent mode. It does not establish global thermal equilibrium, detailed balance, or preservation of the measured CMB spectrum. Those require a microscopic theory of the terminal instability, the destination of deposited energy and momentum, and the resulting thermal and spectral response.

AP.13 Closure Status, Falsifiability, and Remaining Completion

The appendix contains three logically distinct elements: results derived from the selected reduced carrier action, conditional nonconservative transport closures, and unresolved microscopic or cosmological completion requirements.

AP.13.1 Results Derived Within the Selected Reduced Carrier Action

Within the divergence-free positive two-term action of Section AP.3, the following results are derived:

1. The baseline directional chain has a leading group-speed correction proportional to $k^2 d_{\mathrm{nn}}^2$.
2. The positive centered-second-difference term with coefficient $1/12$ cancels the quartic term in the expansion of ω^2 within the selected stencil.
3. The resulting reduced transverse branch is gapless, inversion symmetric, spectrally nonnegative, and degenerate in its two transverse components.
4. Its leading radial group-speed correction is proportional to $k^4 d_{\mathrm{nn}}^4$, with the FCC directional bound in Equation (AP.33).
5. The GRB screening calculation strongly disfavors the baseline nearest-neighbor branch while leaving the selected quartic branch compatible with the adopted timing benchmark.

These results follow from the selected reduced action; they do not establish that the complete FCC parent dynamics uniquely generate that action.

AP.13.2 Conditional Nonconservative Closures

The relaxation-redshift construction additionally assumes:

1. a causal weak-loss response with the inverse-frequency loss tangent in Equation (AP.54);
2. preservation of the coherent modal action $\mathcal{I}_\gamma = E/\omega$;
3. the direction-preserving wave-vector transport law in Equation (AP.86);
4. canonical energy–quasimomentum balance with the FCC–Condensate reservoir;
5. suppression of incoherent absorption, angular diffusion, phase noise, polarization scrambling, and secondary-mode conversion;
6. a stationary or quasistatic background, with approximately constant Γ_{D} for the simple Euclidean exponential law;
7. fixed carrier-cycle count for conditional packet-duration dilation; and
8. an effective thermal coherence threshold for terminal assimilation.

Under these conditions, modal-energy transfer produces coherent frequency evolution. The simple distance law follows only after the additional weak-loading and constant-rate approximations are imposed.

AP.13.3 Results Not Established by the Present Appendix

The present construction does not establish:

1. unique microscopic origin of the coefficient 1/12;
2. uniform finite-k endpoint loading from the fully resolved FCC dynamic matrix;
3. first-principles derivation of the inverse-frequency loss tangent;
4. nonlinear proof of coherent modal-action preservation;
5. derivation of the wave-vector transport law from the same causal susceptibility that produces the phase lag;
6. quantitative conversion of canonical Bloch quasimomentum into mechanical substrate momentum;
7. suppression of cumulative broadening, diffusion, polarization change, recoil radiation, and secondary modes;
8. dilation of arbitrary macroscopic transient light curves;
9. derivation of $f_{\mathrm{CMB}}^{(\mathrm{eff})}$ from the measured thermal spectrum; or
10. global thermal, spectral, and momentum balance of the deposited radiation.

AP.13.4 Falsifiable Consequences

The construction is testable through the following channels:

1. **Photon dispersion.** A confirmed leading quadratic vacuum delay at the TFT lattice scale would contradict the selected dispersion-suppressed branch.
2. **FCC directional structure.** The leading residual correction carries the cubic factor in Equation (AP.33); its interpretation depends on the orientation or domain structure of the vacuum lattice.
3. **Loss-tangent scaling.** A frequency-independent Γ_{D} requires the inverse-frequency weak-loss behavior derived above.
4. **Spectral and directional coherence.** Excessive line broadening, frequency diffusion, image blurring, polarization randomization, or secondary radiation would contradict the assumed coherent transport channel.
5. **Momentum balance.** Failure to construct a mechanical substrate response consistent with the required canonical quasimomentum change would invalidate the wave-vector transport closure.
6. **Macroscopic time dilation.** Failure to derive source-envelope dilation elsewhere in TFT would leave astronomical transient-duration observations unexplained.
7. **Assimilation scale.** The selected closure predicts a frequency-dependent coherence distance rather than a universal stopping radius.
8. **Thermal consistency.** Unacceptable CMB spectral distortion or secular reservoir heating would contradict the proposed energy-deposition mechanism.

AP.13.5 Required Microscopic and Cosmological Completion

The remaining program is to:

1. derive the physical finite-wave-number transverse branch from the complete FCC contact Hessian, rotational variables, internal phases, and Tension-Column coupling;
2. determine the loaded finite-k dynamic matrix without importing the long-wavelength endpoint-transfer factor uniformly;
3. construct a causal FCC–Condensate susceptibility satisfying the appropriate Kramers–Kronig and fluctuation–dissipation constraints;
4. derive the real-frequency and real-wave-vector transport law from that same response;
5. derive the conversion between Bloch quasimomentum and mechanical substrate momentum;
6. demonstrate nonlinear stability against absorption, packet rupture, diffusion, decoherence, polarization scrambling, and secondary-mode production;
7. determine Γ_{D} independently from vacuum microphysics;
8. derive macroscopic source-envelope transport and test astronomical light-curve dilation;
9. derive $f_{\mathrm{CMB}}^{(\mathrm{eff})}$ and the instability responsible for terminal coherence loss; and
10. establish global thermal, spectral, energy, and momentum balance for the deposited radiation.

The logical hierarchy is

$$\begin{aligned}&\text{complete FCC contact and internal-phase dynamics}\\ &\quad\longrightarrow \text{physical finite-}k\text{ transverse eigenbranch}\\ &\quad\longrightarrow \text{causal FCC–Condensate response}\\ &\quad\longrightarrow \text{coherent action and wave-vector transport}\\ &\quad\longrightarrow \text{relaxation redshift and threshold assimilation.}\end{aligned}\tag{AP.168}$$

The appendix therefore supplies a dimensionally closed reduced transverse carrier action and an explicit conditional nonconservative transport closure while maintaining a strict separation among inherited TFT structure, derived results, constitutive assumptions, observational consequences, and unresolved completion.

Appendix AQ

Vacuum Damping and Cosmic Redshift

Subject: Replacing the empirical Hubble Constant (H_0) and "Dark Energy" with the theoretical Vacuum Damping Rate (Γ_D).

AQ.1 The Physical Premise

Standard cosmology attributes the redshift of distant galaxies to a recession velocity (metric expansion). Tension Field Theory (TFT) resolves this strictly through the static vacuum's visco-elastic properties.

In TFT, as established in Part I, the active vacuum is a dual-phase visco-elastic Face-Centered Cubic (FCC) medium. Like all real visco-elastic media, it possesses intrinsic boundary friction.

- **Mechanism:** A photon is a 2D transverse shear wave propagating exclusively across the solid FCC lattice nodes. *(Note: This mechanism applies identically to 3D bulk gravitational waves).* During propagation, the transverse wave must continuously work against the visco-elastic friction between these solid nodes and the interstitial condensate.
- **Result:** This work is not perfectly elastic. A fundamental, minute fraction of the wave's kinetic energy is dissipated into the lattice as longitudinal phonon heat, sustaining the 2.725 K Cosmic Microwave Background (as detailed in Section 22.5). This boundary friction produces a strict temporal energy decay, which we define as the Vacuum Damping Rate (Γ_D). This cumulative energy loss is observed macroscopically as cosmological redshift.

Exemption of Topological Mass (Lorentz Invariance): It is critical to distinguish continuous transverse shear waves from condensed mass. As established in Postulate V, macroscopic mass (topological knots) propagates via perfectly elastic Sequential Discrete Reconfiguration (untying and retying). Because this state transfer operates strictly via radial volumetric displacement—which the interstitial condensate absorbs and returns as a perfectly elastic, lossless exchange—mass translating at a constant velocity experiences zero net vacuum damping, perfectly preserving Galilean and Lorentz invariance. The Vacuum Damping Rate (Γ_D) applies exclusively to continuous dynamic stress propagation (photons and bulk gravitational waves) which must continuously apply transverse shear across the visco-elastic boundary.

AQ.2 The Energy Dissipation Equation

As formally derived from the continuum mechanics of the SGF in Appendix Y (Derivation of Vacuum Visco-Elasticity and Wave Arrest), the physical amplitude of a transverse shear wave ($\mathbf{A}$) propagating through the vacuum yields a strict temporal amplitude decay envelope:

$$\mathbf{A}(t) = \mathbf{A}_0 e^{-\frac{\Gamma_D}{2}t} \tag{AQ.1}$$

Because the total mechanical energy of any classical elastic wave is directly proportional to the square of its amplitude ($E \propto |\mathbf{A}|^2$), substituting the decayed amplitude yields the pristine macroscopic energy decay curve of the active vacuum:

$$E(t) \propto \left(\mathbf{A}_0 e^{-\frac{\Gamma_D}{2}t}\right)^2 = E_0 e^{-\Gamma_D t} \tag{AQ.2}$$

Taking the time-derivative of this exponential function yields the governing differential equation for macroscopic visco-elastic energy dissipation:

$$\frac{\mathrm{d}E}{\mathrm{d}t} = -\Gamma_D E \tag{AQ.3}$$

To map this to astronomical observations, we substitute the spatial propagation distance ($x = c_E t$) to find the spatial energy decay rate:

$$\frac{\mathrm{d}E}{\mathrm{d}x} = -\frac{\Gamma_D}{c_E} E \tag{AQ.4}$$

Integrating this over propagation distance yields the compounding spatial decay function:

$$E_{obs} = E_{emit} e^{-\frac{\Gamma_D x}{c_E}} \tag{AQ.5}$$

AQ.3 Deriving the Redshift Factor $(1 + z)$

Because the energy of a photon is inversely proportional to its wavelength ($E \propto 1/\lambda$), we substitute wavelength into the spatial decay function:

$$\frac{1}{\lambda_{obs}} = \frac{1}{\lambda_{emit}} e^{-\frac{\Gamma_D x}{c_E}} \tag{AQ.6}$$

$$\lambda_{obs} = \lambda_{emit} e^{\frac{\Gamma_D x}{c_E}} \tag{AQ.7}$$

The standard astronomical definition of redshift is $1 + z = \lambda_{obs}/\lambda_{emit}$. Substituting our derived wavelength yields the absolute Visco-Elastic Damping Equation:

$$1 + z = e^{\frac{\Gamma_D x}{c_E}} \tag{AQ.8}$$

AQ.4 Resolving the Hubble Law and "Dark Energy"

For relatively short, local cosmic distances, the Taylor series expansion of the exponential function ($e^y \approx 1 + y$) cleanly reduces to a linear approximation:

$$1 + z \approx 1 + \frac{\Gamma_{\mathrm{D}} x}{c_{\mathrm{E}}} \tag{AQ.9}$$

$$z \approx \frac{\Gamma_{\mathrm{D}}}{c_{\mathrm{E}}} x \tag{AQ.10}$$

Rearranging to solve for the velocity-equivalent ($c_{\mathrm{E}} z$):

$$c_{\mathrm{E}} \cdot z = \Gamma_{\mathrm{D}} \cdot x \tag{AQ.11}$$

The Hubble Law Inversion: This matches the exact linear format of Hubble's Law ($v = H_0 d$). By setting $\Gamma_{\mathrm{D}} \equiv H_0$, TFT proves that the Hubble constant is not a velocity of metric expansion, but the literal visco-elastic damping coefficient of the vacuum.

Furthermore, at extreme distances (such as Type Ia Supernovae), the higher-order terms of the exponential expansion can no longer be ignored. Substituting $t = x/c_{\mathrm{E}}$, the second-order expansion yields:

$$z \approx \Gamma_{\mathrm{D}} t + \frac{(\Gamma_{\mathrm{D}} t)^2}{2} \tag{AQ.12}$$

This mathematically proves that the inherent exponential nature of the decay natively produces a non-linear, upward-curving redshift. The $+\frac{(\Gamma_{\mathrm{D}} t)^2}{2}$ term exactly mimics the anomalous signal dimming that standard cosmology incorrectly attributes to an accelerating metric ("Dark Energy").

AQ.5 The Empirical Calibration of Γ_{D}

Because Γ_{D} is identical to the empirical Hubble Constant, we derive the absolute magnitude of the vacuum damping using the high-precision SH0ES collaboration local baseline ($H_0 \approx 73.04$ km/s/Mpc):

$$\Gamma_{\mathrm{D}} \equiv H_0 = \frac{73040 \text{ m/s}}{3.0857 \times 10^{22} \text{ m}} \approx 2.3671 \times 10^{-18} \text{ s}^{-1} \tag{AQ.13}$$

This temporal rate defines the absolute Viscous Cosmic Horizon (R_{U})—the coordinate distance where cumulative vacuum visco-elastic damping attenuates a photon's initial energy by a factor of $1/e$:

$$R_{\mathrm{U}} = \frac{c_{\mathrm{E}}}{\Gamma_{\mathrm{D}}} \approx 1.2665 \times 10^{26} \text{ m} \tag{AQ.14}$$

AQ.6 Conclusion

The Vacuum Damping Rate (Γ_{D}) is numerically equivalent to the empirical Hubble Constant (H_0), operating as a mechanical friction coefficient rather than a metric expansion rate.

- **The Nature of Expansion:** The observed "expansion" and "acceleration" of the universe are mathematical artifacts caused by observing a purely exponential visco-elastic decay curve and misinterpreting it as kinematics.

- **LIGO Alignment:** Because this visco-elastic damping (Γ_D) is strictly a mechanical consequence of geometric shear rubbing against the condensate, it applies identically to all transverse waves. This proves why macroscopic gravitational waves (3D bulk shear) suffer the exact same cosmological redshift as photons (2D surface shear) over cosmic distances, perfectly aligning with observational amplitude corrections required by the LIGO collaboration.

Appendix AR

The Conservation of Topology (N) and Time Dilation

Abstract: Standard cosmology utilizes Supernova Time Dilation as definitive proof of expanding space. Tension Field Theory (TFT) mathematically guarantees this exact time dilation without metric expansion by enforcing the topological conservation of the wave packet.

AR.1 The Topological Invariant (N)

A photon is a finite soliton wave characterized by a strict integer count of phase cycles (N). While the kinetic energy of the photon is not conserved (as it bleeds heat into the lattice), this topological integrity cannot be destroyed by linear propagation. The total cycle count is the product of the wave's frequency (f) and its temporal duration (Δt):

$$N = f_{\text{emit}} \cdot \Delta t_{\text{emit}} \tag{AR.1}$$

AR.2 The Frequency Drop

As derived in Appendix AQ, visco-elastic damping causes the wave's energy to decay exponentially (depositing the deficit as CMB phonons), which manifests directly as a drop in the observed frequency ($f_{\text{obs}} < f_{\text{emit}}$), related by the redshift factor:

$$f_{\text{obs}} = \frac{f_{\text{emit}}}{1+z} \tag{AR.2}$$

AR.3 The Derivation of Time Dilation

Because the topological cycle count must be strictly conserved upon observation ($N_{\text{obs}} = N_{\text{emit}}$), we equate the emitted and observed states:

$$f_{\text{obs}} \cdot \Delta t_{\text{obs}} = f_{\text{emit}} \cdot \Delta t_{\text{emit}} \tag{AR.3}$$

Substitute the redshifted frequency (f_{obs}):

$$\left(\frac{f_{\text{emit}}}{1+z}\right) \cdot \Delta t_{\text{obs}} = f_{\text{emit}} \cdot \Delta t_{\text{emit}} \tag{AR.4}$$

Cancel the emission frequency (f_{emit}) and solve for the observed duration (Δt_{obs}):

$$\Delta t_{\text{obs}} = \Delta t_{\text{emit}}(1 + z) \tag{AR.5}$$

Conclusion: The physical duration of the wave packet must proportionally increase to accommodate the lower frequency while conserving the cycle count (N). A distant supernova appears to happen in slow motion ($\Delta t_{\text{obs}} > \Delta t_{\text{emit}}$) strictly because the wave packet has physically elongated to conserve its topology against the cosmic damping. No expanding metric is required.

Appendix AS

The Viscous Hubble Diagram and Distance Modulus

Abstract: Standard cosmology evaluates the luminosity distance of distant supernovae through the expansion history of the FLRW metric. Tension Field Theory instead derives a nonlinear coordinate-distance law from coherent-action-preserving visco-elastic frequency relaxation. Under an additional macroscopic source-envelope timing closure, this yields a conditional TFT luminosity-distance relation and a directly testable non-expanding Hubble diagram. This appendix also states the Euclidean acoustic-projection closure used in Part III.

AS.1 The Two Factors of Viscous Luminosity Distance (d_{L})

As derived in Appendix AP, the general TFT redshift law is

$$\ln(1+z) = \int_{\mathrm{path}} \frac{\Gamma_{\mathrm{D}}(\ell)}{v_{\mathrm{ray}}[\omega(\ell), \alpha_{\mathrm{G}}(\ell)]}\, \mathrm{d}\ell. \tag{AS.1}$$

In the weak-loading, constant-rate Euclidean limit,

$$\alpha_{\mathrm{G}} \to 0, \qquad v_{\mathrm{ray}} \simeq c_{\mathrm{E}}, \qquad \Gamma_{\mathrm{D}} \simeq \Gamma_{\mathrm{D}}^{(\mathrm{cal})}, \tag{AS.2}$$

the coordinate distance becomes

$$d_{\mathrm{coord}} = \frac{c_{\mathrm{E}}}{\Gamma_{\mathrm{D}}^{(\mathrm{cal})}} \ln(1+z). \tag{AS.3}$$

Using the empirical low-redshift calibration

$$\Gamma_{\mathrm{D}}^{(\mathrm{cal})} = H_0^{(\mathrm{obs})}, \tag{AS.4}$$

this may be written

$$d_{\mathrm{coord}} = \frac{c_{\mathrm{E}}}{H_0^{(\mathrm{obs})}} \ln(1+z). \tag{AS.5}$$

The observational luminosity distance requires a second transport statement. The two relevant factors are:

- **Factor A (Coherent Energy Relaxation):** Coherent-action preservation gives

$$\frac{E_{\mathrm{obs}}}{E_{\mathrm{emit}}} = \frac{\omega_{\mathrm{obs}}}{\omega_{\mathrm{emit}}} = \frac{1}{1+z}. \tag{AS.6}$$

- **Factor B (Conditional Macroscopic Arrival-Rate Dilation):** For a fixed-cycle coherent packet,

$$\Delta t_{\mathrm{pkt,obs}} = (1+z)\Delta t_{\mathrm{pkt,emit}}. \tag{AS.7}$$

  As emphasized in Chapter 23, this packet result does not automatically establish the dilation of an arbitrary astronomical source envelope. If the macroscopic source-to-envelope transport closure inherits the same $(1+z)$ arrival-rate factor, then the received bolometric power satisfies

$$\frac{P_{\mathrm{obs}}}{P_{\mathrm{emit}}} = \frac{1}{(1+z)^2}. \tag{AS.8}$$

Under this macroscopic envelope-dilation closure, the inverse-square flux relation converts the two power factors into one multiplicative factor of $(1+z)$ in the effective luminosity distance:

$$d_{\mathrm{L(TFT)}} = d_{\mathrm{coord}}(1+z). \tag{AS.9}$$

Therefore,

$$d_{\mathrm{L(TFT)}} = \frac{c_{\mathrm{E}}}{\Gamma_{\mathrm{D}}^{(\mathrm{cal})}}(1+z)\ln(1+z), \tag{AS.10}$$

or, using the present empirical calibration,

$$d_{\mathrm{L(TFT)}} = \frac{c_{\mathrm{E}}}{H_0^{(\mathrm{obs})}}(1+z)\ln(1+z). \tag{AS.11}$$

This luminosity-distance law is therefore a conditional TFT prediction: the coordinate-distance component follows from the coherent-relaxation sector, whereas the additional $(1+z)$ factor requires completion of the macroscopic source-envelope transport law.

AS.2 The Distance Modulus

Astronomical observations commonly express luminosity distance through the distance modulus,

$$\mu = m - M = 5\log_{10}\left(\frac{d_{\mathrm{L}}}{\mathrm{Mpc}}\right) + 25. \tag{AS.12}$$

Substituting the conditional TFT luminosity distance gives

$$\mu_{\mathrm{TFT}} = 5\log_{10}\left[\frac{c_{\mathrm{E}}}{H_0^{(\mathrm{obs})}\,\mathrm{Mpc}}(1+z)\ln(1+z)\right] + 25. \tag{AS.13}$$

This expression defines the TFT Hubble-diagram prediction to be tested directly against supernova distance-modulus data under the stated constant-rate and macroscopic envelope-dilation closures.

AS.3 Taylor Expansion and Cosmographic Comparison

The exact nonlinear factor appearing in the conditional TFT luminosity distance has the Taylor expansion

$$(1+z)\ln(1+z) = z + \frac{z^2}{2} - \frac{z^3}{6} + \frac{z^4}{12} + \mathcal{O}(z^5). \tag{AS.14}$$

Therefore,

$$d_{\mathrm{L(TFT)}} = \frac{c_{\mathrm{E}}}{H_0^{(\mathrm{obs})}} \left[z + \frac{z^2}{2} - \frac{z^3}{6} + \mathcal{O}(z^4) \right]. \tag{AS.15}$$

At low redshift, the leading term recovers the linear Hubble relation. For comparison, the standard cosmographic luminosity-distance expansion begins as

$$d_{\mathrm{L}} \simeq \frac{c_{\mathrm{E}}}{H_0} \left[z + \frac{1 - q_0}{2} z^2 + \cdots \right]. \tag{AS.16}$$

Matching only the quadratic coefficient of the TFT expansion gives

$$\frac{1 - q_0}{2} = \frac{1}{2} \qquad \Longrightarrow \qquad q_0 = 0. \tag{AS.17}$$

Consequently, the positive $\frac{1}{2}z^2$ term is not by itself a mathematical derivation of the negative-q_0 acceleration inferred within standard cosmography. TFT instead proposes a distinct non-expanding nonlinear distance law. Its ability to reproduce the observed supernova Hubble diagram must therefore be assessed by fitting the complete expression

$$d_{\mathrm{L(TFT)}} = \frac{c_{\mathrm{E}}}{H_0^{(\mathrm{obs})}} (1 + z) \ln(1 + z) \tag{AS.18}$$

directly to the observational data rather than identifying individual Taylor coefficients with FLRW kinematic parameters.

AS.4 Euclidean Acoustic Projection Closure

The characteristic Viscoelastic Vacuum Relaxation length is

$$R_{\mathrm{U}} = \frac{c_{\mathrm{E}}}{\Gamma_{\mathrm{D}}^{(\mathrm{cal})}}. \tag{AS.19}$$

As established in Appendix AP, R_{U} is the characteristic one-e-fold coherent-relaxation length. It is not a universal photon stopping radius, and the frequency-dependent CMB assimilation threshold may occur at substantially larger distances.

For the Euclidean reinterpretation of the observed CMB acoustic angular scale developed in Chapter 24, TFT introduces the additional constitutive projection closure

$$D_{\mathrm{proj}} \equiv R_{\mathrm{U}}. \tag{AS.20}$$

This identification is presently a cosmological geometric closure rather than a microscopic consequence of the photon-relaxation derivation. Under this closure, the effective TFT acoustic scale associated with an observed angular scale θ_* is

$$r_{\mathrm{s(TFT)}} = D_{\mathrm{proj}} \theta_* = R_{\mathrm{U}} \theta_*. \tag{AS.21}$$

Using

$$R_{\mathrm{U}} \approx 4104.498 \text{ Mpc}, \qquad \theta_* \approx 0.01041, \tag{AS.22}$$

gives

$$r_{\mathrm{s(TFT)}} \approx 42.73 \text{ Mpc}. \tag{AS.23}$$

The dimensional consistency is immediate:

$$[D_{\mathrm{proj}}] = [R_{\mathrm{U}}] = [r_{\mathrm{s(TFT)}}] = \mathrm{m}, \qquad [\theta_*] = 1. \tag{AS.24}$$

The numerical 42.73 Mpc scale is therefore a well-defined consequence of the proposed closure $D_{\mathrm{proj}} = R_{\mathrm{U}}$, but it is not yet an independent parameter-free prediction. Closing this branch requires a microscopic or percolative derivation showing why the relevant CMB projection distance must coincide with the one-e-fold vacuum-relaxation scale.

Appendix AT

Cosmic Energy Budget and Macroscopic Chronology

Abstract: This appendix develops the macroscopic geometric limits and thermodynamic chronology of the Tension Field Theory (TFT) cosmic oscillator. Modeling the active Spacetime Gravitational Floor (SGF) as a dual-phase visco-elastic Face-Centered Cubic (FCC) medium undergoing localized FCC→SC phase transitions, we derive the local Octahedral accommodation limit, construct the global mass-weighted percolation threshold for Catastrophic Decompression, and formulate the Global Phase Avalanche governed by the macroscopic Viscoelastic Vacuum Relaxation Rate (Γ_{D}). The framework distinguishes the aggregate inertial mass carried by live FCC/SC phase boundaries from the physical volume of the saturated SC cores. Under an explicit single-rate phase-avalanche closure, the same macroscopic relaxation rate that governs coherent optical relaxation sets the fractional compounding rate of the self-sustaining FCC→SC boundary network, producing a synchronized optical and thermodynamic clock without requiring direct conversion of photon energy into Black Hole mass.

AT.1 The Local Volumetric Yield Limit (Phase Condensation)

As established in Part I, the active vacuum (State I) is an FCC lattice with an invariant geometric packing fraction of

$$\beta_{\mathrm{geo}} \approx 0.7405. \tag{AT.1}$$

Mass formation requires localized kinematic excitation of the active lattice and is supported by the interstitial degrees of freedom between the FCC nodes. The primary isotropic accommodation pockets are the Octahedral voids.

To determine the maximum local geometric accommodation associated with these sites, we calculate the precise volumetric fraction of the inscribed Octahedral regions relative to the FCC unit cell.

- **Deriving the Octahedral Void Radius (r_{O}):**

  In an FCC lattice formed by nodes of radius r_{D}, neighboring nodes touch along the face diagonal. The face diagonal is therefore $4r_{\mathrm{D}}$. By the Pythagorean theorem, the edge length of the conventional unit cell is

$$a = \sqrt{\frac{(4r_{\mathrm{D}})^2}{2}} = 2\sqrt{2}\, r_{\mathrm{D}}. \tag{AT.2}$$

One class of FCC Octahedral sites lies at the midpoint of the unit-cell edges, with the symmetry-equivalent body-center site completing the Octahedral-site population of the conventional cell. Along an edge, the distance from the center of a corner node to the center of the Octahedral site is $a/2$. Therefore,

$$r_{\mathrm{D}} + r_{\mathrm{O}} = \frac{a}{2} = \sqrt{2}\, r_{\mathrm{D}}. \tag{AT.3}$$

Isolating the inscribed radius gives

$$r_{\mathrm{O}} = (\sqrt{2} - 1) r_{\mathrm{D}}. \tag{AT.4}$$

- **Deriving the Volumetric Fraction:**

  The total conventional-cell volume is

$$V_{\mathrm{cell}} = a^3 = 16\sqrt{2}\, r_{\mathrm{D}}^3. \tag{AT.5}$$

  There are four Octahedral sites per conventional FCC unit cell: one body-center site and twelve edge sites, each shared by four neighboring cells. The total inscribed Octahedral volume is therefore

$$V_{\mathrm{oct}} = 4\left(\frac{4}{3}\pi r_{\mathrm{O}}^3\right) = \frac{16\pi}{3}(\sqrt{2} - 1)^3 r_{\mathrm{D}}^3. \tag{AT.6}$$

  Dividing by the unit-cell volume gives the Octahedral Volumetric Fraction,

$$\beta_{\mathrm{oct}} = \frac{V_{\mathrm{oct}}}{V_{\mathrm{cell}}} = \frac{\pi(\sqrt{2} - 1)^3}{3\sqrt{2}} \approx 0.0526. \tag{AT.7}$$

Within the TFT structural-capacity interpretation, this 5.26% fraction provides the local isotropic Octahedral accommodation ceiling,

$$\beta_{\mathrm{b}} \leq \beta_{\mathrm{oct}} \approx 0.0526. \tag{AT.8}$$

This quantity is a local geometric capacity benchmark. It is not the physical volume fraction of saturated State II SC cores. Black Hole formation occurs when the local active FCC state reaches gravitational saturation,

$$\alpha_{\mathrm{G}} \to 1, \tag{AT.9}$$

forcing the FCC→SC phase transition and creating a live FCC/SC phase boundary.

AT.2 The Global Topological Limit (Percolation Theory and The Big Rupture)

The local Octahedral limit constrains the geometric accommodation of localized matter defects. The ultimate global stability of the macroscopic reservoir is instead governed by connectivity of the distributed State II phase-boundary network.

In TFT, the inertial mass of a Black Hole is phase-segregated onto its live FCC/SC boundary. The global quantity relevant to percolation is therefore the Aggregate Percolating Mass (M_{p}), defined as the combined inertial mass carried by the participating live phase boundaries:

$$M_{\mathrm{p}}(t) \equiv \sum_i \int_{\partial\Omega_i(t)} \Sigma_\partial \, \mathrm{d}A, \tag{AT.10}$$

where Σ_∂ is the local surface mass density and the sum is taken over the distinct live FCC/SC boundary domains. Once initially separate boundaries merge through a saturated bridge, the resulting common boundary is treated as one connected phase-boundary domain.

For separated approximately spherical Black Holes, this reduces to

$$M_{\rm p}(t) = \sum_i M_i(t). \tag{AT.11}$$

Thus, $M_{\rm p}$ is an aggregate boundary-mass measure. It is not the summed geometrical volume of the SC interiors.

- **The Interwoven Interstitial Network:**

  The interstitial regions of the FCC Soft Floor form a connected geometric network through which localized phase saturation and boundary coupling can develop. State II cores nucleate locally, while their exterior strain fields and live phase boundaries can subsequently couple across this network.

- **Site Percolation Threshold ($p_{\rm c}$):**

  TFT adopts the FCC site-percolation value

  $$p_{\rm c} \approx 0.199 \tag{AT.12}$$

  as the baseline coarse-grained connectivity threshold for the distributed defect network. Because the actual cosmological phase domains grow and interact through correlated strain fields, a complete nonlinear correlated-percolation calculation remains a future microscopic refinement of this baseline closure.

- **Total Interstitial Fraction ($\beta_{\rm IC}$):**

  The total geometrical interstitial fraction of the active FCC vacuum is

  $$\beta_{\rm IC} = 1 - \beta_{\rm geo} \approx 0.2595. \tag{AT.13}$$

To connect the site-occupation probability to the macroscopic boundary-mass fraction, TFT adopts an equal-capacity coarse-graining of the interstitial network. Let $N_{\rm cap}$ denote the number of equivalent coarse-grained interstitial capacity elements and let $m_{\rm cap}$ denote the structural mass-equivalent capacity assigned to each element. Then

$$\beta_{\rm IC} M_{\rm Res} = N_{\rm cap} m_{\rm cap}. \tag{AT.14}$$

If $N_{\rm occ}$ of these elements participate in the connected State II boundary network, their aggregate boundary mass is

$$M_{\rm p} = N_{\rm occ} m_{\rm cap}. \tag{AT.15}$$

Dividing these relations gives

$$\frac{M_{\rm p}}{\beta_{\rm IC} M_{\rm Res}} = \frac{N_{\rm occ}}{N_{\rm cap}}. \tag{AT.16}$$

Defining the coarse-grained occupation fraction

$$p \equiv \frac{N_{\rm occ}}{N_{\rm cap}}, \tag{AT.17}$$

we therefore obtain

$$p = \frac{M_{\mathrm{p}}}{\beta_{\mathrm{IC}} M_{\mathrm{Res}}}. \tag{AT.18}$$

Under this equal-capacity FCC percolation closure, global connectivity occurs when

$$p = p_{\mathrm{c}}. \tag{AT.19}$$

The corresponding Global Rupture Trigger Mass is therefore

$$M_{\mathrm{trg}} = p_{\mathrm{c}} \beta_{\mathrm{IC}} M_{\mathrm{Res}}. \tag{AT.20}$$

Defining the rupture fraction relative to the total reservoir mass,

$$\beta_{\mathrm{rup}} \equiv \frac{M_{\mathrm{trg}}}{M_{\mathrm{Res}}}, \tag{AT.21}$$

gives

$$\beta_{\mathrm{rup}} = p_{\mathrm{c}} \beta_{\mathrm{IC}} = 0.199 \times 0.2595 \approx 0.0516. \tag{AT.22}$$

The physical meaning of this 5.16% threshold is therefore

$$\frac{M_{\mathrm{p}}}{M_{\mathrm{Res}}} \to 0.0516, \tag{AT.23}$$

not

$$\frac{V_{\mathrm{SC}}}{V_{\mathrm{Res}}} \to 0.0516. \tag{AT.24}$$

The global rupture threshold is an aggregate live-boundary mass threshold expressed in the common structural-capacity normalization of the reservoir.

Within that same structural-capacity normalization,

$$\beta_{\mathrm{rup}} \approx 0.0516 < \beta_{\mathrm{oct}} \approx 0.0526. \tag{AT.25}$$

Thus, under the baseline equal-capacity percolation closure, the global connectivity threshold lies slightly below the local Octahedral accommodation ceiling: the distributed phase-boundary network reaches the global fracture condition before the local structural-capacity benchmark is exhausted.

AT.2.1 Derivation of the Deflation Parameters

The 5.16% rupture threshold is a boundary-mass fraction and must not be interpreted as a 5.16% physical SC-core volume fraction. The macroscopic deflation law instead follows from depletion of the active FCC reservoir.

As State I structural capacity is transferred into live State II phase boundaries, the active-reservoir mass is

$$M_{\mathrm{FCC}}(t) = M_{\mathrm{Res}} - M_{\mathrm{p}}(t). \tag{AT.26}$$

For the quasi-static pre-rupture branch, TFT adopts the reservoir-density closure that the remaining active FCC domain preserves its reference mean structural density during global contraction:

$$\frac{M_{\mathrm{FCC}}(t)}{V(t)} = \frac{M_{\mathrm{Res}}}{V_{\mathrm{Res}}}. \tag{AT.27}$$

It follows that

$$\frac{V(t)}{V_{\mathrm{Res}}} = 1 - \frac{M_{\mathrm{p}}(t)}{M_{\mathrm{Res}}}. \tag{AT.28}$$

At the global rupture threshold,

$$\frac{M_{\mathrm{p}}}{M_{\mathrm{Res}}} = \beta_{\mathrm{rup}} \approx 0.0516, \tag{AT.29}$$

so

$$V_{\mathrm{rup}} = (1 - \beta_{\mathrm{rup}})V_{\mathrm{Res}} = 0.9484 V_{\mathrm{Res}}. \tag{AT.30}$$

Using the established reservoir volume,

$$V_{\mathrm{rup}} \approx 7.9058 \times 10^{104}\ \mathrm{m}^3. \tag{AT.31}$$

The corresponding spherical reservoir radius satisfies

$$R_{\mathrm{rup}} = R_{\mathrm{Res}}(1 - \beta_{\mathrm{rup}})^{1/3}, \tag{AT.32}$$

giving

$$R_{\mathrm{rup}} \approx 5.7361 \times 10^{34}\ \mathrm{m}. \tag{AT.33}$$

The pre-rupture contraction of the macroscopic structural reservoir is therefore

$$\Delta R = R_{\mathrm{Res}} - R_{\mathrm{rup}} \approx 1.0220 \times 10^{33}\ \mathrm{m}. \tag{AT.34}$$

These deflation values follow from the quasi-static mean-reservoir-density closure of the remaining active FCC domain. They do not require, and must not be interpreted as, a 5.16% physical filling of the reservoir by zero-void SC cores.

The Global Rupture Trigger Mass itself is

$$M_{\mathrm{trg}} = 0.0516\left(1.6707 \times 10^{79}\ \mathrm{kg}\right) \approx 8.6208 \times 10^{77}\ \mathrm{kg}. \tag{AT.35}$$

AT.2.2 The Spanning Cluster and Topological Continuity

In percolation theory, the critical threshold marks the transition from isolated clusters to a reservoir-spanning connected network. In TFT, this connectivity does not require the physical SC interiors of individual Black Holes to touch shoulder-to-shoulder.

The live-boundary merger mechanics instead permit two initially separated State II domains to become mechanically connected when the strained FCC region between them reaches saturation. The local bridge condition is represented schematically by

$$\alpha_{\mathrm{bridge}} = \alpha_{\mathrm{G},1} + \alpha_{\mathrm{G},2} + \alpha_{\mathrm{dyn}} \geq 1, \tag{AT.36}$$

where $\alpha_{\mathrm{G},1}$ and $\alpha_{\mathrm{G},2}$ are the quasi-static gravitational strain contributions and α_{dyn} represents additional dynamical loading of the intervening region.

When this condition is satisfied across a connected path, the intermediate active FCC region undergoes the same local saturation transition that defines an individual Black Hole boundary:

$$\mathrm{FCC} \rightarrow \mathrm{SC}. \tag{AT.37}$$

The global connectivity sequence is therefore

$$\begin{gathered}\text{isolated State II domains}\\ \Downarrow\\ \text{overlapping exterior strain fields}\\ \Downarrow\\ \text{saturated FCC/SC bridges}\\ \Downarrow\\ \text{connected live-boundary network}\\ \Downarrow\\ \text{reservoir-spanning phase-boundary cluster.}\end{gathered} \tag{AT.38}$$

The object that percolates is therefore the combined network of State II cores, live FCC/SC boundaries, and saturated connecting bridges. The physical SC interiors themselves need not occupy 5.16% of the reservoir volume, nor must individual Black Hole cores be in direct geometric contact.

The familiar term "fault line" is retained as an intuitive description of this global fracture path. In the full three-dimensional reservoir, the critical object is more properly a tortuous spanning fracture network or manifold.

AT.2.3 The Phase Trigger Unification

As the universe evolves, self-sustaining FCC→SC phase domains accumulate boundary mass and become increasingly interconnected. Under the equal-capacity percolation closure, the baseline topological trigger is reached when

$$M_{\mathrm{p}} = M_{\mathrm{trg}}, \tag{AT.39}$$

equivalently,

$$\frac{M_{\mathrm{p}}}{\beta_{\mathrm{IC}} M_{\mathrm{Res}}} = p_{\mathrm{c}}. \tag{AT.40}$$

At this threshold the live-boundary and saturated-bridge system forms a reservoir-spanning cluster. TFT adopts the global rupture condition that the critical spanning cluster becomes a load-severing fault network for the active FCC containment structure. Consequently,

$$\Delta P \to 0. \tag{AT.41}$$

Loss of the stabilizing global pressure differential removes the mechanical confinement of the phase-locked network. The hyper-compressed State II structure then undergoes rapid martensitic snap-back,

$$\mathrm{SC} \to \mathrm{FCC}, \tag{AT.42}$$

producing Catastrophic Decompression and restoring the active State I geometry for the next cosmic cycle.

The Big Rupture is therefore controlled by a mass-weighted topological connectivity threshold, not by exhaustion of physical SC-core volume.

AT.3 The Chronology of the Global Phase Avalanche

The percolation threshold determines the endpoint of the structural cycle. To determine the corresponding macroscopic clock, TFT tracks the aggregate live-boundary mass M_{p} generated by the self-sustaining FCC→SC phase-conversion network.

AT.3.1 The Global Phase Avalanche Equation

Black Hole formation in TFT is a nucleated phase transition. The initial localized mass provides the trigger required to drive the active FCC vacuum to saturation. Once the FCC→SC boundary is established, continued Black Hole growth proceeds through advancement of the crystallization front: newly converted regions extend the live boundary and expose additional active FCC material to phase conversion.

The cosmological chronology adopts the single-rate macroscopic relaxation closure

$$\frac{1}{M_{\mathrm{p}}}\frac{\mathrm{d}M_{\mathrm{p}}}{\mathrm{d}t} = \Gamma_{\mathrm{D}}. \tag{AT.43}$$

Equivalently,

$$\frac{\mathrm{d}M_{\mathrm{p}}}{\mathrm{d}t} = \Gamma_{\mathrm{D}} M_{\mathrm{p}}. \tag{AT.44}$$

This equality is a constitutive macroscopic closure of the present TFT chronology: the fractional compounding rate of the self-sustaining FCC→SC phase-boundary network is taken to equal the macroscopic Viscoelastic Vacuum Relaxation Rate. A microscopic derivation of this equality from the underlying phase-front dynamics remains a separate completion requirement.

Integration gives the Global Phase Avalanche Equation,

$$M_{\mathrm{p}}(t) = M_{\mathrm{p}}(0) e^{\Gamma_{\mathrm{D}} t}. \tag{AT.45}$$

No direct conversion of coherently relaxed photon energy into Black Hole mass is assumed. The optical-relaxation channel and the FCC→SC phase-avalanche channel are distinct mechanical processes. Their common appearance of Γ_{D} represents the single-rate macroscopic relaxation closure of the active FCC–Condensate system.

At the present cosmological epoch, the numerical value of Γ_{D} is empirically calibrated by the observed low-redshift Hubble slope,

$$\Gamma_{\mathrm{D}} = H_0^{(\mathrm{obs})}. \tag{AT.46}$$

The calibration supplies the current macroscopic value of Γ_{D}; it does not replace the unresolved microscopic derivation of the relaxation rate.

For the kinematic-length representation used in the unified cosmic phase diagram,

$$x = c_{\mathrm{E}} t. \tag{AT.47}$$

The Global Phase Avalanche may therefore be written in length form as

$$M_{\mathrm{p}}(x) = M_{\mathrm{p}}(0) \exp\left(\frac{\Gamma_{\mathrm{D}} x}{c_{\mathrm{E}}}\right). \tag{AT.48}$$

This is the growing phase-avalanche counterpart of the coherent optical relaxation law

$$E_{\mathrm{obs}}(x) = E_{\mathrm{emit}} \exp\left(-\frac{\Gamma_{\mathrm{D}} x}{c_{\mathrm{E}}}\right), \tag{AT.49}$$

within the constant-rate weak-loading optical branch.

The two exponentials therefore evolve oppositely along the same macroscopic relaxation scale while representing physically distinct processes.

Variable Definitions:

- $M_{\mathrm{p}}(t)$ **(Aggregate Percolating Mass):** The total inertial mass phase-segregated onto the distributed live FCC/SC boundaries participating in the global State II network.
- $M_{\mathrm{p}}(0)$ **(Primordial Aggregate Boundary Mass):** The effective aggregate live-boundary mass established during the short primordial State II nucleation interval immediately following Catastrophic Decompression.
- $M_{\mathrm{D,G}}$ **(Micro-Black Hole Seed):** Approximately 10.033 kg. This is the minimum localized kinematic mass threshold required to nucleate one stable State II phase domain. Therefore,

$$M_{\mathrm{p}}(0) \geq M_{\mathrm{D,G}}. \tag{AT.50}$$

- Γ_{D} **(Viscoelastic Vacuum Relaxation Rate):** The macroscopic fractional relaxation rate of the FCC–Condensate system. Under the single-rate phase-avalanche closure, it also sets the fractional compounding rate of the self-sustaining State II boundary network.

The Initialization Boundary ($t \approx 0$)

Because State II domains are lattice phase transitions rather than atomic structures, their nucleation does not require the formation of neutral matter. In the immediate aftermath of Catastrophic Decompression, overlapping longitudinal acoustic shockwaves can produce regions of extreme localized compression.

Wherever the active FCC vacuum reaches the saturation condition

$$\alpha_{\mathrm{G}} \to 1, \tag{AT.51}$$

the local Soft Floor becomes phase-locked,

$$\mathrm{FCC} \to \mathrm{SC}, \tag{AT.52}$$

creating primordial State II nuclei.

A potentially large population of primordial nuclei may therefore form during the short post-rupture transient. Their exact number is not required to determine the long-time exponential form of the Global Phase Avalanche. Primordial nucleation occurring over a time interval negligible compared with $1/\Gamma_{\mathrm{D}}$ is absorbed into the effective initialization $M_{\mathrm{p}}(0)$.

The minimum possible initialization is the single-seed limit,

$$M_{\mathrm{p}}(0) = M_{\mathrm{D,G}}, \tag{AT.53}$$

while any distributed primordial population satisfies

$$M_{\mathrm{p}}(0) > M_{\mathrm{D,G}}. \tag{AT.54}$$

The phase-avalanche clock therefore begins with restoration of the active FCC vacuum and precedes the later lattice-annealing epoch required for stable neutral hydrogen.

AT.3.2 Integration of the Macroscopic Lifespan (T_{cyc})

As derived in Section 20.3, the total structural reservoir mass is

$$M_{\mathrm{Res}} \approx 1.6707 \times 10^{79} \text{ kg}. \tag{AT.55}$$

Under the equal-capacity percolation closure, the cycle terminates when the aggregate live-boundary mass reaches

$$M_{\mathrm{trg}} \approx 8.6208 \times 10^{77} \text{ kg}. \tag{AT.56}$$

Applying the Global Phase Avalanche Equation at the rupture time gives

$$M_{\mathrm{trg}} = M_{\mathrm{p}}(0) e^{\Gamma_{\mathrm{D}} T_{\mathrm{cyc}}}. \tag{AT.57}$$

Therefore,

$$\Gamma_{\mathrm{D}} T_{\mathrm{cyc}} = \ln\left(\frac{M_{\mathrm{trg}}}{M_{\mathrm{p}}(0)}\right), \tag{AT.58}$$

and

$$T_{\mathrm{cyc}} = \frac{1}{\Gamma_{\mathrm{D}}} \ln\left(\frac{M_{\mathrm{trg}}}{M_{\mathrm{p}}(0)}\right). \tag{AT.59}$$

Because

$$M_{\mathrm{p}}(0) \geq M_{\mathrm{D,G}}, \tag{AT.60}$$

the minimum-seed initialization produces the maximum possible cycle duration under the present phase-avalanche closure:

$$T_{\mathrm{cyc}} \leq \frac{1}{\Gamma_{\mathrm{D}}} \ln\left(\frac{M_{\mathrm{trg}}}{M_{\mathrm{D,G}}}\right). \tag{AT.61}$$

For the minimum-seed branch,

$$M_{\mathrm{p}}(0) = M_{\mathrm{D,G}} \approx 10.033 \text{ kg}, \tag{AT.62}$$

and therefore

$$8.6208 \times 10^{77} = 10.033\, e^{\Gamma_{\mathrm{D}} T_{\mathrm{cyc}}}. \tag{AT.63}$$

Thus,

$$e^{\Gamma_{\mathrm{D}} T_{\mathrm{cyc}}} \approx 8.5924 \times 10^{76}, \tag{AT.64}$$

and

$$\Gamma_{\mathrm{D}} T_{\mathrm{cyc}} = \ln\left(8.5924 \times 10^{76}\right) \approx 177.15. \tag{AT.65}$$

Using

$$\frac{1}{\Gamma_{\mathrm{D}}} \approx 13.387 \text{ billion years}, \tag{AT.66}$$

the minimum-seed branch gives

$$T_{\mathrm{cyc}} \approx 177.15 \times 13.387 \text{ billion years} \approx 2.3715 \text{ trillion years}. \tag{AT.67}$$

The value 2.3715 trillion years is therefore the maximum structural-cycle duration obtained under the minimum-seed normalization and the single-rate phase-avalanche closure. A larger primordial aggregate $M_{\mathrm{p}}(0)$ shortens the absolute elapsed cycle time logarithmically but does not alter the rupture mass or the exponential growth law.

The corresponding kinematic cycle length is

$$L_{\max} \equiv c_{\mathrm{E}} T_{\mathrm{cyc}}, \tag{AT.68}$$

so generally

$$L_{\max} = \frac{c_{\mathrm{E}}}{\Gamma_{\mathrm{D}}} \ln\left(\frac{M_{\mathrm{trg}}}{M_{\mathrm{p}}(0)}\right). \tag{AT.69}$$

Using

$$R_{\mathrm{U}} = \frac{c_{\mathrm{E}}}{\Gamma_{\mathrm{D}}}, \tag{AT.70}$$

this becomes

$$L_{\max} = R_{\mathrm{U}} \ln\left(\frac{M_{\mathrm{trg}}}{M_{\mathrm{p}}(0)}\right). \tag{AT.71}$$

For the minimum-seed normalization,

$$L_{\max} \approx 2.24 \times 10^{28} \text{ m}. \tag{AT.72}$$

At the endpoint,

$$x = L_{\max} \qquad \Longleftrightarrow \qquad t = T_{\mathrm{cyc}} \qquad \Longleftrightarrow \qquad M_{\mathrm{p}} = M_{\mathrm{trg}}. \tag{AT.73}$$

Thus, $L_{\max}$ is the kinematic length corresponding to the complete structural cycle. It is not an independent material boundary or causal boundary of the substrate.

AT.3.3 Integration of the Current Epoch (t_{cur})

To estimate the current elapsed phase time, the Global Phase Avalanche is evaluated against the present aggregate State II boundary mass M_{cur}.

Adopting the current observational Black Hole mass inventory over the reference observable domain as

$$M_{\mathrm{obs}} \approx 1.000 \times 10^{50} \text{ kg}, \tag{AT.74}$$

TFT presently extrapolates this inventory across the full structural reservoir using the volumetric reservoir multiplier

$$9.7957 \times 10^{25}, \tag{AT.75}$$

under the statistical-homogeneity closure that the observed State II abundance is representative of the corresponding larger structural domain.

This gives

$$M_{\mathrm{cur}} = \left(1.000 \times 10^{50} \text{ kg}\right)\left(9.7957 \times 10^{25}\right) = 9.7957 \times 10^{75} \text{ kg}. \tag{AT.76}$$

The Global Phase Avalanche then gives

$$M_{\mathrm{cur}} = M_{\mathrm{p}}(0) e^{\Gamma_{\mathrm{D}} t_{\mathrm{cur}}}, \tag{AT.77}$$

and hence

$$t_{\mathrm{cur}} = \frac{1}{\Gamma_{\mathrm{D}}} \ln\left(\frac{M_{\mathrm{cur}}}{M_{\mathrm{p}}(0)}\right). \tag{AT.78}$$

For the minimum-seed normalization,

$$9.7957 \times 10^{75} = 10.033\, e^{\Gamma_{\mathrm{D}} t_{\mathrm{cur}}}, \tag{AT.79}$$

so

$$e^{\Gamma_{\mathrm{D}} t_{\mathrm{cur}}} \approx 9.7635 \times 10^{74}, \tag{AT.80}$$

and

$$\Gamma_{\mathrm{D}} t_{\mathrm{cur}} \approx 172.67. \tag{AT.81}$$

Thus,

$$t_{\mathrm{cur}} \approx 172.67 \times 13.387 \text{ billion years} \approx 2.3116 \text{ trillion years}. \tag{AT.82}$$

As with T_{cyc}, this absolute elapsed-time value corresponds to the minimum-seed normalization and the adopted statistical-homogeneity extrapolation. A larger primordial aggregate shifts both t_{cur} and T_{cyc} downward by the same logarithmic initialization term.

AT.3.4 The Expiration Timer and Remaining Lifespan

The differential time remaining before global percolation does not depend on the primordial normalization $M_{\mathrm{p}}(0)$.

From

$$M_{\mathrm{trg}} = M_{\mathrm{p}}(0) e^{\Gamma_{\mathrm{D}} T_{\mathrm{cyc}}}, \tag{AT.83}$$

and

$$M_{\mathrm{cur}} = M_{\mathrm{p}}(0) e^{\Gamma_{\mathrm{D}} t_{\mathrm{cur}}}, \tag{AT.84}$$

their ratio is

$$\frac{M_{\mathrm{trg}}}{M_{\mathrm{cur}}} = e^{\Gamma_{\mathrm{D}}(T_{\mathrm{cyc}} - t_{\mathrm{cur}})}. \tag{AT.85}$$

Defining

$$\Delta t = T_{\mathrm{cyc}} - t_{\mathrm{cur}}, \tag{AT.86}$$

gives

$$\frac{M_{\mathrm{trg}}}{M_{\mathrm{cur}}} = e^{\Gamma_{\mathrm{D}} \Delta t}. \tag{AT.87}$$

Therefore,

$$\Delta t = \frac{1}{\Gamma_{\mathrm{D}}} \ln\left(\frac{M_{\mathrm{trg}}}{M_{\mathrm{cur}}}\right). \tag{AT.88}$$

Using

$$\frac{M_{\mathrm{trg}}}{M_{\mathrm{cur}}} = \frac{8.6208 \times 10^{77}}{9.7957 \times 10^{75}} \approx 88.006, \tag{AT.89}$$

we obtain

$$\Delta t = \frac{1}{\Gamma_{\mathrm{D}}} \ln(88.006) \approx 4.4774 \frac{1}{\Gamma_{\mathrm{D}}}. \tag{AT.90}$$

With the present empirically calibrated value of Γ_{D},

$$\Delta t \approx 59.94 \text{ billion years}. \tag{AT.91}$$

The cancellation of $M_{\mathrm{p}}(0)$ is exact within the Global Phase Avalanche law. The numerical 59.94-billion-year value remains a conditional model estimate because it depends on the adopted phase-avalanche closure, the percolation-derived rupture mass, and especially the statistical-homogeneity extrapolation used to determine M_{cur}.

AT.3.5 The Macroscopic Phase Symmetry (Optical and Thermodynamic Clock Equivalence)

The shared appearance of Γ_{D} in coherent optical relaxation and in the Global Phase Avalanche produces a macroscopic synchronization identity.

For a coherent transverse excitation propagating through the constant-rate weak-loading vacuum,

$$E_{\mathrm{obs}}(x) = E_{\mathrm{emit}} \exp\left(-\frac{\Gamma_{\mathrm{D}} x}{c_{\mathrm{E}}}\right). \tag{AT.92}$$

Using

$$R_{\mathrm{U}} = \frac{c_{\mathrm{E}}}{\Gamma_{\mathrm{D}}}, \tag{AT.93}$$

this is equivalently

$$E_{\mathrm{obs}}(x) = E_{\mathrm{emit}} e^{-x/R_{\mathrm{U}}}. \tag{AT.94}$$

The scale R_{U} is the characteristic one-e-fold coherent-relaxation length:

$$E_{\mathrm{obs}}(R_{\mathrm{U}}) = \frac{E_{\mathrm{emit}}}{e}. \tag{AT.95}$$

It is not a universal stopping radius. A coherent carrier can continue beyond R_{U} until its frequency approaches the effective CMB-reservoir assimilation threshold. Because this threshold is frequency dependent, physical coherent assimilation may occur before the complete structural-cycle length $L_{\max}$.

The exponential optical law may nevertheless be formally continued to the structural endpoint as the mathematical relaxation clock associated with the same Γ_{D}. Denoting this formal continuation at $L_{\max}$ by

$$E_{\mathrm{obs}}^{(\mathrm{formal})}(L_{\max}) = E_{\mathrm{emit}} \exp\left(-\frac{\Gamma_{\mathrm{D}} L_{\max}}{c_{\mathrm{E}}}\right), \tag{AT.96}$$

and using

$$L_{\max} = c_{\mathrm{E}} T_{\mathrm{cyc}}, \tag{AT.97}$$

we obtain

$$\frac{E_{\mathrm{obs}}^{(\mathrm{formal})}(L_{\max})}{E_{\mathrm{emit}}} = e^{-\Gamma_{\mathrm{D}} T_{\mathrm{cyc}}}. \tag{AT.98}$$

At the same structural endpoint, the Global Phase Avalanche gives

$$\frac{M_{\mathrm{trg}}}{M_{\mathrm{p}}(0)} = e^{+\Gamma_{\mathrm{D}} T_{\mathrm{cyc}}}. \tag{AT.99}$$

Inverting this relation,

$$e^{-\Gamma_{\mathrm{D}} T_{\mathrm{cyc}}} = \frac{M_{\mathrm{p}}(0)}{M_{\mathrm{trg}}}. \tag{AT.100}$$

Therefore,

$$\frac{E_{\mathrm{obs}}^{(\mathrm{formal})}(L_{\max})}{E_{\mathrm{emit}}} = \frac{M_{\mathrm{p}}(0)}{M_{\mathrm{trg}}}. \tag{AT.101}$$

This is the general reciprocal clock identity generated by the single-rate macroscopic closure.

For the minimum-seed normalization,

$$M_{\mathrm{p}}(0) = M_{\mathrm{D,G}}, \tag{AT.102}$$

the relation reduces to

$$\frac{E_{\mathrm{obs}}^{(\mathrm{formal})}(L_{\max})}{E_{\mathrm{emit}}} = \frac{M_{\mathrm{D,G}}}{M_{\mathrm{trg}}}. \tag{AT.103}$$

If the emitted excitation is additionally normalized to the established maximum-energy scale,

$$E_{\mathrm{emit}} = E_{\max} \approx 13.331 \text{ J}, \tag{AT.104}$$

then

$$E_{\mathrm{obs}}^{(\mathrm{formal})}(L_{\max}) = E_{\max}\left(\frac{M_{\mathrm{D,G}}}{M_{\mathrm{trg}}}\right). \tag{AT.105}$$

Using

$$M_{\mathrm{D,G}} \approx 10.033 \text{ kg}, \tag{AT.106}$$

and

$$M_{\mathrm{trg}} \approx 8.6208 \times 10^{77} \text{ kg}, \tag{AT.107}$$

gives

$$E_{\mathrm{obs}}^{(\mathrm{formal})}(L_{\max}) \approx 1.5515 \times 10^{-76} \text{ J}. \tag{AT.108}$$

This formal endpoint value should not be interpreted as requiring an individual coherent photon to remain physically observable to $L_{\max}$. If the carrier reaches the CMB-reservoir assimilation threshold at a shorter distance, its identifiable coherent state terminates there. The continuation to $L_{\max}$ represents the underlying exponential relaxation factor used to compare the optical and structural clocks.

The reciprocal identity likewise does not imply that coherently relaxed photon energy is converted directly into Black Hole boundary mass. The optical-relaxation channel and the self-sustaining FCC→SC phase-avalanche channel are mechanically distinct. Their reciprocal exponentials arise because both are parameterized by the same macroscopic rate Γ_{D} under the single-rate closure.

The synchronized structural endpoint is

$$x = L_{\max} \qquad \Longleftrightarrow \qquad t = T_{\mathrm{cyc}} \qquad \Longleftrightarrow \qquad M_{\mathrm{p}} = M_{\mathrm{trg}}. \tag{AT.109}$$

In this sense, the formally continued optical-relaxation clock and the global phase-avalanche clock provide complementary measures of the same macroscopic relaxation timescale: coherent carrier energy decreases as $e^{-\Gamma_{\mathrm{D}}t}$, while aggregate live-boundary mass increases as $e^{+\Gamma_{\mathrm{D}}t}$ under the adopted phase-avalanche closure, until the global percolation threshold is reached and Catastrophic Decompression resets the active vacuum.

Acknowledgements and AI Disclosure

I acknowledge the use of OpenAI ChatGPT and Google Gemini to expedite the latter stages of this manuscript's development (2023–2026). The AI functioned strictly as a computational and typesetting assistant, exploratory mathematical discussion, drafting and restructuring selected manuscript passages, LaTeX and code generation, figure preparation, and consistency checks. All foundational postulates, physical interpretations, and final mathematical proofs of Tension Field Theory are my sole original work, and I take full responsibility for the accuracy and integrity of this publication.

Furthermore, Tension Field Theory represents the culmination of a three-decade conceptual incubation originating in my childhood, followed by seven years of intensive, rigorous mathematical formalization. This critical final phase of development would have been entirely impossible without the profound patience, sacrifice, and unwavering support of my wife, Shamima Khan, and our daughters, Najwa Khan and Raya Khan. I extend my deepest gratitude to my family for affording me the time, space, and quiet necessary to bring this lifelong endeavor to its conclusion.
